Further conclusive evidence of "self-sorting" was found in tissue cultures in which random mixtures of suspensions of cells of different embryonic origins —for instance, cartilage and kidney cells—had been combined.[9] These cultures developed compound structures in which islands of pure cartilage were sharply demarcated from blocks of pure kidney tissue, indicating that cells had become re-associated like-to-like. Thus, even *in vitro* cells, which have acquired in their prior embryonic history some biochemical differential related to their subsequent development as either kidney cells or cartilage cells, can assort themselves according to type. Since the cells make contact only with their surfaces, one must assume that some property associated with differentiation into kidney cells or into cartilage cells has imparted type-specific markers to their surfaces for mutual recognition. But how such "recognition" leads to active sorting remains obscure.

How do mixed cell populations achieve this orderly reassortment? Do like cells "attract" each other? Or do they "recognize" each other only after chance encounters? A clue came first from some observations on selective wound healing after the grafting of various kinds of epithelia into skin gaps in the flanks of amphibian embryos.[10] The first coverage of a wound is effected by the migration of epithelial cells of the wound edge over the raw surface. When these advancing cells reach a graft, fusion of the two fronts occurs only if the graft contains an epithelium of a type which normally borders on skin epidermis. In that event, the advancing cells stop in their tracks, so to speak, merge into a uniform sheet with the graft, and no further proliferation occurs. Implants of skin, or of cornea or oral lining—which are normally continuous with skin—are accepted in this manner. But, when a fragment of lung or gall bladder or esophagus is implanted in a skin wound, the migrating skin epidermis is not halted on contact with those foreign-type cells. The epidermal edges glide over or under the graft and continue until they meet with the skin advancing from the opposite side.

Results of this kind have long been known in surgery and lead to the conclusion that, whether we have a plausible explanation for the phenomenon or not, cells of identical or conforming constitution (as epidermis, cornea, and oral lining) will recognize each other as akin and stay put; whereas cells of unlike character develop a reaction which will cause them to separate.

With these facts as background, we proceeded to study the contact reactions between different kinds of cells directly *in vitro*,[1] by taking phase-contrast time-lapse motion pictures of encounters among cultured cells.* If the cells that make contact are all of the same kind—all liver cells, for example—they aggregate and stay together. The free borders of roaming cells are in constant motion; but wherever two like cells touch each other, that portion of their surfaces becomes quiescent. The bond between them, however, is not static; there is no cement which sticks them together as in an immunological precipitin reaction. On the contrary, the cells continually glide over one another, constantly changing their positions relative to each other and, by the time others have joined them, their positions in the group.

On the other hand, if cells of two different types are cultured together (e.g., lung and liver or lung and kidney), the result is quite different. As the loose cells stray about, they collide at random. There is not the slightest indication that they would react to each other's presence unless or until their free borders touch. Neither do like cells "attract" each other, nor do unlike cells avoid each other. Mutual recognition and consequent discriminatory behavior are decidedly contact responses. All cells, whether alike or not, make primary contact indiscriminately. But, whereas like pairs thereafter draw closer together and remain joined, unlike pairs separate secondarily by reciprocal withdrawal of those parts of their borders that had been in fleeting touch. While the mechanism of identification undoubtedly resides in the surface, the interior of the cell seems to be engaged in the withdrawal reaction, giving the phenomenon the general appearance of a "reflex" response with a "sensory" and a "motor" component. The "reflex time" is of the order of 10^3 sec, varying both with the strangeness of the confronted cells and with their respective rates of motility. In conclusion, self-sorting of scrambled cell types results from chance collisions with matching combinations holding on to each other, whereas nonmatching ones do not last.

"Matching" combinations involve either cells of the same type or of complementary types, the latter being types that normally cooperate in the building and functional operation of complex organs. For instance, an active mutual adhesion between nerve processes and enveloping sheath cells has been demonstrated,[11] and our motion pictures reveal a similar marked tendency of macrophages to confine their excursions to within the borders of the large flattened lung cells with which they have been jointly explanted.

The discriminatory response is strictly cell-type specific, but it is not species specific. That is to say, cartilage cells of the chick will reject association with liver or kidney cells of the same chick, but they will combine readily with cartilage cells of a mouse. This fact, derived earlier from reaggregation experiments,[12] has now

* These moving pictures, made in collaboration with A. C. Taylor and A. Bock, were shown at the Study Program in Biophysical Science in conjunction with the lecture on which this article is based.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

been proven visually by the motion pictures. On the other hand, the same cell type may undergo progressive alterations with age, so as to make more mature and less mature cells of the same strain less acceptable to each other than cells of the same age would be. Furthermore, there are signs that the differentials among cell types, which underly their discriminatory responses to each other, may be subject to gradations in accordance with their ontogenetic relationships.

The details of this principle still remain to be worked out. But what has emerged thus far is enough to force a substantial revision of former excessively static pictures of the organism as a fixed framework of parts shifted into predestined places by a rigidly prescribed system of tracks and schedules and then immured by fibrous cements. Although, grossly, this picture still holds, it gains much greater flexibility in detail from the realization that the eventual pattern of combination, association, and segregation among cell types in typically ordered arrays is not just passively arrived at, but is actively insured and guarded—and restored after disturbance—by a system of subtle mutual conformances and nonconformances with which the various cell types have been endowed as a corollary of their ontogenetic differentiation.

The principle of the self-linking of cells into matched groups by contact affinities and disaffinities has an important bearing on the explanation of the establishment and maintenance of order in the networks of the nervous system. The building up of central and peripheral nerve cables by the selective attachment of nerve fibers of a given type to others of like specificity has already been referred to in the foregoing. The same principle holds for interneuronal relations, as well as for the relations between neurons and their non-neural receptor and effector organs, on an even subtler scale. Since this is one of the most compelling, yet at the same time least recognized, instances of specificity and selectivity in cell-to-cell interactions, it is well to recapitulate briefly the relevant experiments, which I started almost forty years ago (see a recent review[13]) and which have more recently been amplified by my student, Sperry.[14]

During development, countless connections are established among individual neurons and between neurons and peripheral sense organs and muscles. The latitude inherent in the primary developmental mechanisms of neurogenesis[5] is so great that it would rule out any such microprecision in the details of the neuronal circuitry as is usually postulated as basis for coordinated functions. On the other hand, there is equally conclusive evidence to show that the nervous system does emerge from its embryonic phase with a large list of ready-made coordinated performances, which, since learning by trial and error could have played no part in their formation, must be explicable in terms of developmental interactions. The dilemma was solved by the demonstration of secondary processes which adjust the details within the gross primary system of connections to the unique arrangements of each individual specimen. Although nerves from the same central sources may in different individuals end up in different muscles, the muscles themselves then send a specifying influence back into the centers with the information on just what muscle of what name lies at the end of what line.

The test experiment consisted of transplanting a supernumerary muscle (or a whole set of limb muscles) near a normal limb and hitching it to a random branch of the local nerve supply. This amounted to "tapping" the communication network by inserting an extra receiver. What was observed then was that the transplanted muscle responded in the course of normal activities of the animal always at the precise time and with the same strength as the muscle bearing the same name in the normal limb. Thus, each muscle is called up, as it were, by the central system by its proper name, and if there are several muscles of the same name present in a common innervation district, they all respond simultaneously when the particular code is called. Since the test muscle was inserted arbitrarily, it is clear that it must have established its name-specific correspondences in the nerve centers secondarily. The same correspondence between periphery and centers was also confirmed for the sensory part of the system, first for proprioceptive[15] and tactile[16] sensations and later for the visual field.[14]

It all boils down to the following. Even though it is impossible to distinguish different skeletal muscles by present biochemical methods, the nervous system can tell them apart very well. Whatever the telling difference between muscles, it must be something that can make itself known in a retrograde manner over the motor nerve fiber in such a way that the central apparatus thereby gains exact information about its peripheral terminations. Motor fibers are initially blank and unspecified. They acquire specific identity only after they penetrate identified muscles at the periphery, and the same holds for sensory neurons in regard to their endings. Somehow, the acquired detailed specificity is then transmitted still further back from the primary to secondary neurons, and so on up the lines.

By this device, the neuronal population becomes progressively specialized into subunits whose member cells can henceforth regulate their own mutual relations by virtue of their acquired distinctive properties. Neurons of corresponding or complementary specificities thus become joined into cooperative systems. The proposition that this implies only linkage of a static morphological order all the way through the nerve centers[14] does not seem to go far enough if one is to explain either the aforementioned experimental results or the general problems of neural coordination.[13] But, if one adds the assumptions: that synaptic contact between neurons is merely an enabling, but not a decisive, condition for impulse transmission; further, that actual transmission requires specifically matched states of two apposed surfaces; and, finally, that the specificities

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

underlying this conformance are subject to modification by both peripheral and central influences; one comes closer to a satisfactory concept. The nervous system would then emerge as a vast system of resonance circuits, the elements of which would be linked by conforming molecular surface configurations, partly permanently, partly variably in response to changing central and peripheral influences.

From these remarks, it can readily be seen that compatibilities and incompatibilities along the boundaries between neurons are as significant as discriminatory devices as are the signs of surface "recognition" described earlier in this article for other cell types. Indeed, the direct demonstration of cell discrimination in the motion pictures should help to make the corresponding property of neurons acceptable, if not more palatable, to those who had hoped to be able to maintain their oversimplified faith in the essential identity of all neurons so long as they were faced only with the more indirect earlier evidence. In reopening the whole question of specificity in the nervous system, which of late has been lying dormant, our observations on cell encounters in tissue culture thus assume added significance, as they also open the way to a more direct practical study of the nature of the specificities concerned.

The reference to the progressive diversification within nerve-cell populations points logically to the more elementary question of how any primitive cell types, including neurons, acquire their distinguishing characteristics in the first place. To discuss the problem of divergent differentiation would go far beyond the scope of this article. There is one aspect, however, that fits into the context. Differentiation occurs essentially by dichotomies in the courses of transformation of cells with basically identical physical and chemical endowments.[17] Any cell strain is, by virtue of such endowments, initially capable of effecting a limited variety of qualitatively different reactions. Every step of differentiation implies that from that multiple repertory one definite course has become activated in some members of the group, and an alternative course in the other members, the two courses being mutually exclusive. Sooner or later, the different reactions lead to manifest diversity. Development is composed of long series of such steps. Present evidence is that each step has its own mode of triggering mechanism, and that, contrary to earlier illusions, there is no single master agent that could be held generally accountable for the various and successive dichotomous changes. Formally, however, one can distinguish two classes—one in which the differentiating activity plays entirely within the bounds of a group of similar cells, referable perhaps to differential interactions among the members of the group depending on their relative positions; and another in which the reaction of a given cell group is decisively influenced by an extraneous cell group.

This second class is usually termed "induction"; again, different steps of "inductive" influences need have little in common but the name. Some of them operate over distances, others only between adjacent tissues. Evidently, these latter raise the issue of whether true contact interactions are involved. The answer seems to be that in some instances and for certain steps of differentiation, intimate contact between the interacting cells is essential, whereas, in other cases, such direct contact is dispensable, the interaction being mediated by diffusible substances.

Some cases in which direct contact is necessary may be cited as examples. When devitalized (frozen-dried and rehydrated) cartilage is transplanted into the vicinity of a limb bone in amphibian larvae, the implant can induce the formation of new cartilage in contact with its surface.[1] Thus, competent living host cells build on cartilage to the dead cartilage model as bees would build on new honeycomb to an artificial wax honeycomb presented to them. This is a particularly interesting case, because the bodies of the cells in the implant cannot have been the inducing agents directly, as they are enclosed and insulated in the cartilaginous matrix; therefore, the inductive stimulus to surrounding host cells must have originated in the exposed surface of that matrix. Another set of experiments showed the same thing for bone.[1] A frozen-dried and rehydrated metatarsal bone of a rat, inserted into the leg of a host rat, induced there new bone, including new bone marrow, in contact with the old bone. That contact is essential has been confirmed from other sources.[18] Such observations support the conclusion that extracellular materials may play important roles in certain inductive interactions.[19]

The next case is of special interest to students of collagen. The stroma of the cornea consists of layers of collagen in a characteristic regular arrangement. When frozen-dried cornea was transplanted into a corneal defect in rabbits, the grafted stroma as such persisted for many months. In addition, however, it induced along its inner side the formation of several new layers of typical stroma.[20] Thus, the architecture of the dead stroma matrix has in some fashion been transmitted to the induced layers, so that they assumed the characteristic pattern of collagenous corneal lamellae. This result again proves that not only cells but cellular products likewise can influence other cells inductively.

The intimacy of submicroscopic cell contact, in the sense of the introductory remarks, which may be required for "contact inductions" has not yet been clarified. One of the few clues is the fact that, during the period of inductive interaction between eye cup and prospective lens epithelium, the attachment between the interacting cell layers is so firm as to resist mechanical separation.[21] But, it is still undecided whether the specific transmission across the cell borders is simply an orienting or sorting influence on pre-existing molecular populations[22] or whether it involves the actual passage of substance,[23] perhaps prepared by molecular reorienta-

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

tion.[1] There is a vast field here for exact studies on the relations between physical configuration and chemical activities. These relations are bound to remain in obscurity so long as one focuses attention on those cell-to-cell influences that are mediated not by contact, but by remote control through diffusible agents. The latter, although equally real, can tell only part of the story of cellular interaction.

In summing up, to state that all of the specific interactions among cells exemplified in this article are based on specific properties of the interacting cells is a truism. But, it explains why so little is known about the molecular phenomena governing cell-to-cell relations. There just has not been enough preoccupation with the molecular basis of cellular specificity. Unquestionably, cell "recognition" and selective response must eventually be reduced to terms of properties of molecules and molecular populations. But, so far, there has been very little tangible progress in that direction. There have been a few hypothetical suggestions to explain cell-to-cell conformances, none of them quite tenable in the light of recent observations. I had proposed[24,25] that some sort of steric fitting (e.g., by corresponding charge distributions) between complementary molecules might produce bonds or linkages between like cells, whereas unlike cells without conforming molecules in their surfaces to interlock could establish no connections. Yet, this supposition is now clearly contradicted by the fact that like cells, while remaining together, are not fastened but move continuously around each other. This leaves us for the time being without substantial explanation of the phenomena of selective aggregation as shown in the films.

The only thing that seems clear is that these phenomena point to the same general area of specificity that covers immune reactions,[26] enzyme-substrate interactions, pairing of chromosomes, fertilization, parasitic infection, and phagocytosis. The latter clearly involves selective uptake of particles of suitable molecular surface organization. The problem is no different from that met in cell-to-cell encounters, except for the great disproportion of size between the members of the pair in phagocytosis. Presumably, the selective ingestion of macromolecules belongs in here, too, with the discrepancy of size even more pronounced. The opposite extreme is found in a cell which spreads out selectively over a large body of proper substratum, where the cell is very small in comparison to the partner which it tries to engulf. So, from phagocytosis and the uptake of macromolecules, through cell-to-cell contacts with specific "recognitions," up to the problem of selective adhesion of a cell to its substratum, one deals with a continuous spectrum of problems of the same nature.

This very fact holds promise of progress, as advances in any one sector of that broad area will shed light on other sectors. On the other hand, cleverly getting around the acknowledgment of specificity in any one sector, whether by theoretical constructs or by unrealistic models, will not strip the other sectors of their aspect of specificity, and, hence, will not relieve the intellectual discomfort engendered by our inability to squeeze the broad subject of specificity into the limited conceptual framework which we have erected from the study of fragmentary vital phenomena lacking that aspect. Specificity, as a real and basic control mechanism of cell behavior, can no longer be relegated to a corner, but must be placed in a central position in cellular and molecular biology. The less that is known about it, the greater is the challenge. If there has been some dodging in the past, it was because of some concealed hope that the whole thing might yet in the end turn out to have been an illusion born of inadequate penetration. Exactly the opposite has happened. The more penetrating the analysis, the more cogent has the evidence of specificity become; witness the motion pictures of cell discrimination. There seems little doubt that once the reality and universality of the problem are generally acknowledged, and the promising techniques at our disposal for its disciplined study are recognized, progress can be rapid. But there is even less doubt that, if the existence of the problem continues to be widely ignored, or even denied, some of the major clues to the understanding of living systems will remain missing.

Molecular Organization of the Nerve Fiber*

FRANCIS O. SCHMITT

Department of Biology, Massachusetts Institute of Technology, Cambridge 39, Massachusetts

IN the context of these studies in the biophysical sciences, it is the purpose of this contribution to identify some of the basic problems of nerve that may be effectively studied at the molecular level by the methods of biophysics and biophysical chemistry, and to describe certain nerve structures, such as the myelin sheath, which provide great scope for the application of such methods and which have important application also to such general biological problems as the nature of cell membranes.

The primary function of neurons is the transfer of information from one region to another, the message being propagated along the fiber from cell body to axon terminals by means of a local disturbance or propagated bioelectric impulse. To many, particularly to those studying the activity of the larger nerve units in the processing of information by the central nervous system or in the behavior of the organism as a whole, the individual neuron is but the structural and functional unit in a highly complex network whose basic function involves the all-or-nothing, on-or-off responses of the units. Thus, in neurophysiology, as well as in bioelectrical studies generally, the most elementary problem which could be posed to the molecular biologist or biophysicist would doubtless be the elucidation of the mechanism by which the impulse is propagated along nerve fibers—i.e., the nature of the changes in the properties of the surface film of the axon that underlie excitation and propagation of the action wave.

If this were in fact the only problem to be dealt with, the present contribution would be very short indeed. Little is known about the molecular composition of the axon surface membrane and even less is known about changes that occur in it during propagation of the impulse. However, for several reasons, I do not wish to take such a limited point of view. In the first place, the axon surface membrane does not exist as a separate entity. It is but part of the neuron which, as a complex reacting system, contains many constituents. Even if one were interested only in bioelectric processes, it would be impossible to understand the phenomena going on in the surface membrane without reference to the structural and biochemical properties of the fiber as a whole. Moreover, nerve performs many functions other than that of propagating impulses. Some of these functions are known, some can be guessed, while others are completely unknown.

For example, somewhere in the neuron there are synthesized certain highly active substances, such as acetyl choline and adrenergic substances, which have transmitter functions; i.e., they transmit the impulse across the junction from the nerve fiber to the muscle fiber or other end organ. The site of synthesis of this material in the neuron, its mode of transfer from this site to the nerve endings (possibly enclosed there in vesicles) and its transmission to the innervated tissue are at present very poorly understood. Certain neurons also produce neurosecretions that can be identified cytologically and histochemically and can be demonstrated to pass from the nerve cell body down the axon to the axon terminals. Possibly other hormonal substances are similarly produced and transmitted, but have thus far escaped detection.

Neurons also manifest certain properties, especially during embryogenesis or regeneration, that are highly specific. Thus, each motor fiber grows out and eventually innervates its appropriate muscle. This innervation is not only highly specific with respect to the muscle fiber which is "sought out" and innervated, but also it is necessary for the stability and maintenance of the normal properties of the muscle fiber. Cutting the nerve fiber to a muscle may cause the latter to change its physiological and pharmacological properties markedly, or even to degenerate.

Finally, it is probable that certain aspects of nerve function may involve chiefly the nerve cell or axoplasm without obvious relationship to the axon surface film. Such processes would probably not lend themselves to study or detection by bioelectric methods. For example, as is discussed in more detail below, certain constituents, such as the fibrous protein, seem to be present in all neurons and to represent one of the characteristic features of neurons generally. However, there is still not the foggiest notion as to the biochemical and physiological function of this protein or protein complex.

It is desirable, therefore, that the biophysical and biochemical investigation of the neuron be not limited to bioelectric processes, but be systematic and exhaustive so as to reveal "what is there," particularly at the molecular and macromolecular level. One has only to consider the history of other fundamental biological problems, such as that of muscle contraction, to realize the importance of such a systematic biochemical and biophysical approach. Only when significant advances in knowledge of the composition and molecular organi-

* These studies were aided by a research grant (B-24) from the National Institute of Neurological Diseases and Blindness, of the National Institutes of Health, Public Health Service, U. S. Department of Health, Education, and Welfare; by a contract between the Office of Naval Research, U. S. Department of the Navy, and the Massachusetts Institute of Technology (NR 101-100); and by grants from the Trustees under the wills of Charles A. King and Marjorie King, and from Lou and Genie Marron.

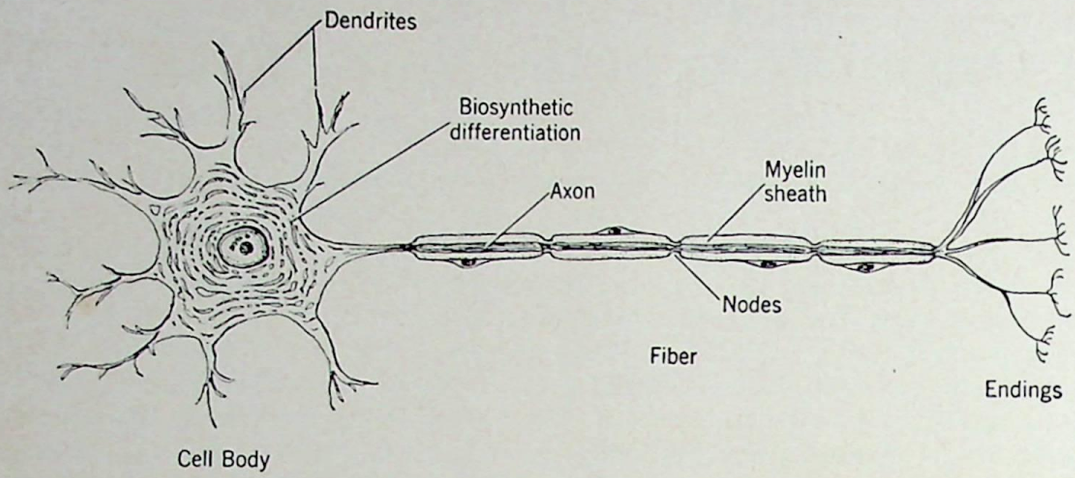

FIG. 1. Diagrammatic representation of a myelinated nerve fiber. Note cell body with dendrites and cytoplasmic organelles, axon, myelin sheath with Schwann cells and nodes of Ranvier, and terminal twigs making synaptic connection with peripheral tissue.

zation of muscle and its fibrous proteins were obtained, could the fundamental problem of the molecular mechanism of contractility be fruitfully attacked. By comparison with muscle, despite much research extending over a century, knowledge of the composition and molecular organization of nerve is still primitive. Moreover, impulse propagation in the nerve fiber is a subtle phenomenon which, unlike contractility in muscle, is not revealed in structural alterations thus far demonstrable even in the electron microscope.

The investigation of the molecular biology of nerve is, therefore, very challenging, particularly to young biophysical scientists not yet steeped in traditional concepts of neurophysiology. This article, which is necessarily limited in space, is meant to be provocative rather than exhaustive in its treatment of basic matter. For more extensive information, the reader is referred to reviews by Schmitt.[1–3]

I. NEURON

The unit of the nervous system, the neuron, consists of a nerve cell body with its dendritic arborization and synaptic connections with the terminal twigs of other neurons; of an axon which is the thin, cylindrical outgrowth of the nerve cell; and of the endings or terminal twigs which make apposition with the innervated cell or tissue through the synapse (see Fig. 1). The neuron has physiological as well as morphological polarization. The impulse passes from presynaptic fiber to nerve cell, down the axon and across the terminal synaptic membrane to the innervated tissue, but not in the reverse direction. For present purposes, it is convenient to consider the cell body, axon, and endings separately.

(A) The Cell Body

The nerve cell body has the task of spinning out the axon in development and of regenerating it in the event of injury. Since the volume of axoplasm to be biosynthesized in a long fiber may be hundreds and, in some cases, thousands of times that of the cell body, it is not unexpected that the metabolism of the nerve cell is very high. To accomplish its impressive task of biosynthesis, the cell is equipped with the cytological differentiation found by electron microscopists characteristically in highly active, secreting gland cells. Particularly prominent are the membrane-limited structures (endoplasmic reticulum, ergastoplasm) richly studded with RNA-rich ribosomes (see Palay[4]). These basophilic structures are identical with the Nissl substance, which has long been studied by cytological methods and by microabsorption spectroscopy and which is known to reflect the synthetic activity of the nerve cell. With improved spectrophotometric methods, such as those developed by Hydén, it has been possible to follow quantitatively the changes in RNA, protein, lipid, and dry weight of regenerating neurons and to correlate these changes with the peripheral growth of the axon (see Brattgård *et al.*[5]). Despite the increase in protein, lipids, and water during the axon outgrowth, the amount of RNA appears to remain constant. However, changes occur in the state of aggregation of RNA; small, finely dispersed particles are formed in the process of "chromatolysis," long known to occur during regeneration. When contact is re-established between the outgrowing axon and the peripheral innervated cell, there is characteristically an increase of RNA and of cell volume until the original values are restored. According to these authors, the only type of cell that can compete with the nerve cell in biosynthetic activity and with the degree of cytological differentiation for such processes, particularly that involving the RNA system, is the exocrine cell of the pancreas of small animals. The neuron is visualized as "an enormous gland cell structure whose lively protein metabolism serves the specific nerve function."[5]

The high metabolic activity of nerve cells (as distinguished from nerve fibers), long known to be characteristic also of normal, unregenerating cells (as in the brain), may be owing in part to the constant synthesis of axoplasm which—according to Weiss and Hiscoe[6] and supported recently by Waelsch[7] and by Ochs and Burger[8]—passes continuously, during the life of the neuron, as a plastic, gelled mass down the axon at a slow rate (*ca* 1 mm/day). The manner in which axoplasm disappears peripherally, e.g., by oxidation or

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

other metabolic process, is not known. If nerve cells are in fact constantly synthesizing axoplasm, it becomes important to establish the purpose served by such a metabolically expensive process. It is possible that one such purpose may be the maintenance of the turgor of the axon over its long extent to the endings. One constituent that would also be constantly synthesized in such a process is the fibrous protein of the axon. When the function of this protein is discovered, light may be shed also on the apparent necessity for its constant synthesis.

The metabolism and the cytological differentiation of the nerve cell are responsive not only to the need for active biosynthesis, as in the regeneration of a severed axon, but also to physiological activity of the neuron. This apparent energy dissipation is in contrast to the highly conservative nature of the process of impulse propagation in the peripheral fiber.

The evidence for the highly developed membrane-limited structures in the cytoplasm of living nerve cells and for the presence of fibrous protein oriented with long axes parallel to the distinguishing directions of the nerve cell is not merely cytological and electron microscopical, but derives also from polarization-optical studies of fresh nerve cells.[9]

(B) Axoplasm and the Axon

As a differentiated type of nerve-cell cytoplasm, axoplasm is a highly complex system. Noteworthy is the low absorption at about 2600 A which characterizes the region peripheral to the axon hillock, roughly at the junction of the nerve-cell cytoplasm with the axon. This is in agreement with the relative scarcity in the axoplasm of ribosomes, as seen in the electron microscope, and of basophilic material, as seen cytologically. Membranous material, possibly consisting chiefly of fragments of the membrane-rich cytoplasmic system, have been observed in squid axoplasm in this laboratory by Maxfield[10] during the process of protein fractionation and physicochemical analysis of axon proteins. Peripheral axoplasm is low in materials absorbing at 2600 A (see von Muralt[11]), consistent with the apparent lack of substantial biosynthesis in this region of the neuron.

Among the particulates commonly present in cytoplasm, only the mitochondria of axoplasm have been subjected to special study. These have properties similar to those isolated from other tissues (Foster[12]). In thin sections of lobster fibers, they have been observed to occur preferentially near the Schwann-cell surface, suggesting the possibility that metabolic energy utilization may occur in this region (Geren and Schmitt[13]).

Although axoplasm is a highly complex, specially differentiated form of nerve-cell cytoplasm, it is highly desirable that the main features of its composition and macromolecular organization be established, not merely for the light it might throw upon the energy coupling involved in active ion transport and in other processes related to impulse propagation, but also as clues to the discovery of other processes carried out by nerves, possibly unrelated to, and not predictable from, those which may be studied by electrical methods.

For such studies of axoplasm, the squid giant fiber is uniquely suited. Axoplasm, relatively uncontaminated by sheath constitutents and other nonaxonic material, can be readily obtained from these fibers. From axoplasm obtained from *Loligo pealii*, the New England squid, analyses have demonstrated (Koéchlin[14]) the presence of previously unknown substances, particularly isethionic acid, which turns out to be the major anion in the acid-base balance of the squid nerve fiber. The fibrous protein of axoplasm has also been studied in this material (Maxfield,[10] Maxfield and Hartley,[15] Schmitt[16]).

More recently, the large squid, *Dosidicus gigas*, that abound in the waters of the Humboldt current off the western coast of South America, have been utilized for chemical investigations. Deffner and Hafter[17] have demonstrated the presence in this axoplasm of some fifteen free amino acids, as well as cysteic amide (a sulfonate closely related to isethionic acid and taurine, which are also present in relative abundance) and other low molecular weight constituents (see Table I), including some five peptides whose composition is now being investigated and whose function is not known. Using high-capacity methods of electrophoretic fractionation and large amounts (10 to 20 g) of freeze-dried axoplasm, these substances are being isolated in quantities sufficient to permit determination of their composition and biological properties.

Among the macromolecular constituents of axoplasm, the fibrous protein is of special interest. Polarization-optical analysis (Bear *et al.*[18]) demonstrated (1) that the fibrous protein exists in the normal fresh axon where it is oriented with long axes parallel to the fiber axis, (2) that the intrinsic birefringence of the protein macromolecules is similar in magnitude to that of other fibrous proteins, and (3) that the partial volume occupied by the oriented fibrous protein is probably relatively small. Electron-microscopic observations[19,20] revealed that the fibrous protein occurs characteristically as thin (*ca* 100 to 200 A) filaments of indefinite length and with no demonstrable axial discontinuities or periodic structure. P. F. Davison and E. W. Taylor in this laboratory have made recent physicochemical studies (unpublished) on fresh axoplasm of *Dosidicus* shipped iced from Chile to Cambridge. From these, it appears that the fibrous protein may have a molecular weight in the order of millions and may be very long and thin. However, the possibility cannot be excluded that the protein as it occurs in the axoplasm so far available (i.e., suspended in cold saline and studied some days after removal from the squid) may in fact be a high polymer, of which the monomer may have a length of the order of 2500 A. In addition, the material which has so far been isolated may represent a complex of two or more proteins. Only when this protein or protein complex has been isolated and characterized chemically and structurally will it be

possible to determine its biological role. Meanwhile, as it is purified and fractionated, it will be subjected to screening tests intended to provide clues regarding its biological activity.

(C) The Axon Surface Membrane

Electron microscopy permits one to visualize directly the axon surface membrane, though admittedly this is possible only in fibers which have been fixed, embedded, and cut into ultrathin sections. This membrane, or some component of it, presumably corresponds to the irritable membrane whose physical properties before, during, and after the passage of the nerve impulse have been studied by electrophysiologists. Some of the functions that must be subserved by membrane constituents are shown schematically in Fig. 2.

At high resolution, the membrane appears as a double-edged structure with two dark edges separated by a less dense area (see Robertson[21,22]). The total thickness is about 60 to 70 A, the dark and light lines having about equal thickness. The apparent thickness of the dense regions in the membrane may be reduced as methods are improved. A satisfactory interpretation of this structure, in terms of the lipid and protein components of the membrane, must await a detailed study of model systems of lipids and lipid-protein systems. The consensus at present seems to be that the dark regions represent the aqueous, protein-containing interfaces. The less dense regions represent the lipid phase with its preponderant aliphatic hydrocarbon chains. This point of view is not shared by all. Stoeckenius[23,24] believes that the osmium-tetroxide deposits electron-dense material in the region of the unsaturated double bonds of the lipids rather than at the protein, aqueous interface.

Whatever may be the eventual interpretation of the structure of the axon surface membrane, it is perhaps safe to say that the membrane includes a bimolecular

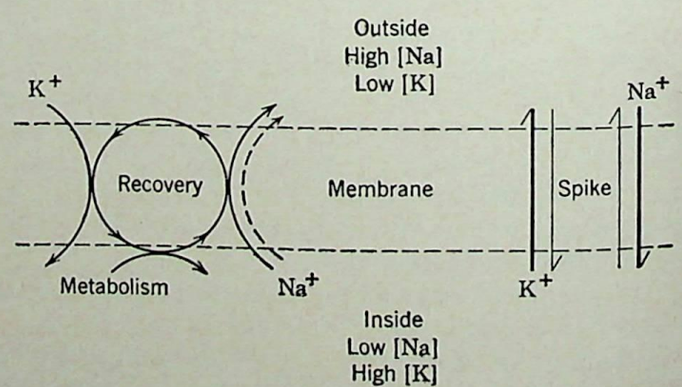

FIG. 2. Diagrammatic illustration of ion movements through the nerve membrane [after A. L. Hodgkin and R. D. Keynes, J. Physiol. 128, 28 (1955)]. Ion movements occurring during the action wave are shown at the right; active transport, involving coupling of metabolic energy, is shown on the left. The excitable membrane pictured is presumably identical with the limiting surface membrane of the axon, or some portion thereof.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

leaflet of mixed lipids and at least a monolayer of protein or other hydrophilic, osmiophilic material on either side of the lipid layer. This represents the "unit" membrane structure, thought by many competent electron microscopists to be characteristic of biological membranes generally. In addition to this structure, which might be thought of as the "floor space" of the cellular factory, one supposes that there are mounted upon or within this membrane the enzymes responsible for the special molecular and biochemical processes which underlie the rapid change in cation permeability at the time of impulse propagation and the "pumping" of sodium ions from axoplasm against an activity gradient into extracellular space. Obviously, much research is required before the details of the molecular organization of the membrane can be established. Meanwhile, in describing the membrane structure, it is perhaps desirable to avoid terms such as "triple" membrane (so-called because of the two dense and one less dense regions); this might cause investigators of the nature of the true "physiological" membrane (i.e., that deduced from indirect, chiefly electrical, methods) to identify one or another component of the fixation artifact seen in the electron microscope as a self-sufficient entity, ignoring the fact that the membrane must almost certainly be considered as a complex system of interacting, interdependent components. Precisely in such situations are the methods of molecular biology different from those of descriptive morphology.

(D) Nerve Endings and the Synapse

At axon endings, electron microscopy reveals an accumulation of particulates, particularly mitochondria. Also characteristic is the presence of small (*ca* 200 to 500 A) vesicles, appearing sometimes in large quantity. It has been suggested that these vesicles contain acetyl choline, adrenalin-like materials, and other physiologically and pharmacologically active substances such as histamine and serotonin. If transmitter substances occur in packets and if such packets were presented at the end organ, perhaps as a secretion across the membrane, certain electrophysiological studies of synaptic potentials might thus find explanation (Katz, p. 524). At present, the origin of the vesicles is still unknown, as are the details of the mechanism by which they or their contents find their way into the endings.

Of considerable theoretical significance is the problem of the nature of the relationship between the limiting membranes of the nerve terminals and of the muscle or other innervated cell. If, as current consensus indicates, there is a space of at least a few hundred Ångström units between these membranes, the problem of the mechanism whereby transmitter substances pass from neuron to innervated tissue is a different one than if the two membranes were strictly in molecular contact. This is still a matter for discussion. The factors involved in determining membrane separation by electron microscopy are considered below in more detail.

II. SATELLITE-CELL DIFFERENTIATIONS AND RELATIONSHIP TO THE AXON

Extending to the farthest reaches of the body, portions of the nerve axon may be very remote from the metabolic center near the nucleus of the cell body. This would constitute an inherently very unstable system. However, the axon is probably seldom actually remote from metabolic centers because it is everywhere surrounded by thin satellite cells, the Schwann cells, which are themselves metabolically active. These cells may well have intimate biochemical relationship with the axon. Such cell-to-cell biochemical relationship and interdependence have in fact been demonstrated *in vitro*. Puck,[25] for example, has shown that a monolayer of cells of a certain type, which are themselves unable to obtain all of their nutritional requirements from the medium, can be stabilized by depositing upon them a layer of cells which can provide or utilize the required factor. These act as "feeder" cells to the underlying cells and constitute a stable system. It seems possible that the evolutionary advance to the higher organisms, with their extensive nervous system, depended upon the development of the process whereby satellite cells come to envelop outgrowing axons, thus permitting the fibers to extend to the extremities of the body as stable neurons.

The satellite cells may function in relation to the axon in other ways also. In any homogeneous group of nerve fibers, the velocity of impulse propagation is a direct function of the diameter of the fiber. In invertebrate fibers, to achieve relatively high velocity of propagation (30 to 40 m/sec), the axon diameter becomes relatively enormous (0.5 to 1.0 mm in the squid). However, in myelinated fibers in which the axon is covered to some 99% by myelin, impulse-propagation velocity may be high (50 to 100 m/sec) in fibers of modest diameter (10 to 20 μ). In these cases, impulse propagation is believed to be saltatory in nature rather than continuous; i.e., the membrane changes responsible for excitation occur in very restricted regions (at the nodes of Ranvier), and internodal segments respond as entire units. The investigation of the molecular organization of the myelin, which acts as internodal insulation, and of its mode of formation by the Schwann cell, present a most rewarding opportunity for the methods in the molecular biology of nerve.

(A) Myelin

From polarization-optical analyses, it was shown by Schmidt[26] that the lipid molecules in the myelin sheath are oriented with their paraffin chains extending radially, whereas the protein components are oriented with their distinguishing directions perpendicular to this direction, i.e., tangential. The lipid-protein layers must be thin with respect to the wavelength of light, constituting a Wiener mixed body.[27]

X-ray diffraction studies supported this view and

(b)

FIG. 3. (a) Schematic representation of molecular organization of the nerve myelin sheath (after Schmitt, Bear, and Palmer[28]). *A*, concentric lipid-protein layered structure deduced from polarization optics and from small-angle x-ray diffraction; *B*, unit lipid-protein structure in the radial direction (perpendicular to the planes of the layers); *C*, sections through the molecular chains in the planes of the layers. (b) Diagram summarizing molecular organization of nerve myelin from x-ray diffraction data, as suggested by Finean.[34]

small-angle diffraction showed that the lipid-protein layers have a characteristic thickness of about 171 A in cold-blooded animals and about 185 to 190 A in warm-blooded animals (Schmitt *et al.*[28]). On the basis of extensive studies of the individual lipid types both dry and in aqueous systems, these authors showed that the identity period in the radial direction must include two bimolecular leaflets of mixed lipids, and that the protein and water components must occupy approximately 25 A each. Several alternative models involving bimolecular leaflets flanked by monolayers of protein were proposed (see Fig. 3). It was pointed out[29] that nerve myelin, being susceptible to x-ray diffraction analysis and having a lipid-protein architecture similar to that of cell membranes, might provide a model for the study of such membranes which, because of their thin paucimolecular nature, could not be similarly studied.

The concentric-layered structure of myelin was confirmed by direct visualization in the electron microscope (see Fernández-Morán[30] and Sjöstrand[31]) after development of the technique of thin sectioning for electron microscopy. The thickness of the layers was somewhat less than that demonstrated by x-ray diffraction for the fresh fibers. This difference was shown to be owing to the fixation, dehydration, and embedding required in the electron-optical technique; nerves were subjected to diffraction analysis after each step in the preparative technique, and the thickness of the layers was determined by electron-microscopic examination of thin sections of the same specimens.[32–34]

After the main features of myelin architecture had been determined, the question arose as to how such a structure is produced by the Schwann cell, in collaboration with the axon. A clear-cut answer to this question was provided by Geren,[35,36] at least in the case of peripheral fibers. From observations of embryonic sciatic nerves in chick embryos,[37] Geren proposed her membrane theory which is schematically illustrated in Fig. 4. According to this ingenious theory, now verified by the observations of many investigators (e.g., Robertson[38]), the Schwann cells, after enveloping the outgrowing axons and causing their respective surface membranes to adhere firmly, wrap themselves many times around the axon by a continuous infolding of the outer Schwann-cell surface membrane. The mechanism of myelination in the central nervous system is less clear. Although

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

various authors have seen the myelin layers as a spiral (in transverse section), as in peripheral fibers, others (Luse[39] and DeRobertis *et al.*[40]) have obtained evidence which they interpret as indicating that lipid-protein layers are formed in the cytoplasm of the oligodendrocyte, perhaps by the fusion of vesicles 200 to 800 A in diameter, which condense into the compact myelin layers. The myelin layers are hence not concentric but are spirally wrapped about the axon. After many wrappings (or few, depending upon the fiber type) the Schwann-cell cytoplasm is pressed from among the layers which become condensed into the smectic, paracrystalline material of the finished myelin. This process requires a prolific biosynthesis of lipid-protein material. Where this is synthesized in the cell and how it comes to be incorporated in the cell membrane is not yet known. The myelination process would seem to provide an ideal system in which to study the molecular mechanism of lipid-protein synthesis and of membrane formation in general.

From Geren's membrane theory, it immediately becomes obvious why there are *two*, rather than one, bimolecular layers of lipids in the x-ray identity period in the radial direction (see Schmitt, Bear, and Palmer[28]). As the outer Schwann-cell membrane infolds, the outer surfaces of the membrane remain in contact. As the layers condense, with the expulsion of Schwann-cell cytoplasm, the membrane surfaces which faced the Schwann-cell cytoplasm also adhere, fuse, and form the darkly staining line seen in the electron micrographs (see Fig. 5). The alternate less-dense line represents the fusion of membrane surfaces which originally faced outward to extracellular space. Finean,[34] who has continued the x-ray analysis in a systematic fashion over the last decade, has proposed a molecular model of myelin in which the cholesterol molecules fit in between the phospholipid and cerebroside molecules in characteristic fashion (see Fig. 3). Further refinements in the x-ray and electron-microscopic techniques, together with the study of various lipid-protein models, may provide important new information about membrane structure which will be of vital importance in the rapidly expanding field of molecular biology.

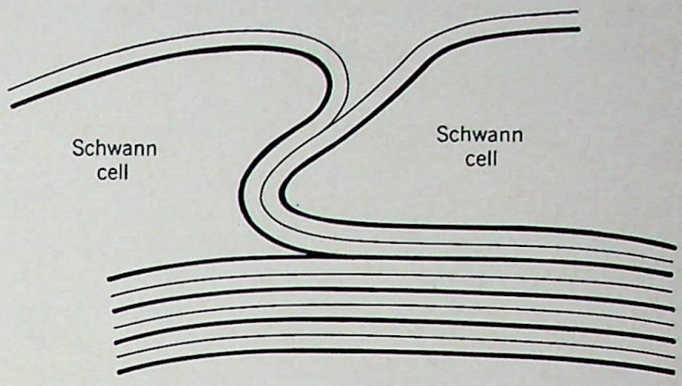

FIG. 5. Illustrating enfolding of Schwann-cell surface membranes to form compact myelin, after the theory of Geren.[35] Note differentiation between inner and outer surfaces of enfolding membrane; in the double membrane, this gives rise to Finean's "difference factor" and explains why the full repeat distance in the radial direction involves two bimolecular leaflets of lipo-protein (two membranes).

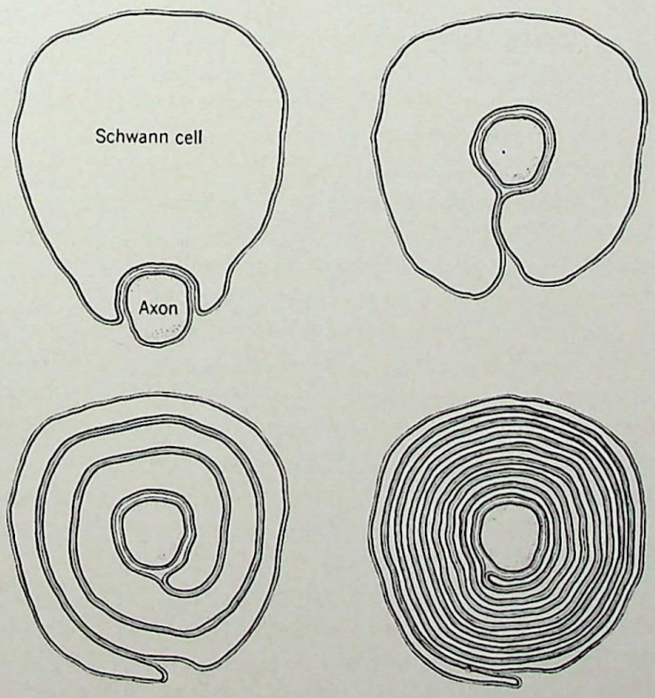

FIG. 4. Schematic representation of the membrane theory of the origin of nerve myelin, (after Geren[35]). Four stages in the engulfment of the axon by the Schwann cell and the wrapping of many double layers which, after condensation, form the compact myelin.

As Schwann or satellite cells envelop the outgrowing axon and start to wrap their surfaces in multiple folds about it, adjacent Schwann cells come into contact and form the nodes of Ranvier. This nodal region of the finished, myelinated fiber has not yet been exhaustively studied in the electron microscope. In view of the critical nature of this region, suggested by the theory of saltatory conduction, its ultrastructure merits careful study. According to a preliminary report by Robertson,[41] the Schwann cells on either side of the node form finger-like processes which interdigitate closely over the node. The region between the processes, presumably containing extracellular fluid, is of the order of several hundred Ångström units thick. To this extent, the axon surface membrane is exposed to extracellular fluid at the node, according to Robertson.

The incisures of Schmidt-Lantermann presented a problem because, if they are continuous channels between the axon and the exterior through the myelin, they would offer conducting paths for current. However, electron microscopy has demonstrated that this is not the case.[42,43] The incisures are produced by a systematic shift in the relationship of all of the helically wrapped membranes, but each membrane is continuous across the incisural gap. There are thus as many layers traversing the incisures as occur in the compact region of the myelin,[5] and the incisures are therefore not regions

through which ions and currents can freely flow into the axon.

III. SATELLITE-CELL-AXON RELATIONSHIPS IN "UNMYELINATED" FIBERS

It has long been known to neurohistologists, particularly to those of the Spanish school, that nerve fibers are everywhere covered by satellite cells. The fact that these cells and their possible functional role—in the mature as well as in developing and regenerating fibers—have not greatly interested physiologists, or even histologists, is to some extent owing to their small size (*ca* 0.1 to 1 in most invertebrate fibers) or to the fact that myelin (which has been much studied by histologists and physiologists) was not recognized as satellite-cell substance (i.e., a compact helical layering of double surface membranes). The fact that, early in the development of histology, a sharp distinction was made between "myelinated" and "unmyelinated" fibers (primarily on the basis of staining reactions), led some physiologists to the mistaken notion that a substantial fraction of the animals' nerve fibers are in effect naked axons. From this, it is obvious why the cellular covering of the axon attracted little interest except to those studying nerve development or regeneration, where the satellite-cell covering is unquestionably of functional significance.

Polarization-optical studies (see Schmitt and Bear[29]), based largely on a reinterpretation of the mechanism of the so-called metatropic reaction discovered by Göthlin,[44] strongly suggested that at the surface of all nerve fibers, vertebrate or invertebrate, myelinated or unmyelinated, oriented lipid-protein material is present which has qualitative similarity of molecular organization though quite variable quantitatively from one fiber type to the next. This led to the notion that "all nerve fibers are to some extent myelinated."[29]

This matter could be clarified only when the region at the surface of nerve fibers—i.e., the monolayer of satellite cells—could be observed at high resolution by the electron microscope. Details of the discoveries thus brought to light are beyond the scope of this paper, but a few of the more significant aspects at the molecular level, particularly insofar as they bear on basic physiological concepts, are considered.

Investigation with the electron microscope of the detailed structure of the satellite cells and their relation to the axon is not yet a decade old, and it is, therefore, not unexpected that knowledge of the subject is still very primitive. No doubt, special methods of fixation and preparation will have to be developed to permit investigation of the most fundamental aspects of the problem, such as the possible variation of intercellular relationship, as manifested morphologically by the apparent spaces or channels between axon surface and satellite cells and between satellite cells themselves, with function.

The typical invertebrate, unmyelinated (but not unsatellited!) nerve fibers, such as those of the lobster leg or claw nerve, are surrounded by satellite cells which are very thin (*ca* 0.1 μ). Except at the region of the nuclei, there is relatively little space between the two parallel surfaces of the cells (i.e., facing the axon surface membrane and that facing the basement membrane, connective tissue investment), although mitochondria and some of the typical equipment of the cytoplasm of active cells may be seen. The axon surface is characteristically highly contorted, and axoplasmic mitochondria are seen with the long axes of their ellipsoids oriented into the folds of these contortions, suggestive of energy utilization at this interface (see Fig. 6). The outpocketings of the satellite cells into the axon may manifest all of the stages to be expected if particulates (mitochondria?) were actually being formed and extruded into the axon by filling such outpocketing with satellite-cell cytoplasm (including its particulates) and pinching them off into the axoplasm (see Geren and Schmitt[13,45]).

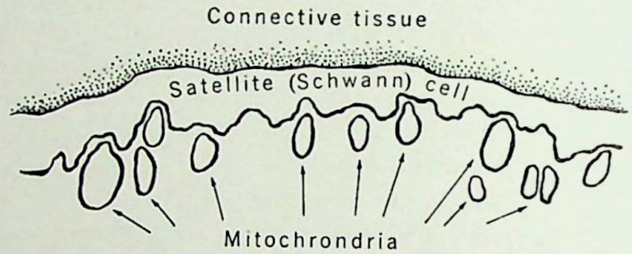

FIG. 6. Diagrammatic illustration of thinness of satellite cell in lobster fiber and of intimate relationship between mitochondria and axon surface membrane (after Geren and Schmitt[41]).

Such very thin cells would be expected to show only a very weak birefringence and metatropic effect, since only two lipid-protein surface membranes are involved. Nevertheless, this optical effect was observed and correctly interpreted, except that the layers were simply assigned to the region at the surface of the axon, rather than to the membranes of the satellite cells.[46]

The satellite cells of squid giant fibers are somewhat thicker (*ca* 1 μ) than those of lobster, though the ratio of thickness to axon diameter may actually be less. In any histological section of the giant fibers, as many as two or three nuclei may be present. If one were to chart the boundaries and domains of the satellite cells upon the axon surface membrane (e.g., by slitting the fiber and flattening out the membrane), one would see that many cells are involved in the formation of the cellular monolayer that surrounds the axon.

The most distinguishing feature of the cytoplasm of these cells is the presence of many (a half-dozen or more) osmiophilic, dense membranous layers lying in planes predominantly parallel with the cell surface. Whether these layers are related to those present in typical, metabolically active cells ("endoplasmic reticulum"), or whether they have a special structure and function in satellite cells remains to be established by more-detailed examination. However, if one assumes that the layers have the composition and ultrastructure typical

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

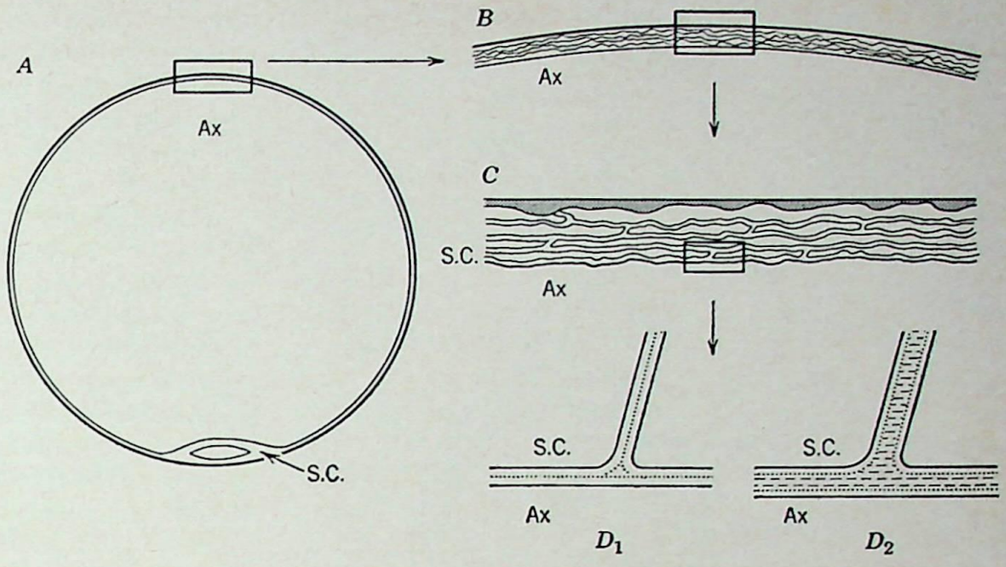

FIG. 7. Relationship of axon (Ax) and Schwann cell (S.C.) in the squid giant fiber (after Schmitt and Geschwind[2]). *A*, cross section of giant fiber showing very thin Schwann cell surrounding axon. ×125. *B*, enlarged segment portion of Schwann cell, ×3000; *C*, same as *B*, showing intracytoplasmic layers, ×9000; and D_1 and D_2, possible relationships at the molecular level of axon surface membrane and Schwann-cell membrane. D_1 presumes layers are in molecular contact. (Water layer does not exceed about 15 A in thickness.) D_2, showing thicker water layers (100 to 200 A) between adjacent membranes. ×150 000.

of lipid-protein membranes generally (hence, also of myelin), it is possible to account for the polarization-optical properties described by Bear *et al.*[47] and ascribed by them to a metatropic layer at the outer surface of the satellite cells—a kind of myelin-like layer. Geren and Schmitt[45] have shown that the optical effects can satisfactorily be accounted for on the basis of the intracytoplasmic dense layers present in the satellite cells. There is no differentiated myelin-like layer at the outside of these cells, only the amorphous basement membrane.

One of the structural details that must await further investigation for clarification, but that may be of great ultrastructural and perhaps functional significance, is the nature of the boundaries between satellite cells and the axon surface membrane, between adjacent satellite cells and between intracytoplasmic membranes. Of particular importance is the thickness of the aqueous regions between these membranes, because ions passing from extracellular space to axoplasm and in the reverse direction must traverse such channels.

The situation is illustrated schematically in Figs. 7 and 8. If the adhesion between the surface membranes were as close as in the myelin sheath, there would be no substantial channels for ion diffusion. The aqueous phase would have a thickness of the order of 12 A according to the x-ray diffraction analysis of myelin struc-

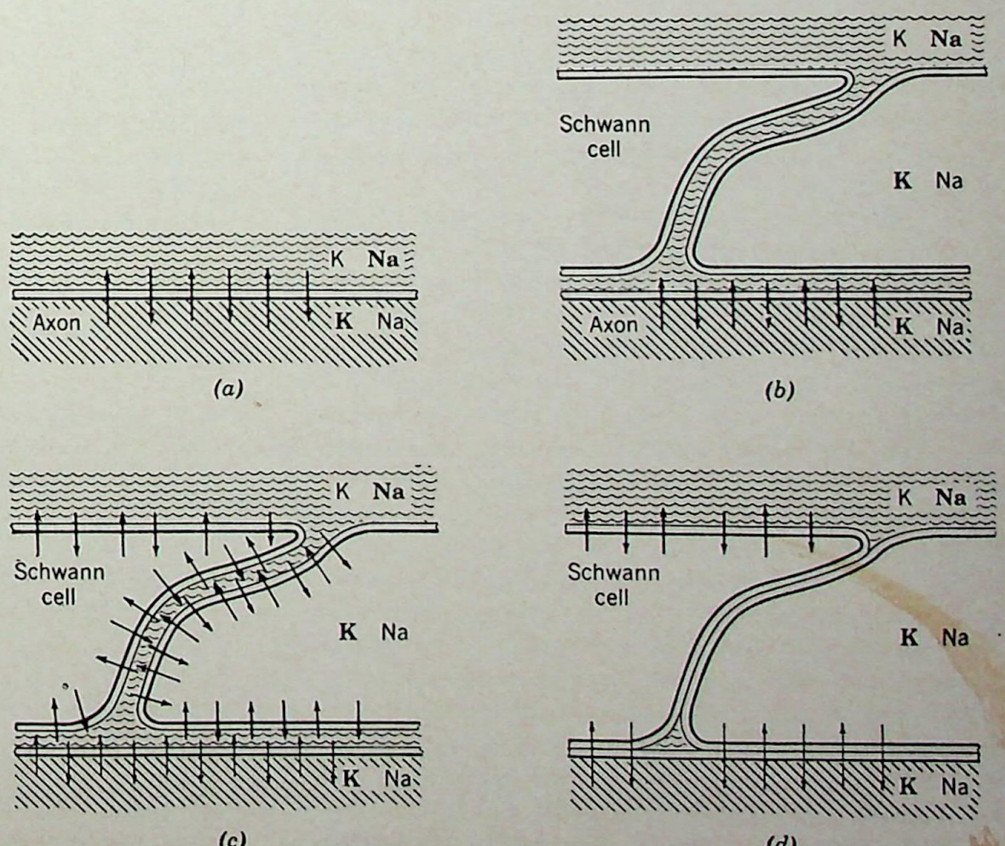

FIG. 8. Possible diffusion pathway for solutes passing between axoplasm and extracellular fluid (after Schmitt[3]). (*a*) bare-axon membrane is exposed to extracellular fluid (*b*) diffusion channel is 150 to 200 A thick, filled with extracellular fluid. Active interchange occurs only between axon surface membrane and fluid in channels; passive diffusion occurs in other channels. (*c*) same as (*b*) except that active interchange of metabolites and solutes occurs across all membrane surfaces; satellite cells participate actively in processes involving interchange between axon and extracellular fluid. (*d*) satellite cells and axon membranes are in molecular contact; water channel not more than 10 to 15 A thick with structure comparable to that of compact myelin.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

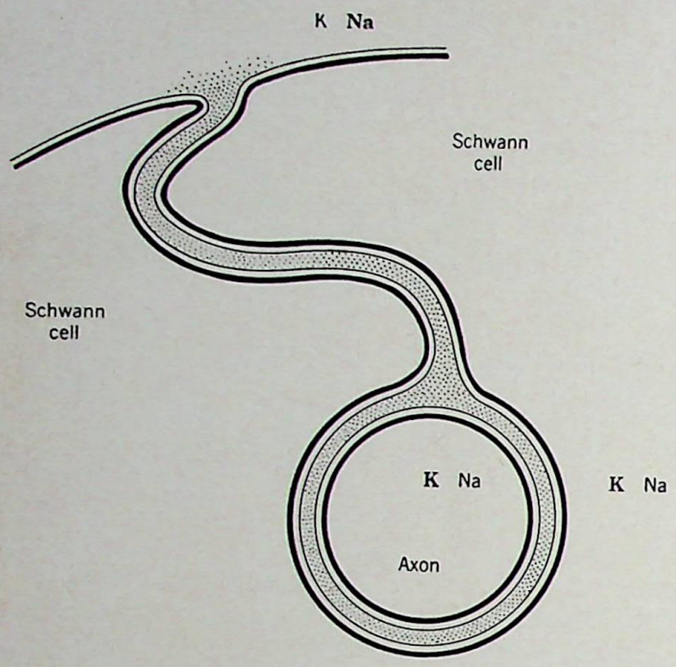

FIG. 9. Diagrammatic representation of relationship of very thin *C* fibers to Schwann cell (after Robertson[48]).

ture.[28] On the other hand, if these intercellular relationships are similar to those found by Robertson[47] and by electron microscopists to obtain between cells generally, the aqueous channels, communicating with the frank extracellular fluid of the ground substance of the surrounding connective tissue, would have a thickness of about 150 A.

Robertson[21,22,48] has found such a membrane relationship in the case of the vertebrate "*C*" fibers. In these nerves, the very thin (*ca* 0.1 μ) axons pass through the satellite (Schwann) cell tube enclosed in a fold of the surface membrane of the satellite cell in a manner analogous to that assumed by Geren's membrane theory to explain the origin of myelin (see also the earlier works of Gasser[49–52]).

In analyzing the functional significance of the intermembrane relationship and the thickness of the aqueous regions between limiting membranes *in life*, several factors must be considered. Indeed, this situation illustrates certain indeterminacies that characterize the electron microscope approach to molecular biology generally.

From the properties of the constituent membranes, including the charge on the membrane molecules, a separation of the order of 100 to 200 A between the membranes might be expected.[53–56] This equilibrium distance will vary with the ionic strength (a statistical physicochemical concept that is difficult to apply to such thin capillary spaces). If the equilibrium distance between surface membranes is responsive to the ionic strength of the environment, it is obvious that a factor of importance is the ionic strength of the fluid used to fix the nerves. Another factor is the osmotic pressure normally characterizing the intercellular fluid. If this is not identical with that of the intracellular fluid, then when the system is placed in the fixative (which presumably quickly destroys membrane semipermeability and such vital equipment as "ion pumps"), an osmotic transfer of water may be expected, and this might importantly influence the distance between surface membranes as observed in the electron microscope after fixation and sectioning.

It has become evident from electron-microscopical studies of metabolically active cells not only that the metabolic activity involves the presence of membranes separated by small distances, but also that the products of the metabolism, presumably including ions, must find their way into the aqueous space between the membranes. The presence of these metabolites in turn must affect the equilibrium separation between the membranes and the properties of the intercellular fluid within these thin capillary spaces. Such factors must be taken into consideration in dealing realistically with these spaces which are the channels of communication between the axon surface membrane (presumably the seat of the rapid alterations responsible for the propagation of the impulse in the nerve fibers) and frank extracellular space. According to Frankenhaeuser and Hodgkin,[57] if such intercellular channels are the route of diffusion of potassium ions from axoplasm to the exterior, the electrical data would require a channel thickness of about 300 A in a structure similar to that shown by Geren and Schmitt[13] assuming a process of passive diffusion calculable on the basis of properties characteristic of macroscopic bulk phases. Whether or not additional properties, deriving from the microscopic dimensions of the intermembrane system and from the presence of solutes, particularly metabolic products of the satellite cells, require modification of this view remains for further analysis to determine. That the satellite cells of the squid giant fiber are indeed metabolically active has been shown by the measurements of oxygen consumption of the sheath cells after removal of the axoplasm,[58] and from an assay of enzyme activities of sheath cells and axoplasm.[59]

Nature of the Nerve Impulse

BERNARD KATZ

Department of Biophysics, University College, London, W. C. 1, England

INTRODUCTION

THE mechanism by which signals are rapidly transmitted over long distances in the body has formed one of the principal preoccupations of biophysicists for well over a century. Since the days of Du Bois-Reymond (about 1850),[1] it was known that nerves not only are excited by electric currents but also produce, in the course of their activity, electric currents of their own. His pupil, Hermann,[2] suggested that the propagation of a signal along a nerve fiber (or axon) involves a process of recurrent electric stimulation from point to point. Hermann also called attention to the apparent cable properties of nerve fibers, although he recognized that, by passive cable transmission alone, nerve signals could not travel over any appreciable length. Later, under the influence of Nernst, Bernstein[3] developed the basis of the modern membrane theory. According to Bernstein, the key to our understanding of the nerve impulse is to be found in the properties of the surface membrane of the axon, and especially its selective and changeable permeability (or conductance) to ambient ions. His theory has been modified in important details, but in essence it still stands, and the advances which have been made in this field during the last two decades have confirmed the usefulness of Bernstein's basic concept.

The view which now has emerged is (a) that the electrical events in a nerve fiber are governed by the differential permeability of its surface membrane to sodium and potassium ions, and (b) that these permeabilities themselves depend upon the electric field across the surface. The interaction of these two factors leads at a certain critical threshold level to excitation, that is, to a regenerative release of electrical energy from the axon membrane, and the propagation of this change along the fiber in the form of a brief, all-or-none, electrical impulse (the so-called spike or action potential).

As F. O. Schmitt has pointed out (p. 455), when a physiologist speaks of the axon membrane, he usually has in mind an abstraction rather than a microscopically identified structure. This point, *viz.*, the relation between fine structure and functional properties, is discussed later in this paper; here the main concern is to indicate what evidence there is for such physiological "abstractions."

RESTING NERVE FIBER

For the purpose of discussing the principal features of the nerve signal, the structural picture can be reduced to that of a long cylindrical tube with a surface membrane which separates two aqueous solutions of equal osmolarity but of different chemical composition. In the external medium, more than 90% of the osmotic balance is made up of sodium and chloride ions; while inside the cell, these ions account for less than 10% of the solutes, potassium taking the place of sodium, and various organic anions (which presumably are synthetized within the cell itself) taking the place of chloride. Our main concern is with the concentration differences of sodium (about 10 times higher outside) and potassium (about 30 times higher inside) across the cell surface. With the use of very fine KCl-filled micropipettes, it has been possible to penetrate the fiber surface without serious damage and to measure the electric PD between inside and outside. There is a potential difference across the membrane of some 60 to 90 mv (inside negative), while there are no detectable potential differences within the interior of the normal resting cell.

Observations of this kind have been made on a variety of nerve and muscle fibers. Most of the evidence described in the following has been obtained from the giant axon of the squid whose large size (nearly 1 mm thick) allows one to introduce an assembly of fine electrodes along the inside to analyze the ionic content of a single fiber and to observe the movement of radio-tracers within selected regions of such fibers (see Hodgkin,[4,5] also Huxley[6] and Katz[7] for review and references).

It should be mentioned perhaps that the nerve fibers of squid and other cold-blooded animals can be isolated and kept in a suitable salt solution. They remain in a functioning condition for many hours during which they can be made to propagate many thousands of impulses of approximately the same voltage and velocity as initially, *in situ* and with the blood circulation intact. Such fibers remain capable, to some extent, of replenishing the losses from their chemical stores which are drawn upon during periods of activity. Nevertheless, it is true that isolated tissues and, in particular, nerve fibers (which, after all, are only peripheral stumps of a cell) are no longer in a steady state, and their electrochemical accumulator gradually runs down.

It is of interest that muscle fibers can be used to study propagation of impulses as well as nerve. Muscle fibers, unlike severed nerve axons, are self-contained cell units which possess a built-in apparatus of distributed nuclei (and which, incidentally, do not possess investing layers of satellite cells). The surface membrane of a muscle fiber has certain important properties in common with that of a nerve: it provides a selective barrier between cytoplasm and surroundings, and it serves to conduct electric excitation rapidly over the whole length from

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

the nerve-muscle junction to the tendon. This is an essential mechanism for the skeletal muscle, for the action potential provides the local stimulus to the contractile process at each point of the fiber, and a high speed of propagation is needed to elicit an efficient synchronous twitch. As far as has been ascertained, the properties of the vertebrate-muscle impulse are exactly analogous to those of the nerve action potential.

MAINTENANCE OF THE STEADY STATE

The first question to consider is: What are the mechanisms responsible for the maintenance of a steady state in a resting (i.e., nonstimulated) nerve or muscle cell? In particular, how are the electrical and ionic concentration differences kept up between interior and surroundings?

Is potassium chemically bound? It has been suggested from time to time that one does not require selective membrane properties in order to explain the preferential accumulation of potassium in the cytoplasm. It would be sufficient, for example, if the cellular proteins had a special chemical affinity to potassium rather than to sodium. This idea of chemical binding of potassium seemed unlikely on several grounds: it would be difficult to account for the osmotic pressure and electric conductivity of the cell contents unless at least a large proportion of the intracellular potassium was present in the form of free ions. The most direct evidence was obtained by Hodgkin and Keynes[8] in the following experiment. A region of an isolated *Sepia* axon (about 150 μ thick) was bathed in a droplet containing radiopotassium. After a quantity of the labeled ions had entered the axoplasm, the external droplet was washed away. It may be noted that the mixing between applied tracer and intracellular potassium takes many hours, but the exposure time was sufficient to build up an adequate amount of radioactivity within the axon. Subsequently, the spread of this patch by diffusion along the interior of the fiber was determined; at the same time, a potential difference was applied to the ends of the fiber, and the speed with which the labeled patch moved toward the cathode was measured. The experiment showed that the diffusion coefficient and the electric mobility of the tracer ions were only slightly less inside the cell than in free aqueous solution. There was clearly a highly resistive surface barrier, for the entry of the externally applied potassium into the axoplasm was very slow; but once the tracer ions had passed this barrier, they continued to behave as free ions.

BERNSTEIN MEMBRANE THEORY

The experiment of Hodgkin and Keynes seems to rule out the suggestion of chemical binding of potassium and provides direct evidence for the existence of a resistive surface membrane as envisaged by Bernstein more than 50 years ago. He postulated that the nerve membrane was selectively permeable to potassium alone, and impermeable to sodium, chloride, and the internal anions. This was an attractive hypothesis, for it would explain not only the maintenance of steady ionic concentration gradients, but also the existence of the resting potential as resulting from a potassium-concentration cell. Moreover, it was possible to predict an inverse logarithmic relation between the external potassium concentration and the membrane PD, and over a fairly wide range there was satisfactory agreement between theory and experiment. Bernstein went one step further. He postulated that the membrane permeability to the other ions increased during electric excitation so that the impulse should be accompanied by a sharp increase of the membrane conductance and a drop toward zero of the membrane potential (or rather to the low level of a liquid junction PD between axoplasm and external fluid). For many years, these ideas were accepted as a reasonable explanation, and the evidence, rather inaccurate and indirect as most of it was, tended to support it. More recently, it was strengthened by the observation of Cole and Curtis[9] that the rising phase of the action potential indeed is accompanied by a rapid 40-fold increase of the ionic membrane conductance.

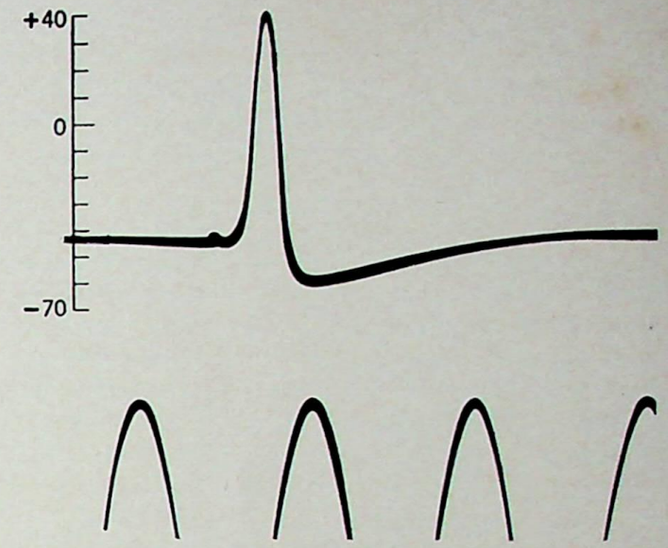

FIG. 1. Action potential recorded with an internal electrode from a squid giant axon. The scale shows the internal potential in millivolts, relative to the outside bath. The time marks are at 2-msec interval [from A. L. Hodgkin and A. F. Huxley, Nature 144, 710 (1939)].

The flaws began to appear soon after, when increasing use was made of the critical methods introduced by Cole and by Hodgkin, *viz.*, the single axon technique and the use of intracellular recording, and also when improved chemical and tracer methods were employed in observing ion movements. In 1939, Hodgkin and Huxley[10] (see also Curtis and Cole[11]) discovered that the membrane potential during the nerve impulse does not move simply toward the zero level (Bernstein's predicted "depolarization"), but reverses substantially to a level of 40 to 50 mv—inside positive (see Fig. 1). This was clearly incompatible with the second part of the Bernstein theory just now outlined. Two years later,

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Boyle and Conway[12] demonstrated that muscle fibers are permeable to chloride as well as to potassium, and shortly afterward it became clear that even sodium can enter the fibers, though apparently it encounters a much higher membrane resistance than does potassium.

SODIUM PUMP

This raised an altogether new problem, for the demonstration of even a small permeability to *sodium* made it impossible to regard the physical properties of the surface barrier as sufficient to maintain the concentration and potential gradients in a steady state. Potassium and chloride appear to be very nearly in electrochemical equilibrium, their large concentration differences being balanced approximately by the membrane potential. But, in the case of sodium, both driving forces act in the same direction and tend to shift the ion into the interior. If the membrane resistance toward sodium is not infinite, then some mechanism entirely different from the ones discussed so far is required to keep its internal concentration at a steady low level.

It was at this stage that the postulate of a metabolic sodium pump was introduced—that is, some secretory process in which an energy-yielding reaction of the cell is utilized to perform the work of a Maxwell demon, moving sodium ions uphill and outward through the membrane as fast as they leak into the cell in the direction of the electrochemical gradient. There was nothing intrinsically implausible about the suggestion, for the permeability of the resting cell surface to sodium is normally so low that the leakage rate remains very small, and the work required of the pumping process amounts to only a small fraction of the energy which is continuously being made available by the metabolism of the cell.[13]

That there is, in fact, a direct relation between cellular metabolism and sodium extrusion was first shown by Hodgkin and Keynes[14] who observed a cessation of the efflux of tracer sodium when the axon was treated with certain metabolic inhibitors (dinitrophenol, azide, cyanide). This was a reversible change and one which specifically affected the extrusion rate of sodium, not its rate of leakage into the cell. More recently, Caldwell and Keynes[15] have shown that "pumping" is temporarily resumed by the cyanide-inhibited axon if a dose of adenosinetriphosphate or arginine phosphate is injected into the axoplasm.

At one time, it was thought that the sodium pump operated by expelling sodium alone, and in doing so was capable of separating electric charges at the fiber surface, moving them against the existing potential gradient, and so contributing directly to the build-up of the resting emf. This idea has been made unlikely by the findings (a) that the extrusion rate of sodium is unaffected by the potential gradient against which such an electrochemical pump would have to work, and (b) that the stoppage of sodium extrusion by metabolic poisons has no immediate effect on the resting (or action) potential, which runs down very slowly as a result of the gradual diminution of the ionic concentration gradients. It appeared, therefore, that the ion pump works on a principle of electroneutrality, either taking sodium out in company with some anion (e.g., bicarbonate or phosphate), or through a cation-exchange process. There is evidence that the latter is the prevailing mechanism, and that extrusion of sodium and internal uptake of potassium are linked closely in the pumping process. The most suggestive piece of evidence is the finding[14] that the extrusion rate of sodium becomes reduced greatly when potassium is withdrawn from the bath solution, and that, in general, the rates of potassium entry and of sodium efflux change simultaneously and in a parallel manner.

To summarize present views of the ionic maintenance mechanisms of the resting cell, one imagines that the cellular metabolism is responsible for the upkeep of ionic concentration differences between cell and surroundings, (1) by synthetizing large organic anions which cannot diffuse through the membrane, and (2) by providing the energy for an active ion-exchange mechanism, expelling sodium and accumulating potassium ions, possibly one for one. The cell membrane has a generally extremely low ionic permeability so that even in the complete absence of pumping action it will take many hours before the Na/K concentration gradients run down. The ionic permeability of the resting membrane, apart from being small, is also differentially very selective, that to potassium being much higher than to sodium, so that the PD across the resting membrane approximates to that of a potassium-concentration cell, though it does not quite reach this level (it would do so only if the sodium permeability were negligible).

The evidence for the existence of a cation pump is impressive; there is little doubt that the required Maxwell demons are being paid for; the account seems satisfactory not only in terms of available calories, but even in the form of the available currency (made up of ATP and other acceptable phosphates). But, as in most instances of specific cellular utilization of metabolic energy yields, there is no theory at present to explain how the so-called driving reaction is geared to the particular purpose of expelling sodium and piling up potassium. This is one of the familiar challenging gaps waiting to be bridged, even if only by a temporary working hypothesis.

CABLE PROPERTIES OF NERVE

It has been seen from the tracer experiments that the surface membrane presents a formidable barrier to the diffusion of ions, which agrees with the conventional picture of the membrane consisting of, or containing, a thin layer of insulating lipid material. It may correspond to the "double contours" of 50- to 100-A thickness which have been seen in electron micrographs of various cellular or intracellular surface structures.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

The conclusions which have been reached from chemical and tracer measurements are in general agreement with what is known about the electrical properties of nerve and muscle fibers. By studying alternating-current impedance, or by analyzing the attenuation and temporal distortion along the fiber surface of a small voltage-step signal applied at one point between inside and outside, it had been shown that the interior of axons and muscle fibers behaves as a conducting cylinder of slightly higher electrolytic resistivity than the outside fluid but is separated from the outside by a surface layer of very low conductance (of the order of 10^{-4} to 10^{-3} ohm^{-1} cm^{-2}) and of high capacitance. The fibers possess, therefore, electrical properties which are analogous to those of a cable, and one may ask to what extent these properties can be used for the purpose of signal transmission. Now, taken as a passive transmission line, the axon would be of little use, for its cable losses are very great: its surface leakage and the resistivity of its core are some 10^8 times greater, and its sheath capacity about 10^6 times higher than those of an ordinary commercial cable. In fact, a weak applied square-pulse signal (i.e., an electric pulse of subthreshold intensity which fails to excite the inherent relay mechanism of the axon membrane) fades out and becomes badly blunted within a few millimeters of its origin. It is clear, therefore, that the cable properties of the nerve are quite insufficient to serve the propagation of a message over the required distances, unless the deficiencies of the cable are made up by a special boosting process. This is indeed the case, and the sole purpose of the excitatory mechanism is to regenerate and to reamplify the signal at each point of the line, and so to insure its forward passage without attenuation or distortion of its brief wave form.

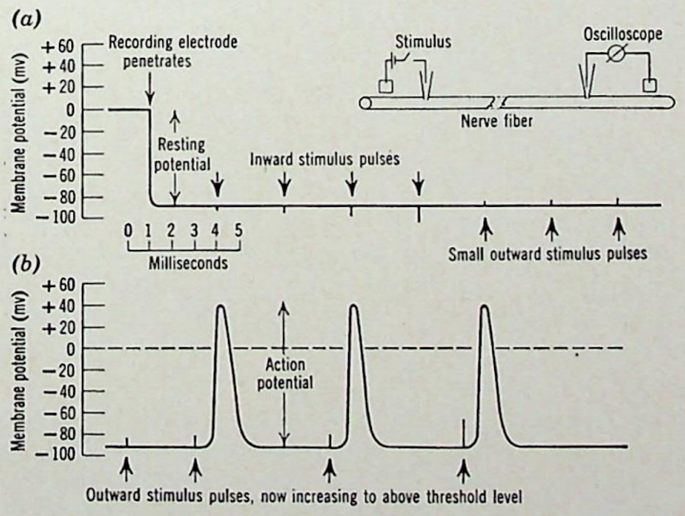

FIG. 2. Diagram illustrating the response of a nerve or muscle fiber to an electric stimulus applied at a distant point. The inset diagram shows the arrangement of stimulating and recording electrodes. In (a), a recording micropipette is inserted into the fiber interior, showing the resting potential across the cell membrane. Vertical scale indicates level of potential at the tip of the micropipette relative to the outside bath. Current pulses are applied through the distant stimulating electrodes, first inward, then outward through the membrane. No response is produced until, in (b), the outward pulses exceed a critical threshold when an all-or-none action-potential wave is recorded.

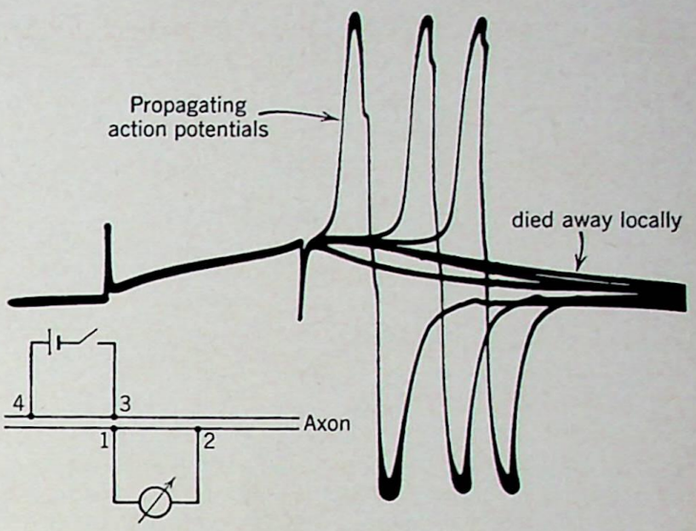

FIG. 3. Local and propagated potential changes, recorded at the site of stimulation from a single crab nerve fiber. Inset diagram shows arrangement of recording (1 and 2) and stimulating (3 and 4) electrodes, all four being placed on the axon surface, 1 and 3 close together. The records show, superimposed, the local potential changes produced by 6 successive pulses of threshold strength (duration of pulse *ca* 2 msec, beginning and end marked by brief artifacts). The potential change either died out locally or flared up after a variable delay into a large propagating action potential (about 100 mv peak-to-peak). Its diphasic nature is due to the wave of surface negativity passing first point 1, then point 2.

It is worth emphasizing that the presence of a cable-like mechanism, insufficient though it is for long-distance signaling, forms an essential link in the process of impulse propagation: it allows the action potential which has arrived at one point to impart a stimulus to the next region and to excite its latent relay mechanism. Moreover, the passive cable spread is of great importance for the integration of converging messages which takes place in the cells of the central nervous system. These cells become excited, or inhibited, by the interaction and summation of many subthreshold electrical changes which are imposed on different points of their surface membrane, all within a short range of the central cell body. The effective summation of such converging electrical influences is possible, because over short distances (a fraction of a millimeter) the cable properties of the cell are quite adequate, and the subthreshold potential changes do not suffer much attenuation. They can, therefore, sum up to the firing point at which an impulse emerges, capable of traveling the whole length of the axon process.

PROCESS OF EXCITATION

What is the nature of the excitatory relay mechanism by which the impulse is boosted to its full strength? The process can be demonstrated by recording the electrical events at the point of the fiber at which an impulse is initiated by an applied electric stimulus (Figs. 2–4). When a square pulse of current is passed inward through the axon membrane, the membrane potential is displaced

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

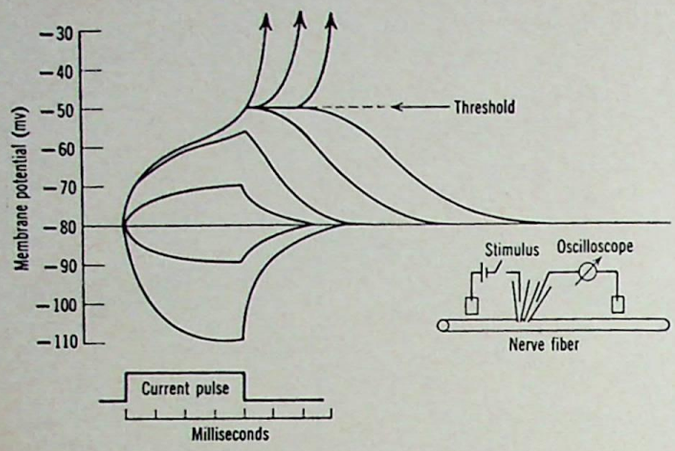

FIG. 4. Diagram showing local potential changes across axon membrane, due to rectangular current pulses (4-msec duration, varying direction and amplitude). At threshold, the membrane potential is displaced to a level at which it is in a state of unstable equilibrium, either flaring up into a propagating signal or subsiding locally.

from its resting level of, say, −60 mv inside to a higher level of internal negativity. The potential change takes a certain time to develop and to decay; this time course depends upon the resistance and capacity of the fiber, as in an ordinary leaky and capacitative cable structure. Currents of this direction, which increase the membrane PD, do not excite, but simply produce local potential changes approximately proportional to current strength, and fading-out along the fiber with a decrement of about 50% per 1 or 2 mm, characteristic of its cable coefficients.

When the polarity is reversed and weak current intensities are employed, very similar local potential changes of the opposite direction (reducing the membrane PD, or partially depolarizing) are observed. However, as the current strength is increased the picture alters. The membrane potential changes progressively, more than in proportion to the applied current, and a point is reached at which the depolarization becomes regenerative and, after withdrawal of the current, the decay of the effect greatly retarded. A slight further increase in current strength causes a flare-up of the potential change which now passes through an automatic cycle; it rises to the full height of the propagating action potential and then returns to the initial level within 1 or 2 msec. This event (known as the spike) travels at constant speed (about 25 m/sec in the squid fiber at 20°C) down the axon, without loss of amplitude anywhere; it leaves behind a short refractory period of a few msec, after which the axon is again excitable and capable of repeating the event. It is interesting that even below the firing point (or threshold), some local "smoldering" seems to go on. Indeed, there is a good analogy between the local electrical events in a nerve fiber and any other form of regenerative chain reaction, in which the initially applied stimulus is reinforced by the reaction which it produces. It would be possible, for instance, to obtain a very similar family of kinetic curves, if one used an explosive gas mixture (say hydrogen and oxygen), applying or withdrawing heat instead of current, and plotting on a suitable time scale the temperature of the gas instead of membrane potential. Well below the ignition point, the temperature changes along an exponential time course and equilibrates at a level determined by a balance between heat leakage to the surroundings and rate of heat supply. Close to the ignition point, some gas molecules combine and produce extra heat, but not at a sufficient rate to keep the reaction going when the applied heat source is switched off. At the ignition point, the rate of reactive heat production just balances the leakage to the cooler surroundings and, for a while, maintains the system in unstable balance from which either an explosive flare-up or a return to the ambient stable temperature occurs. Apart from this formal analogy, there is, of course, little resemblance between an explosive exothermic process and the much more subtle and repeatable release of electric energy by the nerve membrane.

PROPERTIES OF THE NERVE IMPULSE

Several questions arise at this point: (1) What is the nature of the regenerative factor in a nerve fiber which causes an initially applied potential change to amplify itself? (2) What brings the action potential down to the original baseline? (3) What causes the system to become temporarily inexcitable? (4) How does the axon recover from its impulse activity?

Regenerative Factor

It has been shown[16,17] that the sodium conductance of the membrane depends upon the electric field across it; the sodium conductance is very low at the normal level of the resting potential, but increases, temporarily, when this potential difference is reduced. *How* this comes about is not known and remains one of the outstanding problems, but the statement that sodium permeability is raised by a depolarization of the axon membrane is based on very strong evidence. The consequences of this effect are far-reaching: suppose a partial depolarization is produced by passing current outward through the membrane. The consequent rise in sodium permeability causes an increased leakage of these ions down their concentration gradient into the fiber. As a result, positive change is transferred to the interior and the membrane potential is diminished further. This is the regenerative step which causes the permeability to sodium to rise again and more sodium ions to enter. At a certain level of the membrane potential, the threshold, this process becomes progressive and flares up into the action-potential wave. Like the ignition point of the explosive-gas analogy, threshold is a point of unstable equilibrium at which restoring and regenerative tendencies just balance each other. The regenerative factor responsible for the automatic ascent of the action potential is the progressive relation between sodium-conduct-

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

ance change and fall of membrane potential; the restoring factor is to be found in the potassium (and chloride) conductances which tend to reset the membrane potential to the initial stable baseline.

Once the threshold level is exceeded, the sodium conductance becomes rapidly the dominant factor and the regenerative entry of sodium would continue until the membrane potential swings well to the other side, and the interior attains sufficient positive charge to balance the inward concentration gradient and prevent any further net influx of sodium ions. In other words, if the initial excitatory process continued, a new equilibrium level would be reached corresponding to that of a sodium-concentration cell. This is, indeed, the accepted explanation for the reversal of the membrane potential during the peak of the impulse. The level which is attained falls somewhat short of the sodium potential, because the initial permeability change is only transient: within about a millisecond, the high, specific sodium conductance is switched off and apparently is converted into a state of high potassium conductance.

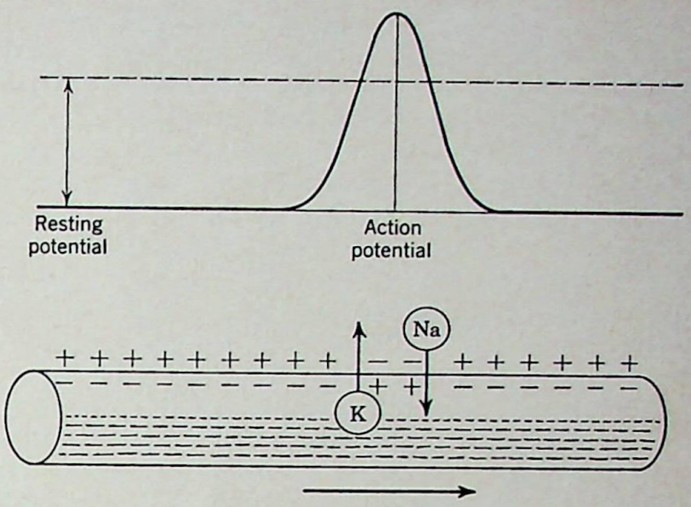

FIG. 5. Diagram of action potential traveling (in direction of arrow) along the axon. During the rise of the wave, sodium ions enter the fiber and charge the interior positively. During the decline, potassium ions leave the fiber and restore the initial membrane potential.

Restoring Factor

This secondary changeover, from sodium to potassium permeability, ensures a rapid return of the potential to its original baseline, for potassium ions now will leave the fiber rapidly in the direction of their electrochemical gradient. Such electric restoration would be effected even without a secondary increase of potassium conductance, provided the initial sodium-permeability rise is cut off (a process known as inactivation). In this event, however, the decline of the action potential would take a relatively long time and proceed with the time constant of the resting-fiber membrane. In the squid axon, it would take several milliseconds at the ordinary leakage rates of potassium (and chloride) to restore the membrane potential to the resting level. By opening up the potassium channels, this process becomes greatly accelerated, and a few milliseconds later the axon is ready to fire again.

The work of Hodgkin and Huxley has shown that a depolarization imposed on the axon membrane (by the so-called voltage-clamp method) produces these two successive permeability changes (Na, then K), the intensity of both changes increasing similarly with the amplitude of the enforced voltage step. During the normal action potential, the sodium-conductance rise is regenerative and self-reinforcing, while the potassium-permeability change is restorative and gradually cuts itself down as the membrane potential is caused to return to the original stable level.

It should be noted that the electrical return of the system during the impulse is *not* brought about by a reversal of the ionic movement (which would mean a forced expulsion of the quantity of sodium which had entered during the ascending phase of the action potential), but by the leakage of an equivalent quantity of potassium ions (see diagram in Fig. 5). Both sodium and potassium are moving downhill during the impulse; the quantities, however, are so small that no detectable change of the internal concentration would occur during one impulse, and there is plenty of time for the pumping process to restore the chemical situation in resting periods later on.

Nature of the Refractory Period

The secondary permeability effects which bring about the decline of the action potential are also responsible for the short period of inexcitability (refractoriness) which follows the propagation of each impulse. Clearly, during the state of inactivation—i.e., while the regenerative dependance of sodium permeability on membrane potential is in abeyance—an applied electric current fails to excite; secondly, a state of very high potassium permeability implies that the restoring factor is greatly strengthened and tends to oppose any displacement of the membrane potential from the stable potassium-equilibrium level. Hodgkin and Huxley have determined the rate constants of these changes and their time course of decline following a restoration of the normal membrane potential. It was found that the period of recovery of excitability after the impulse is simply a measure of the time by which the return of the normal permeability relations lags behind the return of the membrane potential.

Chemical Recovery

There are several phases of restoration: the recovery of the membrane potential is followed by a return of excitability, but the system has not yet reverted completely to its initial state; in fact, a minute fraction of the intracellular potassium store has been lost and replaced by sodium. The downhill movement of sodium and potassium ions across the membrane has provided

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

the energy for the nerve signal. The amount of ions which exchange during the impulse is extremely small; it has been determined for a series of impulses in tracer experiments, and by chemical analysis of single fibers, and was found to exceed the minimum coulomb requirement by a factor of 3. The transfer of charge needed to alter the membrane potential by 100 mv, with a capacity of 1 μf cm^{-2} is 10^{-7} coul which requires a net transfer of about 10^{-12} M of univalent ions: the net exchange of sodium and potassium per impulse is about 3 to 4 times as much.[16] These quantities produce only a minute internal concentration change per single impulse (about 0.0001% in the large squid axon, but considerably more in small fibers whose volume/surface ratio is correspondingly less). Even if the ion pump were not active, a squid axon could conduct some hundred thousands of signals before its accumulated ion store would be exhausted. As in many other forms of brief, high-intensity biological action, a period of impulsive activity is completed at the expense of small but cumulative chemical losses; these are made good during periods of rest by continuous chemical recovery mechanisms which Connelly discusses (p. 475).

A rough qualitative picture has been given here of the conclusions derived from the extremely accurate quantitative work of Hodgkin and Huxley and others, and reference is made to their papers for a description of the experimental evidence on which these conclusions are based.[17–20] Summarizing briefly, it has been found that the resting potential is related to the external potassium but independent of sodium concentration, while the peak of the action potential depends on the sodium-concentration ratio in the way predicted by the Nernst theory. In experiments in which the axon membrane was subjected to a voltage clamp, it was found that a sudden stepwise depolarization (e.g., to zero membrane potential) was followed by a surge of positive inward current followed by a maintained outward current. The first, transient, component (in which current flows "in opposition to Ohm's law" indicating the presence of the required negative resistance, or regenerative factor) could be identified as owing to the inrush of sodium, for it could be made to reverse in polarity by reversing the concentration gradient of sodium ions. With a variety of sodium concentrations, the reversal was shown to occur invariably at the electrochemical equilibrium potential for sodium ions. The second, maintained, component was identified by tracer-efflux measurements as a maintained high-intensity outward current of potassium ions. The rate constants of the several successive conductance changes were determined, and from this information the properties of the impulse, its excitatory threshold, its amplitude, duration, and conduction velocity, could be synthetized with a high degree of precision.

While this series of investigations has been brought to a decisive conclusion, this should, of course, not conceal the fact that the nature of the permeability relations and the reason why membrane potential and ionic conductances are linked in such a specific manner remains an altogether unsolved problem at the present time.

SOME SPECIAL CASES

Medullated Nerve Fibers

The picture presented so far describes the situation in the giant axon of the squid, on which most of the crucial experiments have been carried out. But substantially the same conclusions apply to all other types of nerve fibers and to most types of skeletal-muscle fibers which have been studied. There is, however, an important structural difference between the so-called nonmedullated nerves, and the medullated (myelinated) axons of vertebrates which possess relatively thick, segmented sleeves of myelin broken at regularly spaced intervals (the nodes of Ranvier about one or a few millimeters apart) at which a small area of axon membrane is exposed to the outside fluid. In the ordinary nonmedullated fibers, the propagation of the signal depends upon the existence of a continuous relay mechanism which is built in along the whole line at many scattered random points of the axon membrane. This makes up for the deficiencies of the poor cable transmission: without it, the action potential would be attenuated rapidly in the region ahead. Experimentally, this can be shown to be the case by poisoning or anaesthetizing a narrow region of the axon cylinder and so abolishing locally the regenerative mechanism. Provided, however, the attenuated signal which spreads to the other side of the blocked region exceeds the threshold depolarization (which amounts to only $\frac{1}{10}$ to $\frac{1}{5}$ of the full amplitude of the spike), the relay process will start again and the impulse will jump the block.

In medullated nerves, transmission of signals normally occurs in jumps.[21,22] The segmented myelin sheath provides a relatively good, low-capacity insulation around the axon, and the relay mechanism is concentrated and restricted to the discrete nodes of Ranvier where the axon membrane is exposed. There is, in other words, a rather close miniature analogy to a submarine cable with relay stations interposed at the nodes. In the internodal region, the fiber behaves as a relatively good cable with only slight capacitative losses which are made good at the next node. The final result is a great improvement in speed and economy of signaling: the ionic losses are restricted to relatively few microscopic areas of the fiber surface, and the propagation velocity of the impulse is some 10 times greater than for a nonmedullated axon of the same size. To achieve the speed which medullated axons attain *without* the provision of a myelin sheath, the only alternative way for nature would have been to reduce the internal core resistance; that is, to increase the fiber size. Considering the need for a large number of separate signaling channels within a confined space (there are one million medullated axons

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

in the human optic nerve alone), the great advantages of myelination are obvious.

Other Tissues

Most of the tissues, nerve or skeletal muscle, whose function depends upon the rapid propagation of an all-or-none impulse, appear to make use of a regenerative entry of sodium ions in the course of excitation; there is, however, some doubt as to whether the secondary increase of potassium permeability is a similarly wide-spread phenomenon, or whether it may be a more or less dispensable effect. In some tissues, e.g., certain medullated axons, the potassium resistance and the electric time constant of the resting membrane appear to be sufficiently low to insure a rapid decline of the action potential once the sodium conductance has dropped back towards the initial low level.

In heart muscle, the action potential has a different shape, of "flat top" and long duration. The initial fast rise is probably governed by a sodium mechanism just as in nerve, but the subsequent changes differ at least in quantity. It may be that the maintained plateau of depolarization arises from the increased sodium conductance not being switched off completely, and from a failure of the potassium efflux to rise above its steady rate. It is interesting to consider the usefulness of this long flat-topped heart potential: its duration apparently governs the systolic contraction of the heart muscle, and because of the relatively low frequency of its regular beat, there is no need for rapid electric recovery of the membrane potential.

In skeletal muscle, a quantitative difference from nerve was found in the large capacity of the surface membrane (5 to 10 $\mu f/cm^2$ as against 1 $\mu f/cm^2$ in nerve). There is a correspondingly larger transfer of charge during the action potential, and recent tracer measurements by Hodgkin and Horowicz[23] have shown that the amounts, per unit surface area, of sodium and potassium exchange are about 3 times greater than in the nerve fibers. There appears to be less temporal overlap of the two ionic permeability changes; indeed, resistance measurements indicate that there are two discrete phases of high membrane conductance during the action potential. This would enable the sodium ions which enter to produce a relatively larger net effect. It also seems that the delayed rise of potassium conductance is shortlived and stops before the action potential has returned to the baseline, giving rise to a characteristic long tail (the so-called negative afterpotential) of the muscle spike.

There are finally some tissues (e.g., crustacean muscle and certain conducting plant cells) in which action potentials of the usual propagating all-or-none type can be elicited by electric stimulation, but sodium entry does not seem to be responsible for their regenerative ascent. In many of their features, these action potentials resemble those of the nerve axon very closely. It appears that the underlying events are similar and involve ionic permeability changes, but that the specific channels which are being opened during the depolarization of the membrane are different. For example, in certain algae, a regenerative exit of chloride from the cytoplasm takes the place of sodium entry,[24] while in crustacean muscle, entry of divalent cations possibly may be responsible for the rise of the action potential.[25]

Structure and Function

To return to some of the problems raised by F. O. Schmitt (p. 455): Can one try now to identify our physiological mechanisms with any one of the structures revealed by the electron microscope? The question has been raised, for instance, whether ion permeabilities are entirely to be attributed to the axon membrane, or could they be properties of Schwann cells which envelope the axon? Insofar as the observations have been repeated on skeletal-muscle fibers, which are not invested with satellite cells, and insofar as they corroborate the main conclusions derived from the nerve experiments, one may feel that the presence of a Schwann-cell envelope does little to mask or mimic the electrical properties of the axon membrane. It is important also to recall that the cellular investment of the axon is not complete, but there are gaps through which the axon surface communicates with the extracellular fluid. Although these channels may be narrow (only a few hundred Ångström units wide), they are also short (a few microns long) and probably add only a small resistance in series with the axon membrane. There is evidence for such an external nonreactive resistance of about 5 ohms in series with a resting membrane of approximately 1000 ohms $\times cm^2$. Recent work of Frankenhaeuser and Hodgkin[26] suggests that the presence of this external bottleneck gives rise to a slow accumulation of potassium ions on the surface of the squid axon during a period of prolonged impulse activity. This is associated with cumulative changes in the membrane potential, but these are rather minute by comparison with the main features of the spike. Nevertheless, one must bear in mind the possibility that the distribution of current flowing through the axon membrane may be modified locally by Schwann cells which cling to its surface and by the presence of discrete channels between them.

It may seem a little disappointing that, with all of the high-resolving power which has been attained in recent years, both in the study of fine structure and of the functional mechanism of nerve, there is still such a conspicuous lack of correlation between these two fields of work. One of the reasons is undoubtedly that the details which are revealed in their most striking form by such different techniques are not necessarily related to the same features. In the electron micrograph, the almost complete investment of an axon by a Schwann cell, or the almost intimate contact between the two surfaces, may be the most impressive phenomenon,

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

while from the point of view of electric current distribution the appearance of a fine gap or crack in this investing layer (which is difficult to find and might easily be discarded as an artifact) may be a much more important feature.

A second reason for the apparent discrepancy is that there must be structural counterparts of functional aspects other than those with which the student of the nerve impulse is directly concerned. The purpose of this paper is to describe some efforts that have been made to elucidate the nature of the nerve signal. But, in addition, there is built into the nerve a machinery for chemical recovery processes, and for the maintenance of the axon and its enzymic apparatus, which one associates with the so-called trophic influence of the nerve-cell body and its nucleus. Little is known about this process, but there are many indications that satellite cells are actively involved, both in trophic maintenance and in the disintegrative processes which follow the severance of the axon from the cell body.

The elementary membrane structure which has been seen in electron micrographs, e.g., of permanganate-fixed axons, is a double contoured-layer 50 to 100 A thick. It is not known what fraction of this layer is composed of the insulating lipid material which we hold responsible for the ion-impermeable and capacitive properties of the axon membrane. Nor can one be certain that improvements in microscopic resolution will not show further subdivisions and even thinner membrane elements. And ultimately, the physiologist is interested not so much in the lipid bulk phase of the membrane which occupies most of it, and which seems never to change nor to take part in the transport of ions, but in those very sparse molecular patches—possibly at continuously varying sites, at which ionic gaps or channels are thought to be formed, and where "carrier molecules" are believed to be active in transferring sodium and potassium ions from one side to the other.

Recovery Processes and Metabolism of Nerve

C. M. CONNELLY

The Rockefeller Institute, New York 21, New York

INTRODUCTION

THE prime function of peripheral nerve is the conduction of impulses. In biological terms, the nerve impulse is the means of transmission of an item of information from one point in an organism to another. In terms of physics and chemistry, the impulse is a spatially propagating, transient disturbance in the state of a complex reaction system; it might be detected by, or it might be described in terms of, any of those conceivably measurable changes which are a part of it or to which it gives rise. In thermodynamic terms, the impulse is a dissipative process in which the free energy of the nerve and its environment is decreased, principally by a flow of ions down gradients of their electrochemical potential. In this discussion, attention is focused upon processes by which resting nerve maintains itself in a steady state, ready to function, and upon processes which serve to restore nerve to its resting state after it has conducted impulses. A central question is how energy-yielding processes may be coupled to those requiring energy. In an approach to a more specific formulation of this question, the discussion emphasizes correlations between changes in rate of oxidative metabolism and electrochemical manifestations of ionic movement.

In resting nerve there are at least two processes which may be presumed to require energy. These are the maintenance of structural integrity and the maintenance of the ionic-distribution characteristic of the resting state. About the former very little can be said. Perhaps the cell bodies from which the excised nerve fibers have been severed are the primary site of synthetic reactions underlying such maintenance. During activity and recovery therefrom energy demand may be increased in two ways: there must be an acceleration of ion transport processes in order to reverse the exchange of ions which occurs during the passage of impulses and, secondly, there may be a dissipation of chemical energy associated with the permeability cycle that allows the ionic exchange to take place.

Insofar as nerve at rest is in a steady state and following activity returns to the same steady state, the over-all process of impulse conduction involves no net external work and results only in the conversion of chemical energy to heat.

The following discussion indicates that oxidative metabolism in nerve can serve as an adequate energy source. Brink[1] has recently reviewed the evidence that the biochemistry of peripheral nerve of the frog resembles that of other animal cells; the nerve appears to contain and utilize the Meyerhof-Embden pathway of carbohydrate breakdown, the Krebs tricarboxylic acid cycle, and the cytochrome chain of enzymes. The energy turnover appears to be mediated by the usual system of phosphate compounds (adenosine phosphates and creatine phosphate) which are replenished principally by oxidative phosphorylation carried out by mitochondria. In what follows, it will be assumed (1) that any processes which rely upon metabolic energy do so by chemical reactions coupled to the breakdown of adenosine triphosphate, or its equivalent, and thereby increase the intracellular level of phosphate acceptor; (2) that the kinetics of oxygen uptake by nerve are some reflection or measure of the changes in concentration of phosphate acceptors at the mitochondria. A particularly dramatic experiment directly supporting the first of these assumptions is that in which Caldwell and Keynes[2] injected ATP into a metabolically poisoned squid axon and observed a partial restoration of the rate of sodium extrusion.

Firstly, the kinetics of the increases in oxygen utilization associated with the conduction of impulses is described and compared with the heat measurements of Hill, and then it is shown how the kinetics are modified under circumstances in which rates of ion transport have presumably been affected. Secondly, data on the ionic fluxes across the nerve surface are examined and the estimated energy requirements of transport processes are compared with energy available from oxidative metabolism. Thirdly, some observations are described of prolonged positive afterpotential (post-tetanic hyperpolarization) which appears to be closely related to ionic transport processes.

Most of the observations which follow come from experiments on the excised sciatic nerve of the frog. This preparation has some advantages over the giant axon of the squid in that its metabolic and electrical properties remain more nearly constant over an experimental period of ten to fifteen hours. It has, however, the disadvantage of being a bundle of fibers of several different types and there are complications arising from the existence of an appreciable extracellular space. The minimum environment required by frog nerve to maintain function and a satisfactory steady state at 20°C is a balanced bathing solution containing sodium, potassium and calcium salts, and dissolved oxygen. It should be emphasized that many or most of the electrical and metabolic properties of nerves appear to be basically similar from one species of animal to another, and similar also, in fact, to the properties of other excitable tissues such as skeletal and cardiac muscle.

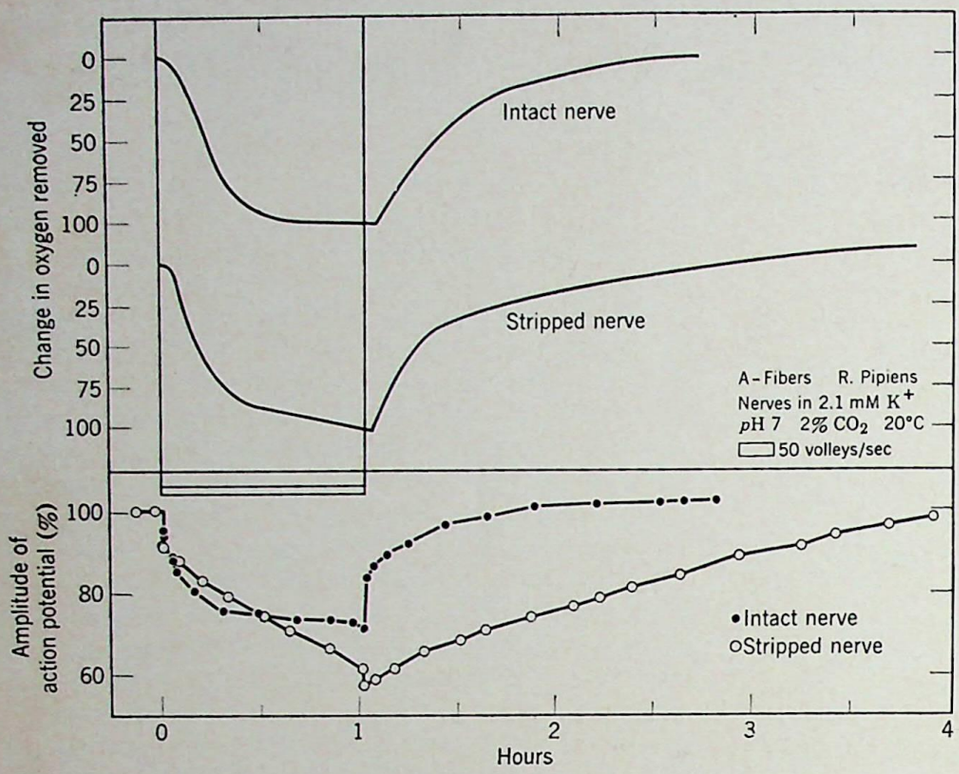

FIG. 1. (Upper) Relative time courses of the increases in oxygen uptake resulting from activity in intact frog sciatic nerve (perineurium not removed) and in stripped nerve (perineurium removed). Measurements made in a flow respirometer[3] with a polarized oxygen cathode. Polarographic current is a linear measure of dissolved oxygen remaining in solution after it has flowed past the nerve, a downward deflection in the trace, as shown, indicating an increase in oxygen uptake. (In all tetani in this and the following figures, only type A fibers stimulated.) (Lower) Time courses of changes in amplitudes of compound action potentials of the two nerves, measured during tetanus and occasionally by test shocks during recovery.

OXIDATIVE METABOLISM AND HEAT PRODUCTION

The oxygen uptake by resting frog nerve is usually 30 to 40 $mm^3/g(wet)/hr$ or about 1.5 μmoles/g(wet)/hr. When a nerve is tetanized, its rate of oxygen uptake increases and approaches a new steady level in about 30 min, closely following an exponential time course with a time constant of 5 to 8 min, Fig. 1, upper curve.[3] The amplitude of the increase is greater the higher the frequency of tetanus, at low frequencies, and approaches a maximum limiting value (of about 1 μmole/g (wet)/hr) at about 100 volleys/sec,[4] as shown in Fig. 2. At the end of tetanus, the rate of uptake declines slowly toward the resting value along an exponential whose time constant is usually 15 to 25 min. [After tetani at frequencies lower than about 10/sec, recoveries may be more rapid than this (see Fig. 11 in an article by Connelly *et al.*[5]).]

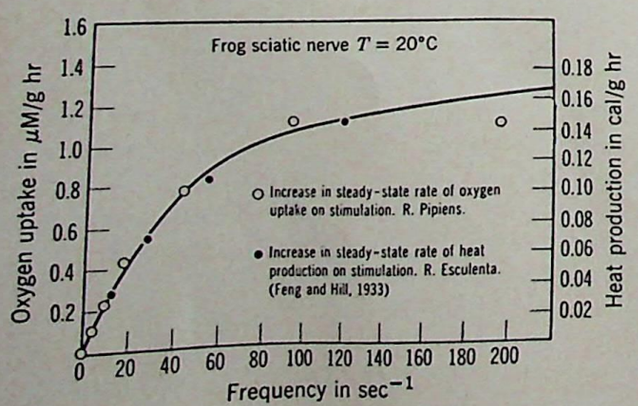

FIG. 2. Oxygen uptake and heat output for active nerve in relation to frequency of conducted impulses. Perineuria not removed. Ordinate scale symbol μM means micromole [from F. Brink, D. W. Bronk, F. D. Carlson, and C. M. Connelly, Cold Spring Harbor Symposia 17, 53 (1952)].

The over-all increases in heat production by tetanized frog nerve show kinetics similar to those of the increases in oxygen consumption.[6] The quantitative comparison of steady-state heat rate and oxygen consumption as a function of frequency is shown in Fig. 2. The ratio of the right-hand to the left-hand scale is within 15% of the accepted value of the calorific equivalent of oxygen, 5 cal/cc. The agreement is quite satisfactory, in view of the difference in species.

A detailed analysis of the heat production of nerve during short tetani reveals the presence of a component whose onset and termination are abrupt and correspond to the beginning and end of the tetanus.[7] This "initial heat," only a few percent of the total heat associated with the tetanus, appears to have no counterpart in the time course of the increase in oxygen uptake, the curve of which rises linearly from the beginning of the tetanus.[4] In recent elegant work, Hill and his coworkers[8] have resolved the initial heat associated with a single volley in crab nerve into a positive phase (heat production) followed by a smaller negative phase (heat absorption). These phases may result from the heats of dilution or mixing of the sodium and potassium ions exchanged during the impulse, but other events of the permeability cycle have not been excluded as contributing causes.

The second curve of Fig. 1 illustrates the time course of increase in rate of oxygen uptake by a nerve trunk from which the perineurium, or connective-tissue sheath, has been removed. The striking difference between this and the upper curve is that the recovery is characterized by two components, the first lasting no more than about 30 min and the second extending over several hours.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

The lower part of Fig. 1 shows the accompanying changes in the amplitudes of the compound action potentials of the two nerves, the stripped nerve showing much less rapid recovery than the unstripped nerve. The possibility that these differences in the metabolic and electrical behavior of stripped and intact nerve might result principally from differences in the extracellular level of potassium ions was tested by the series of experiments illustrated in Figs. 3 and 4. These compare the kinetics of the changes in oxygen uptake and action potentials, respectively, of stripped nerves bathed in solutions containing different concentrations of potassium ion. The three lower curves of Fig. 3 possess fast components of about the same relative magnitude and time course whereas the slow components of these curves show gradation from effectively no recovery in K-free solution, to a slow almost linear recovery in 2.1 mM K^+, to a somewhat more rapid curvature characteristic of an exponential of about a 40-min time constant, in 5 mM K^+. In the top curve (8.5 mM K^+), the over-all recovery is even more rapid than any observed in intact nerve (in 2.1 mM K^+), with an exponential time constant of only 11 min instead of 15 to 25. It is not possible to distinguish two phases of recovery in this case and it is not clear whether the slower phase observed in the lower curves has been speeded up to merge with the rapid phase or whether it has decreased in magnitude to zero. In Fig. 4, one sees that the lower the concentration of potassium in the bathing solution, the more rapid is the decline in height of the action potential during tetanus and the less rapid is its recovery. Recovery of action potential is incomplete in K-free solution, as the recovery of oxygen uptake was seen to be. In 8.5 mM K^+, however, not only does the action potential not decline in amplitude during tetanus but it shows about 13% increase in amplitude during the post-tetanic period.

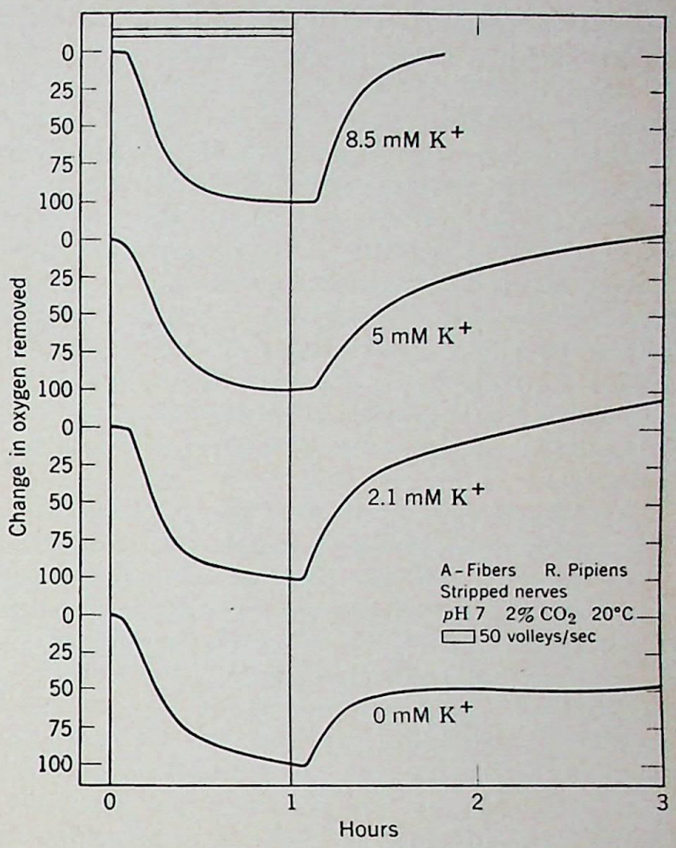

FIG. 3. Relative time courses of the increase in oxygen uptake by stripped nerve bathed in Ringer's solutions containing different concentrations of K^+. Ordinate as described for Fig. 1.

A possible key to the interpretation of these observations is the finding of Hodgkin and Keynes[9] (see also Hodgkin's Croonian Lecture[10] for an extended discussion of the movements of ions in giant nerve fibers) that the efflux of sodium from *Sepia* fibers is increased in a solution containing more potassium than does sea water and is depressed by K-free solution to one-third or one-

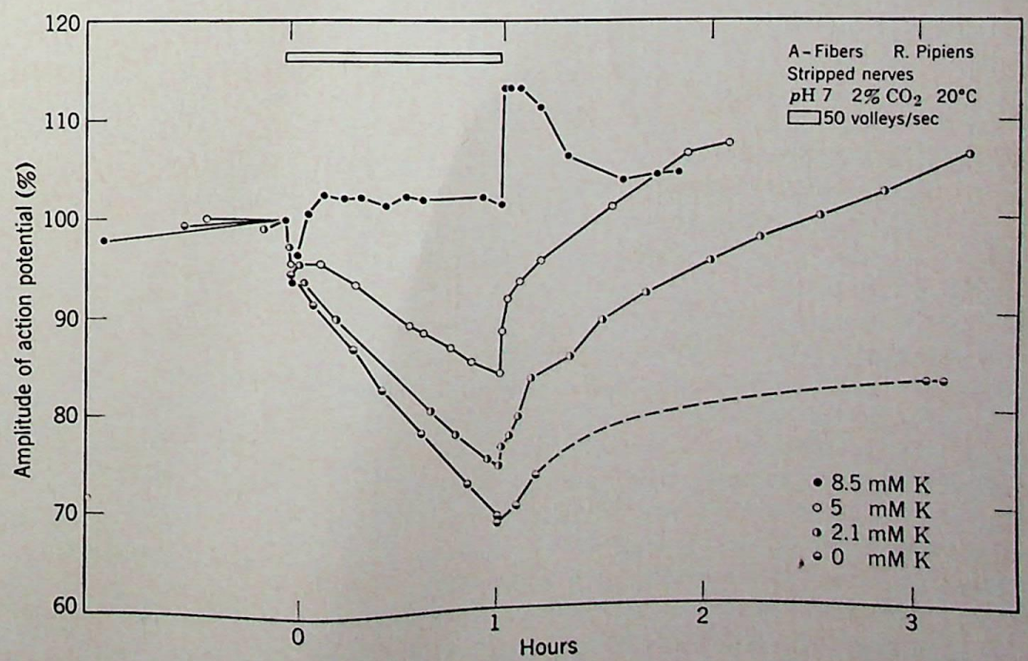

FIG. 4. Time courses of changes in amplitudes of compound action potentials of the four nerves of Fig. 3.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

quarter of the efflux into sea water. If, in frog nerve, the rate of sodium extrusion is similarly dependent upon the level of potassium in the external solution, the slow component of recovery respiration may be interpreted as reflecting the energy demand of the transport machinery. The fast component, on the other hand, might result either from cessation at the end of tetanus of energy demand by the excitability cycle, or from a rapid reduction in rate of ion transport, at the end of tetanus, because of relaxation by diffusion of the internal ionic gradients maintained near the nerve surface by the entrance of sodium and by the exit of potassium during each impulse. The following considerations suggest that additional factors may affect the kinetics of the fast component.

The principal locus of ionic flow during an impulse in a myelinated fiber appears to be across the membrane at the node.[11,12] If ionic recovery takes place principally across the nodal membrane, the question arises as to whether or not phosphate compounds participating in this recovery are rephosphorylated by mitochondria close to the node or by those farther down the internodal space. Thus, longitudinal diffusion of phosphate acceptors in the internode may determine in part the kinetics of changes in rate of oxygen uptake. These considerations apply, as well, to the kinetics of the rising phase of uptake that occurs during the tetanus. The fact that the time constant of this rising phase in intact nerve is as long as it is (5 to 8 min) and does not vary markedly with tetanus frequency[4] is consistent with the idea that the kinetics of this phase are restricted in part by configurational parameters.

The differences in the kinetics of the changes in oxygen uptake and in the action potentials of intact and stripped nerves in 2.1 mM K^+ Ringer's appear, then, to be due to restrictions imposed by the perineurium on the diffusion of ions between the extracellular space and the bathing solution. The differences arise from the secondary effects of a changing ionic composition around the fibers of the intact nerve, especially as regards the concentration of potassium.

A most important and revealing experiment is that of measuring the respiration of nerve bathed by a solution in which lithium has replaced sodium ion. It is known that lithium can substitute for sodium in the conduction process. As soon as lithium Ringer's is substituted for sodium Ringer's, the resting respiration begins a slow decline. Tetanization produces almost no increase in rate; there may result a slowing or interruption in the decline of the resting respiration, but over all the effect of activity during exposure to lithium Ringer's is certainly not more than 5% of the effect measured in sodium Ringer's. The observation suggests strongly that lithium ions are extruded from frog nerve very slowly or not at all. Swan and Keynes[13] have reported that lithium ions are extruded from frog muscle much less rapidly than are sodium ions. Another conclusion from this experiment is that energy demand originating in the excitability cycle is less than 5% of the total. Therefore, it appears unlikely that the fast recovery components of the three lower curves of Fig. 3 result from the cessation of such a demand.

ION TRANSPORT AND ENERGY REQUIREMENTS

In Table I are shown data from the work of Hurlbut and Asano on water distribution, ion distribution and fluxes, and the net ion changes which result from activity or exposure to an altered environment. The water distribution refers to intact nerve. The assignment of water and ions is based upon the assumption that the nerve consists of two compartments, intracellular and extracellular, the latter occupied by bathing solution. The internal concentrations of ions are based upon measurements in which the extracellular space had been washed free of sodium and potassium ions and include a small correction for sodium lost during this washing.[14] The fluxes of sodium and of potassium were measured as outfluxes from resting nerve which had previously been equilibrated with radioactive ions.

At the bottom of Table I the sodium gained and the potassium lost during activity and during exposure to oxygen-free and K-free environments are compared. It is apparent that in each case the sodium gain is nearly equal to the potassium loss. Asano and Hurlbut[15] have shown that ionic recovery does take place in the three or four hours following activity (50 volleys/sec, 1 hr, in 2 mM K^+ Ringer's). Figure 5 indicates that recovery from rather large ionic shifts takes place in such a way that the potassium movement in one direction balances

TABLE I. Frog nerve.

the sodium movement in the other. The rates of ionic recovery during the first hour or two (Fig. 5) produce concentration changes of about 12 mM (intracellular) per hour. This net ionic exchange that is measured during recovery is presumably superimposed upon the normal fluxes, measured in resting nerve, of about 23 mM (intracellular) per hour for sodium and probably about the same for potassium.

For a two-compartment system, the thermodynamic expression for the energy required to move one mole of sodium from inside (i) to outside (o) and one mole of potassium in the opposite direction is

$$RT\left(\ln\frac{Na_o}{Na_i}+\ln\frac{K_i}{K_o}\right),$$

where Na_o, . . . etc., are ion concentrations (strictly activities). This expression has a value of about 3000 cal/mole for the concentrations of sodium and potassium given in Table I. If the energy available from the hydrolysis of one mole of ATP to ADP, under intracellular conditions, is 7000 to 12 000 cal, then energetically it should be possible for some 2 to 4 sodium ions to be extruded for each molecule of ADP produced. Assuming, conservatively, that one ADP is produced for each sodium ion transported, it may then be asked whether the observed oxygen consumption appears to be capable of providing sufficient energy, via phosphorylated intermediates, to transport ions at the rates observed. For frog nerve at rest, the oxygen uptake is about 1.5 μmole/g (wet)/hr and the sodium flux about 6.6 μmole/g (wet)/hr. Thus the ratio Na:O is $6.6/(2\times1.5)=2.2$. If, in the functioning cell, mitochondria maintain an average P:O ratio (phosphate acceptors phosphorylated to oxygen atoms reduced) of about 3, as isolated mitochondria do,[16] then it would seem that oxidation provides adequate energy for transporting one sodium ion per ATP broken down. If the Na:P ratio is actually unity, the comparison implies that only about 30% of the resting respiration is available for processes other than ion transport.

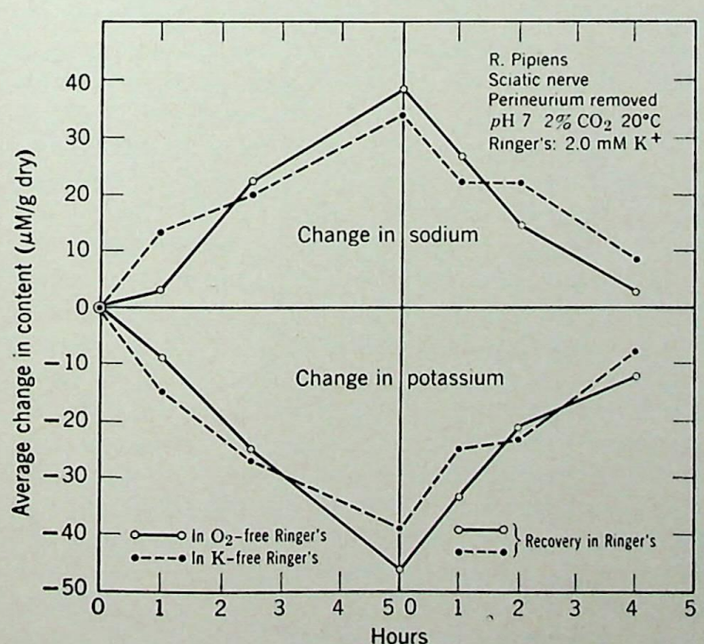

FIG. 5. Time courses of the changes in ionic contents of stripped nerves during and after exposure to oxygen free or potassium-free Ringer's solution. (Partially unpublished observations of W. P. Hurlbut and T. Asano.) Ordinate scale symbol μM means micromole.

An estimate of the increase in rate of sodium extrusion during a period of activity can be made from other observations of Asano and Hurlbut.[15] They found that after one hour of activity at 50 volleys/sec the net gain of sodium averaged 32 μmole/g (dry) when the nerve was bathed with K-free solution and only 16 when the Ringer's contained 5 mM K^+. This is an equivalent difference in rate of 4.2 μmole/g (wet)/hr. If, in the two solutions, about the same amount of sodium entered the nerve during each impulse, the observed difference may be attributed to effective, restorative transport taking place during activity. The ratio of this difference in rate to the increase in respiration during activity in 5 mM K^+ is approximately $Na:O=4.2/(2\times.8)=2.6$. This figure suggests that, in the case of active nerve also, there may be little energy utilized for purposes other than ion transport.

It should be emphasized that only one plausible line of thought has been followed in making these estimates and comparisons and that assumptions without direct experimental support have been invoked. Alternative lines of reasoning may ultimately prove to be more acceptable than the one outlined here.

POST-TETANIC HYPERPOLARIZATION

Experiments which indicate that there are measurable electrical changes associated with the ionic transport events of recovery[17] are now described.

A stripped frog nerve is mounted in a plastic chamber so as to pass through five compartments (separated by grease-seals) containing oxygenated solutions. The first and fifth compartments are connected via calomel half-cells to a stable dc amplifier (chopper amplifier, time constant about 1 sec). The first compartment usually, and the second, fourth, and fifth compartments always contain a 5 mM K^+ Ringer's, in the experiments to be described. The nerve is stimulated before it enters the first compartment and the impulses are blocked in the third which contains a choline chloride (sodium-free) Ringer's. By this arrangement, it is possible to follow the changes in potential developed by an active or recovering region of nerve, the steady potential of an inactive region serving as a reference.

Figure 6 shows the potential changes observed during and following a 25-min period of activity at 50 volleys/sec. The downward deflection at the beginning of the tetanus is the time average of the negative action potentials. Once each minute the tetanus was interrupted for 5 sec and the recorded potential showed a positive deflection which reached its peak within this

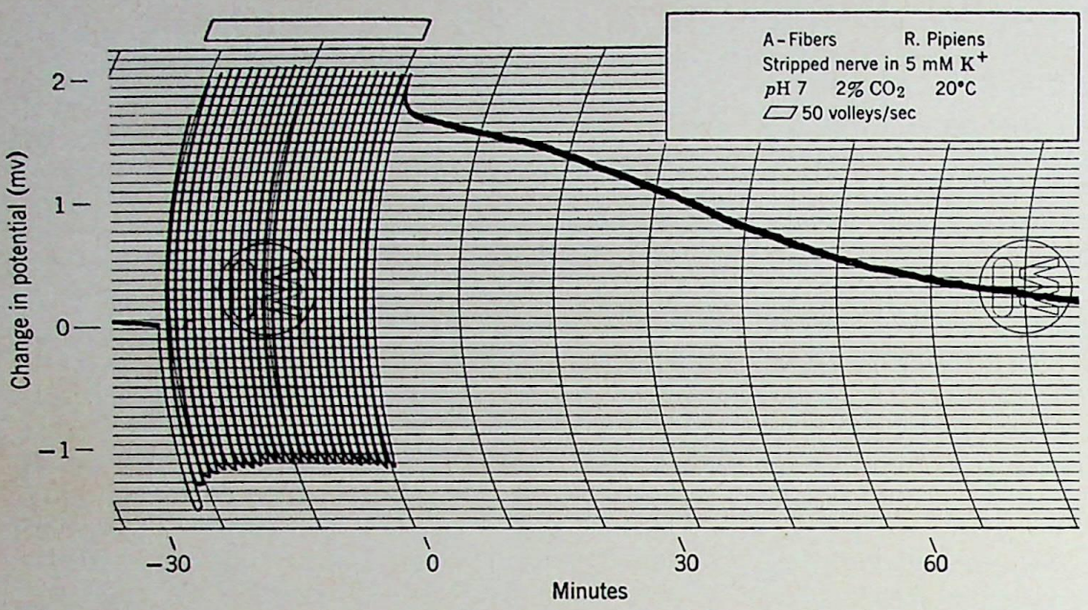

FIG. 6. Changes in average membrane potential recorded during and after 25-min tetanus. Tetanus interrupted for 5 sec each minute [from C. M. Connelly, "Post-tetanic hyperpolarization in frog nerve," in *Proceedings of the National Biophysics Conference, 1957* (Yale University Press, New Haven, to be published)].

interval. The amplitude of this hyperpolarization (net increase in membrane potential) reached a maximum after about 4 min and thereafter changed little. After the end of the tetanus, the hyperpolarization lasted for more than an hour; its recovery time course cannot be described as exponential.

Figure 7 shows how the prolonged positive after-potential is affected by the level of K^+ in the bathing solution (in the first compartment). A stimulation of 25 min in a solution containing 5 mM K^+ was first carried out as a control, and after recovery the solution was changed either to 8.5 mM K^+ (upper) or to K free (lower). The potential changes recorded during tetanus under the modified conditions have been superimposed on the control observations. The amplitude of the hyperpolarization varies appreciably with the level of potassium; recovery is rapid in high potassium and appears to be very slow and prolonged in K-free solution. During recovery from activity, the kinetics of oxidative recovery and the kinetics of the positive after-potential are both affected in much the same way.

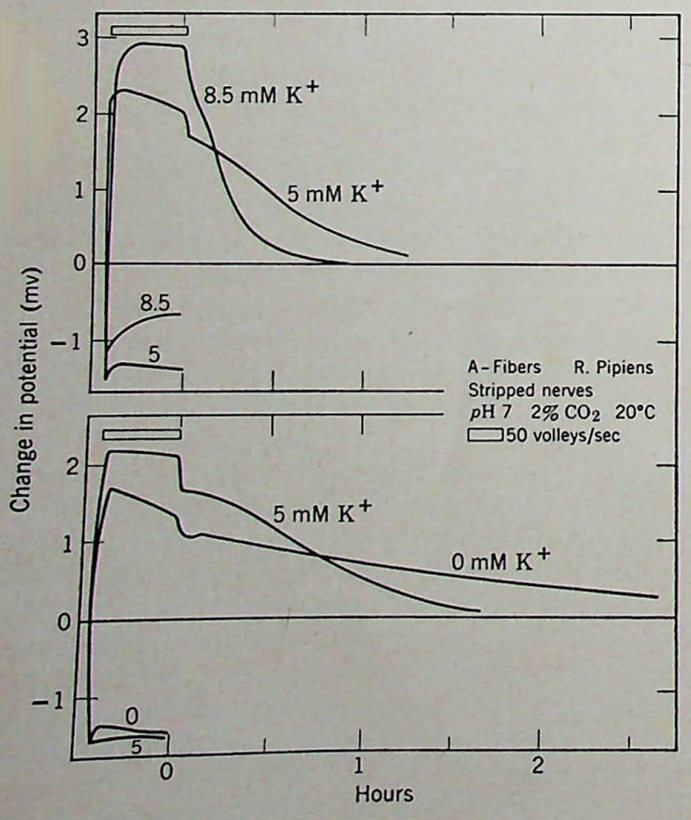

FIG. 7. Superimposed tracings of changes in average membrane potential recorded during and after 25-min tetani in Ringer's solutions containing different levels of K^+. Traces shown during period of tetanus are envelopes of changes similar to those shown in Fig. 6. In each of the two experiments the first tetanus was in Ringer's with 5 mM K^+, and the second tetanus carried out after 30 to 40 min exposure to the second solution. Zeroes of potential adjusted to superimpose at beginning of tetanus.

Other characteristics of this after-potential have been examined. It has been found that the observed amplitude of hyperpolarization approaches a maximum, or "saturation level" as the frequency of tetanus is increased above about 25/sec.[17] This maximum is about 2 mv. Depolarization produced by introducing isotonic potassium chloride into the first compartment averages 10 mv. Thus, maximum hyperpolarization corresponds to an increase in membrane potential of about 20%.

Post-tetanic recovery may be rapid or long-lasting depending on duration and frequency of tetanus. At frequencies above about 25/sec the effect of duration is striking, as illustrated in Fig. 8 which shows, superimposed, the recoveries from four tetani of different durations, at 50 volleys/sec. The longer the tetanus, the longer recovery takes, as if continued activity resulted in an accumulation of something, the final dissipation of which has associated with it an emf. Areas under the total hyperpolarization-time curves (i.e., area above the zero-potential line, including the periods of tetanus and recovery) have been measured as a function of duration of tetanus. Within experimental limits, area varies linearly with duration suggesting that the magnitude of hyperpolarization is approximately a linear measure of the rate of a recovery process.

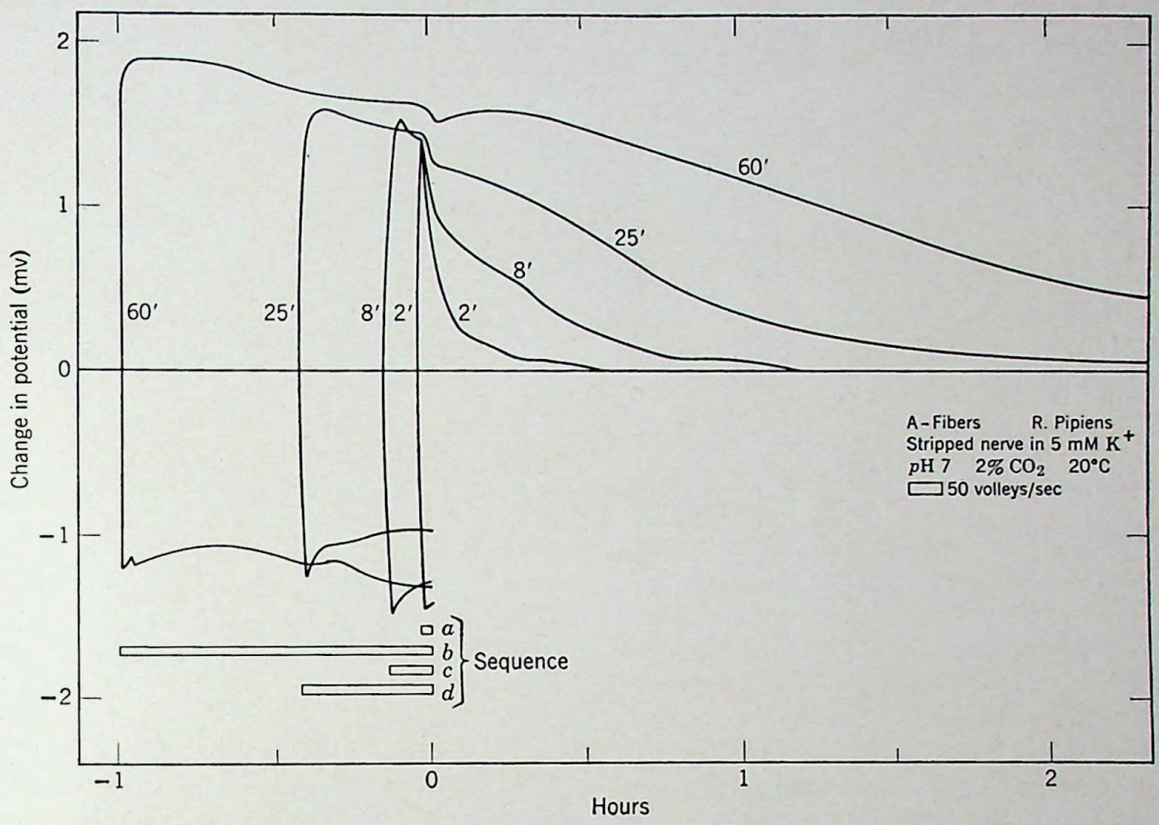

FIG. 8. Superimposed tracings of changes in average membrane potential recorded during and after a series of tetani of different durations. Traces shown during period of tetanus are envelopes of changes similar to those shown in Fig. 6 [from C. M. Connelly," Post-tetanic hyperpolarization in frog nerve," in *Proceedings of the National Biophysics Conference, 1957* (Yale University Press, New Haven, to be published)].

A variety of observations appears to be consistent with the idea that the recovery process involved is the outward transport or extrusion of sodium ions. One experiment which has a direct bearing on the question is illustrated in Fig. 9. The positive afterpotential associated with a tetanus is effectively eliminated upon complete substitution of lithium for sodium in the bathing Ringer's. The parallelism between this result and that described earlier on the effect of lithium Ringer's on activity respiration furnishes strong support for the idea that the activity respiration and the positive after-potential both have their origin in the process involving the outward transport of sodium coupled to the inward movement of potassium.

One further point should be discussed. Ritchie and Straub,[18] in studying the positive afterpotential of

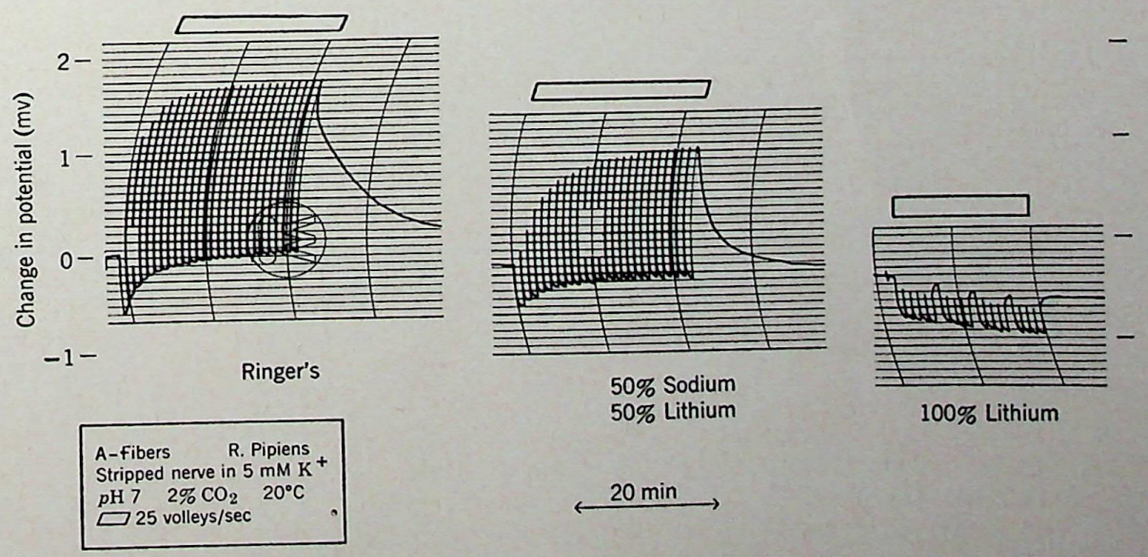

FIG. 9. Changes in average membrane potential recorded during and following tetani in solutions having different proportions of sodium and lithium ions. Potential zero common to the three records. During intervals (about 30 min) between records, nerve was bathed in the next solution. First and second records, 25-min tetani interrupted for 5 sec each minute. Third record, 20-min tetanus with 13 interruptions of 5 sec and 3 interruptions of 1 min each [from C. M. Connelly, "Post-tetanic hyperpolarization in frog nerve," in *Proceedings of the National Biophysics Conference, 1957* (Yale University Press, New Haven, to be published)].

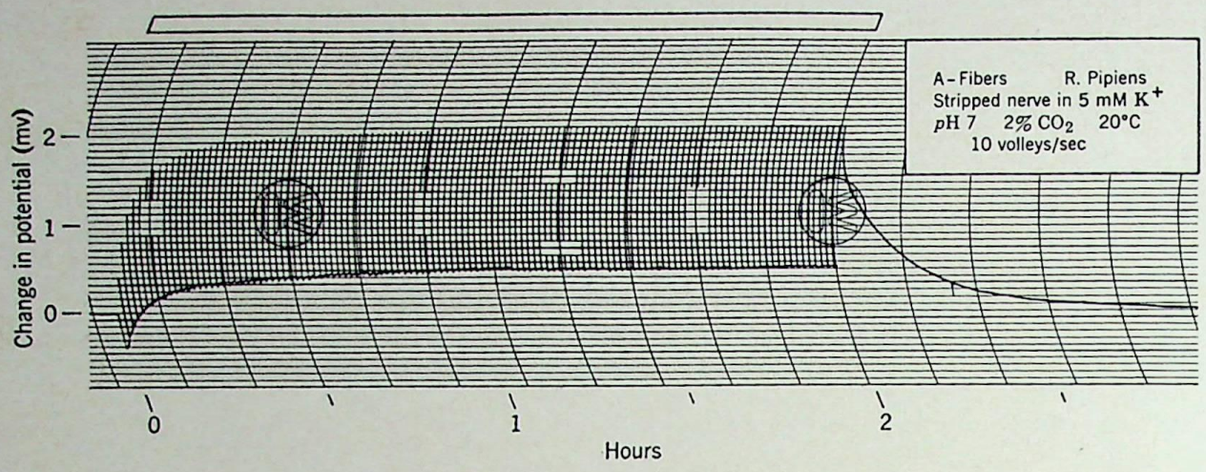

FIG. 10. Changes in average membrane potential recorded during and after 2-hr tetanus at 10 volleys/sec. Interrupted 5 sec each minute.

mammalian C-fibers, came to the conclusion that their observations could be explained solely by an electroneutral pump operating to restore the normal sodium-potassium balance following activity. The after-positivity was described as a variation of membrane potential in response to the variation in the concentration of potassium in the fluid immediately outside the nerve membrane. This happens as follows: during recovery, the pump produces a net flow of potassium inward across the membrane. By this action, the concentration of potassium at the outside surface of the fiber is lowered below its value in the body of the bathing solution. Since it is known that a decrease in external concentration of potassium does produce an increase in membrane potential, the conclusion appears to be unassailable, qualitatively. One must agree that any ion pumping system, whether electroneutral or inherently electrogenic, must have this property. It is to be taken

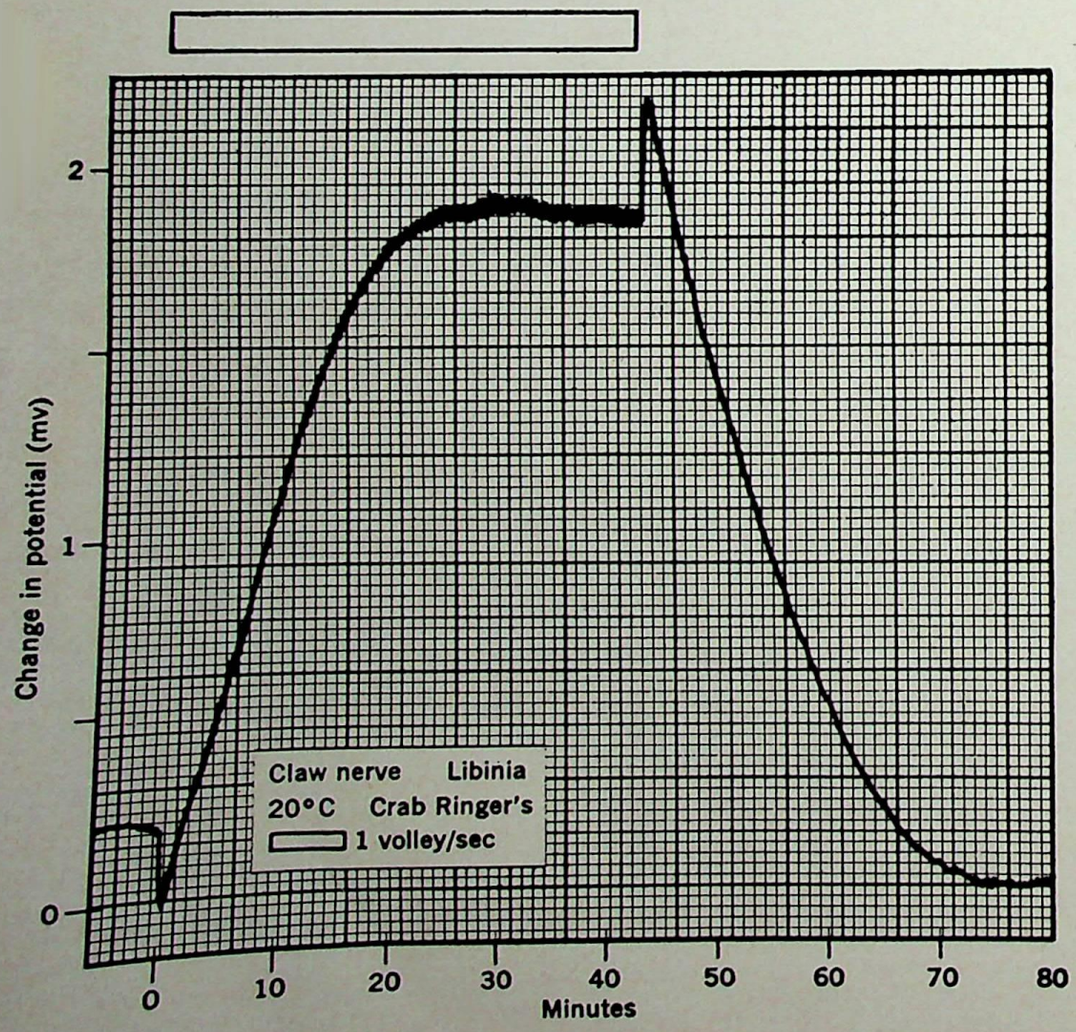

FIG. 11. Changes in average membrane potential of spider-crab nerve recorded during and following 43-min tetanus at 1 volley/sec. Not interrupted during tetanus. Measured depolarization of spider-crab nerve in isotonic potassium chloride about 30 mv.

for granted that the transport system in frog nerve produces some potential by this mechanism. On the other hand, Fig. 10 illustrates an experiment in which the Ritchie and Straub mechanism is not sufficient to explain the observed variations of potential. During a tetanus, the average membrane potential (exclusive of the action potentials) should be either negative or zero, according to the Ritchie and Straub scheme. The average should be negative during periods in which there is a net loss of potassium from the fibers and would approach zero if the system approached a steady state (i.e., K^+ pumped back inside during pulse interval $\equiv K^+$ lost/impulse). The lower envelope of the record in Fig. 10 shows that the membrane became hyperpolarized four minutes after the beginning of the tetanus and remained so for the remainder of it. With correction for the apparent depolarization introduced by averaging the action potentials, the statement could be made that hyperpolarization began at the beginning of the tetanus and reached a final average level (in the 100-msec interval between pulses) of almost one millivolt. Thus, the ionic transport system of frog nerve appears to be inherently electrogenic (positive outward).

A similar statement, based on similar evidence applies to unmyelinated limb nerve of the spider crab, shown in Fig. 11. Here the membrane also develops a net hyperpolarization during low-frequency tetani.

If one takes as a working hypothesis the proposition that the magnitude of hyperpolarization is proportional to the rate of sodium extrusion, how can the shapes of the recovery curves of Fig. 8 be explained? The kinetic behavior of a simple reaction mechanism showing saturation kinetics is portrayed in Fig. 12. It is the classical enzyme-substrate reaction of Michaelis, the rate of which is given by the second expression in the figure, where K_M is the concentration of substrate that produces half-maximal rate. The curve describes the rate of reaction as a function of time as an initially large concentration of substrate decreases. If nerve were to extrude the sodium remaining within it with the kinetics of this mechanism, the hyperpolarization should follow this curve exactly, starting at a point appropriate to the

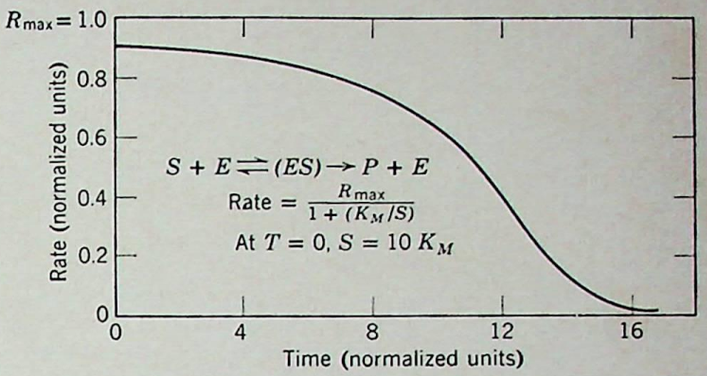

FIG. 12. Calculated time course of rate of disappearance of substrate with Michaelis type of enzyme-substrate reaction mechanism. K_M is concentration of substrate producing half-maximal rate [from C. M. Connelly, "Post-tetanic hyperpolarization in frog nerve," in *Proceedings of the National Biophysics Conference 1957* (Yale University Press, New Haven, to be published)].

amount of sodium accumulated during the tetanus. But, the recovery curves of Fig. 8 cannot be superimposed by displacement along the time axis, and, therefore, do not conform to this model.

If sodium ions enter the active fiber at the nodes and are also extruded principally from the nodes, then ions not extruded immediately after entry must tend to diffuse into the myelin-insulated internodal space. To determine the possible effect of diffusion in the internode on the kinetics of ionic recovery, the analog model shown in Fig. 13 was constructed. The model corresponds to one-half a node and to the adjacent one-half internodal space. A pentode, whose plate current-plate voltage curve is approximately a hyperbolic saturation curve of the Michaelis type, simulates the ion-extruding mechanism at the node; a filter network of 10 *RC* units is the analog of the diffusion field in the internode. Positive charges correspond to sodium ions; potentials at various points in the plate and filter circuits to sodium concentrations; plate current to rate of sodium extrusion; and injection of a constant current to the plate circuit simulates a tetanus. Seconds in the model correspond to minutes in the nerve. Figure 14 shows superimposed records of the output of the analog circuit, with parameters chosen to duplicate as closely as possible the

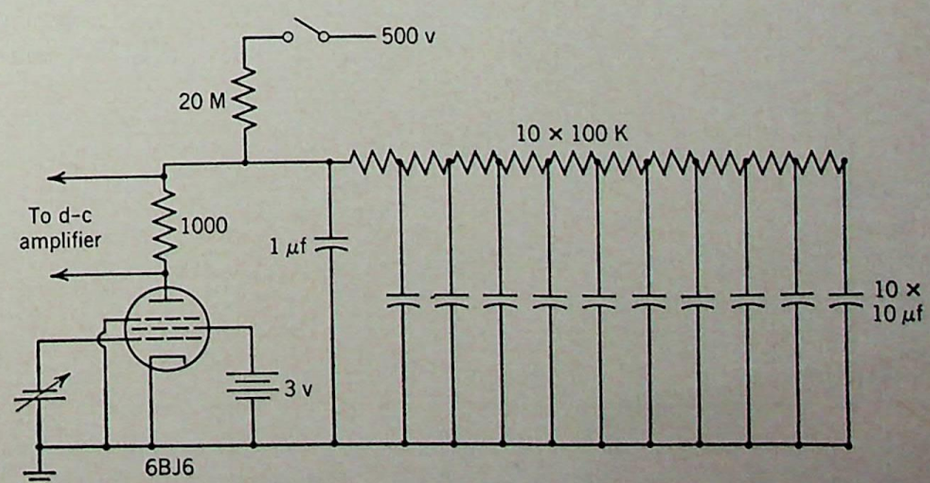

FIG. 13. Analog circuit [from C. M. Connelly, "Post-tetanic hyperpolarization in frog nerve," in *Proceedings of the National Biophysics Conference, 1957* (Yale University Press, New Haven, to be published)].

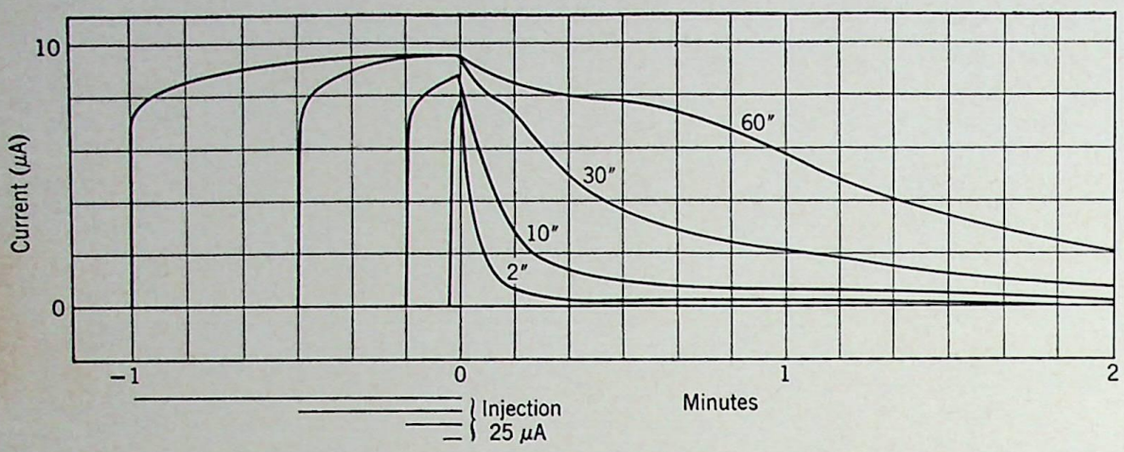

FIG. 14. Superimposed records of changes in plate current of analog circuit of Fig. 13, during and after 25-μA injections of different durations. Grid bias adjusted to give maximum plate current of 10 μA [from C. M. Connelly, "Post-tetanic hyperpolarization in frog nerve," in *Proceedings of the National Biophysics Conference, 1957* (Yale University Press, New Haven, to be published)].

observations of Fig. 8. The time constant of the network in this case is about twice as large as the corresponding time constant for the diffusion of sodium chloride in the internodal space (estimated assuming free aqueous diffusion and node-to-node spacing of 2 mm). It is encouraging that the shape of the recovery curve changes more or less in the proper manner as the duration of tetanus is increased. This oversimplified analysis tends to support the hypothesis that the positive after-potential has its origin in a saturable, ion extruding mechanism operating at the nodes.

CONCLUDING REMARKS

The events of recovery may be described tentatively s follows: Sodium ions enter a fiber during activity. The increase in internal concentration accelerates a saturable ion-transport process in which sodium ions and high-energy phosphate compounds are obligatory participants. Sodium ions are liberated to the exterior, and potassium in the exterior medium participates in the over-all cycle, being transferred to the interior. The operation of the mechanism generates an emf, directed positively outward. Oxidative metabolism maintains the supply of high-energy phosphate compounds.

The observations outlined in this discussion have emphasized the coupling between oxidative metabolism as an energy source and ionic transport processes as an energy sink. The molecular mechanisms of active ionic transport across membranes are almost a complete mystery. Proposed mechanisms range from shuttling carriers to micro-pinocytosis to enzymatic modification of pore configuration or charge distribution. This is an outstanding problem in cellular and molecular biology today.

Sensory Performance of Organisms*

WALTER A. ROSENBLITH

Department of Electrical Engineering and Research Laboratory of Electronics, Massachusetts Institute of Technology, Cambridge 39, Massachusetts

THIS paper is concerned with those aspects of organized neural complexity that permit organisms, such as man, to deal successfully with their sensory environment. Examples presented below illustrate how man, as an organism, detects, orders, and identifies events in his environment to which his sense organs are sensitive. The roles that stimulus intensity and time play in these operations are emphasized, as opposed to those aspects of sensory quality (pitch and hue, for example) for which one might expect the underlying mechanisms to differ rather considerably in going from one sensory modality to another.

Studies of communication processes in the nervous system should be based on a realistic view of the way in which the total organism reacts when it reaches selectively into its surroundings—be it under self-instruction or under instructions from others—to process stimuli that have informational value. This emphasis upon the organism's behavior in communication tasks leads to a preoccupation with certain dependent and independent variables. It leads to an inquiry into the "operating characteristics" of the organism in order to be able to specify, albeit in a statistical manner, its maximum sensitivity, its resolving power, its dynamic range, its characteristics in the frequency and time domains, its information-handling capacity, and so forth.

The data presented in this paper come mainly from *contemporary* psychophysics. Subjects are not asked to introspect, but, rather, to indicate by standardized motor responses (most often verbal responses) whether they judge a stimulus to be present or not, whether they judge two stimuli to differ, whether they can order a set of stimuli or identify members of the set.

Assume that one is dealing with well-instructed cooperative subjects who are skilled in the execution of the expected response and who are familiar with the set of stimuli that will be presented to them.†

Assume also that there is agreement on a program of stimulus presentation and on a method of response analysis. Thus, one must decide whether the admissable response categories shall be simply: "yes" and "no," "same" and "different," "more" or "less," or whether they should include the set of natural numbers. There must also be rules for dealing with false responses (false-alarm rate), and, finally, one must decide whether or not to quantify the temporal aspects of responding in addition to recording the mere emission of responses.

Such considerations may seem unnecessary details that should be left to methodologists, but unless there is a realistic understanding of the measurement and quantification problems in fields like psychophysics and neurophysiology, one can hardly evaluate the store of knowledge they have produced, or understand the relation of such knowledge to the knowledge that exists in the several areas of biophysics.

INFLUENCE OF INSTRUCTIONS UPON THRESHOLD OF DETECTION

The task of detecting the presence of a stimulus includes the classical absolute threshold as well as the generalized "masked" threshold—i.e., detection of the stimulus against a background of sensory stimulation. Such "background noise" refers necessarily to the sense modality under study. Even the best isolation booths do not reduce to zero all unwanted sensory influx other than that under the experimenter's control.

It has long been known that instructions significantly influence both the shape and the anchor points of "frequency-of-seeing" or "frequency-of-hearing" curves. A recent study by Smith and Wilson[2] has forcefully illustrated this dependence upon the judgmental criteria that are suggested to observers. Ten observers were asked to report the presence of a tone in noise. The three curves of Fig. 1 show how the identical group of observers performed this task under three different sets of instructions. Examples of the instructions that were designed to induce a "conservative" or a "liberal" attitude in the reporting of signals follow:

Conservative groups:

"Keep in mind that it is important for you to be sure you hear the tone. In many cases, there will be no tone, and you will be making a mistake if you indicate that you hear one. None of the tones is really easy to hear, but don't push the switch unless you are sure that you heard the tone. If you are in real doubt as to whether or not you heard a tone, assume that there was none."

* This work was supported in part by the U. S. Army (Signal Corps), the U. S. Air Force (Office of Scientific Research, Air Research and Development Command), and the U. S. Navy (Office of Naval Research).

† Experiments parallel to those considered here could be conducted with monkeys or even with rats or pigeons, if appropriate behavioral techniques were used. However, few experimenters[1] have been willing to train their animals thoroughly enough, or to reformulate the required response in a way that was compatible with the animal's behavioral repertory. The short-cut of employing highly motivated and intelligent subjects permits experimenters to bypass a lengthy learning process.

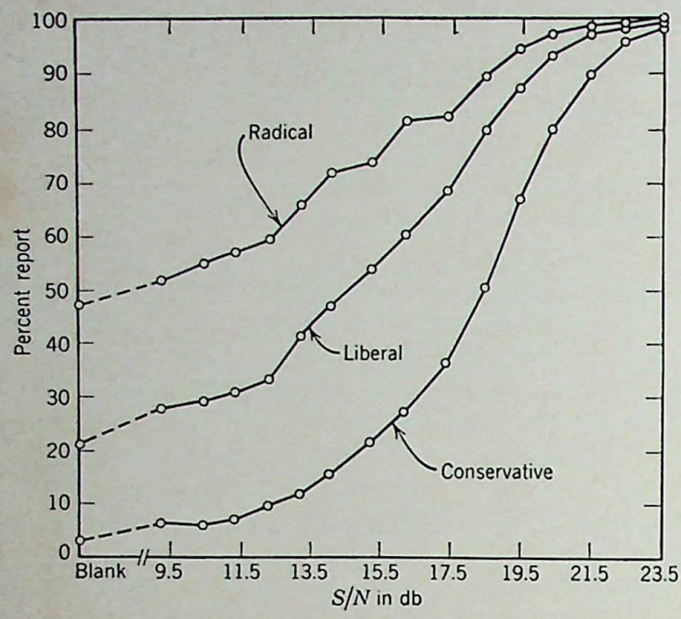

FIG. 1. Cumulative percentage of instances in which the presence of an 800-cps tone was reported as a function of signal/noise ratio. Attitude towards listening tasks is varied by means of instructions (see text). Each of 10 observers made approximately 150 judgments per point.[2]

Liberal groups:

"Keep in mind that all of these tones are hard to hear, and that you will rarely be absolutely sure that you heard something. But if you think you heard something, probably you did—report it. If you are very sure that you didn't hear anything—then don't touch the switch."

The results illustrate clearly that one cannot hope to predict accurately from a knowledge of signal-to-noise ratio alone the performance of a group of observers, even if the task calls for nothing more than the reporting of the presence of a single class of signals against the background of an unvarying noise.

Statistical models of the detection process have been formulated[3] in which performance is predicted not only on the basis of stimulus values and organismic variables; there are additional parameters that are sensitive to instructions and to amounts of reward or punishment. Such models may account for behavior such as is depicted in Fig. 1. A physiological interpretation of this sensitivity of the organism to nonstimulus variables remains to be given, though some physiological phenomena that provide grist for speculation have been reported in recent years.

When tasks that involve some ordering of stimuli are assigned to organisms, three problems are encountered. These stimulus-ordering operations may be listed under the headings of (a) differential sensitivity, (b) identification, and (c) psychophysical scaling.

DIFFERENTIAL SENSITIVITY

Such labels as just-noticeable difference (jnd), differential thresholds, and difference limens have been used to describe the changes in stimulus characteristics that make it possible for an observer to distinguish, with various degrees of certainty, between two stimuli. All of these measures of differential sensitivity are statistical in character and the jnd increases in size if a listener is required to identify correctly the more intense of two sounds in 90% of the trials than if he is required to be correct in 75% of the trials only.

More than a century ago, Weber formulated, on the basis of his own experiments, a generalization according to which the jnd between two stimuli gets larger as the stimuli get larger. This assertion has been called Weber's law, and the expression‡

$$\Delta I/I = k \qquad (1)$$

has been written to express this relative constancy of human differential sensitivity. Here, I is the intensity of the reference stimulus, ΔI represents the difference along the intensity dimension that is discriminable (in 75% of the trials, for example), and k is a constant. Weber's law states, therefore, that the jnd will remain proportional to the intensity of the reference stimulus. Today, there exist Weber functions (see Fig. 2) that cover a wide enough dynamic range to provide a fair test of the validity of Weber's law. The data indicate that, at least for auditory and visual stimuli, this relation breaks down as the absolute threshold is approached. Both frequency and intensity discrimination worsen as the stimulus becomes weaker. The existence of the so-called achromatic and atonal intervals[7] is further evidence along these lines. A better fit to the data of Fig. 2 is then provided by an equation of the form.

$$\Delta I = k(I + N_i); \qquad (2)$$

N_i has such a value that for low values of I, ΔI depends primarily upon N_i, while for medium and high values of I, N_i becomes negligible.

The introduction of N_i can be interpreted in different ways. Years ago, both Fechner and Helmholtz suggested that Weber's law be modified to acknowledge the presence of intrinsic interfering stimulation that could not be eliminated. In contemporary jargon, one might say that N_i corresponds to the "internal noise level" of the organism. This expression should, however, not be taken too literally. Several theoretical models exist in which a generalized noise term is a crucial feature of the discriminating organism. Thus far, modifications of Weber's law have aimed at agreement with the data near the absolute threshold. There is some evidence that the presence of extremely intense sensory stimulation leads again to some deterioration of discrimination. It is easy to see that the model could be further modified

‡ The symbolic notation employed in writing this Weber fraction or Weber ratio seems to emphasize the intensitive aspects of a stimulus. Actually, what is involved is not necessarily some aspect of energy flux, but rather loose usage of the term "intensity." Thus, fractions have been determined for lifted weights, length of line, pressure on the skin, and so forth, and comparisons between sense modalities have been made on the basis of these numbers.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

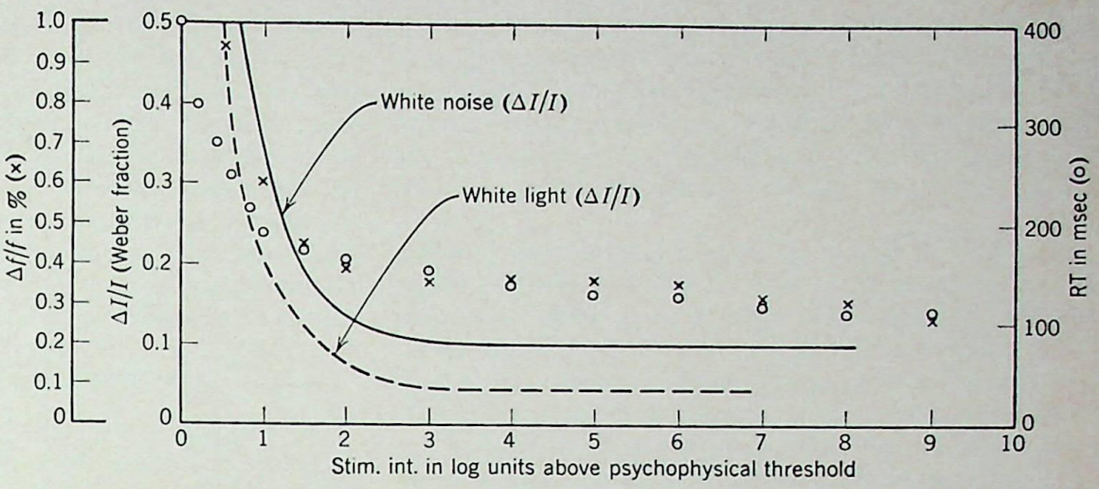

FIG. 2. Just-noticeable differences and reaction times as a function of stimulus intensity. Data on frequency discrimination of a 1000-cps tone after Shower and Biddulph[4]; on intensity discrimination for white light and white noise after Boring, Langfeld, and Weld[5]; data on reaction time after Chocholle.[6]

by the introduction of another term corresponding to an equivalent noise level that would only come into play for large values of I.

One further comment regarding the amount of invariance that it is realistic to expect in psychophysical data. Figure 3 summarizes the findings from more than half a dozen investigators, all of whom were trying to measure man's ability to discriminate pitch. In different experiments, different subjects, several psychophysical methods, several methods of stimulus presentation, and even several response criteria were employed. While it does not seem possible to read from this graph a value for the jnd for frequency, it is possible to point out that practically all of the data lie within the two dashed lines; i.e., their total spread is approximately a decade. The compilers of handbooks or of "Critical Tables on Sensory Performance" would thus be well advised to emphasize those aspects of psychophysical judgments that exhibit what might be called "relative invariance." Instead, they often insist upon quoting numerical values (sometimes with several significant figures), perhaps with the forlorn hope that the users of such tables will take these values with a grain of *ceteris paribus*.

SPAN OF ABSOLUTE JUDGMENT

From data on just-noticeable differences, estimates have been made of the total number of distinguishable sounds, lights, or smells. Usually, the authors of these estimates have simply divided the range over which an organism is sensitive by the corresponding average jnd. Thus, the "auditory area"[9] has been estimated to represent several hundred thousand distinguishable sounds, and the number of distinguishable colors has been estimated to be of the same order.

Several unjustified assumptions underlie these extrapolations. Subjects may find it quite easy to detect a difference between two stimuli without being able to identify either of them. In everyday situations, an individual rarely has difficulties in distinguishing between two other individuals even though he cannot tell which one is Jones and which one is Smith. Absolute identification requires much more information than differential discrimination.

Under the influence of the mathematical theory of communication,[10,11] with its concept of channel capacity, many experiments have been carried out to determine man's capacities to process selective information. By considering man as a communication channel with stimuli for inputs and responses for outputs, it has been possible to estimate maximal rates of transmission through him. The amount of input information can be varied either by varying the amount of information per stimulus or by varying the rate at which stimuli are presented. As Quastler[12] has pointed out, the maximal rate of transmission is limited by two factors: (a) people cannot emit more than 5 to 9 responses per second, and (b) people get confused when they have to discriminate

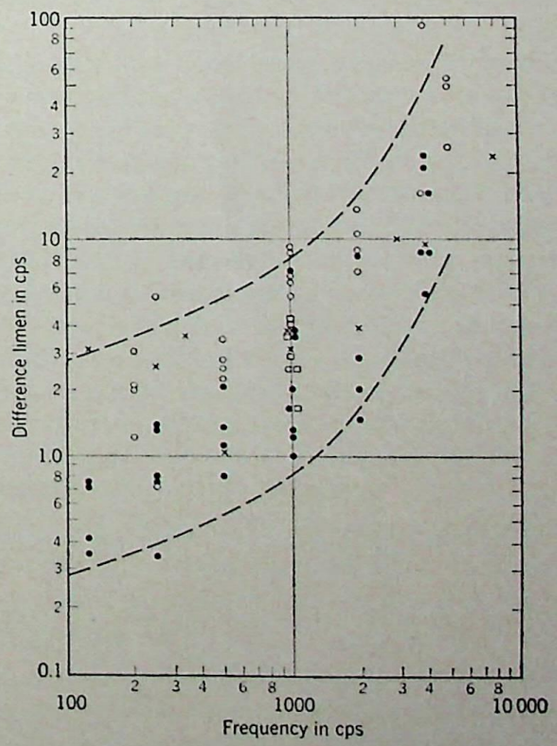

FIG. 3. Data on pitch discrimination reported by several investigators. Different symbols identify different experimental procedures (see Rosenblith and Stevens[8]).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

rapidly among too many alternatives. Thus, even under optimal conditions, transmission rates of more than 25 bits per second are hardly ever observed. The type of motor response required and the degree to which stimuli and responses are "compatible"[13] determine the particular figure that will be obtained for the transmission rate.

A different aspect of man's information handling capacity comes into focus if subjects are no longer required to respond as quickly as possible. They now need simply to tell which of several alternative stimuli occurred on a particular stimulus presentation. Given knowledge of the probability of occurrence for the different stimuli and of the accuracy with which the subjects perform, one can calculate the amount of information in these absolute judgments. This experimental paradigm has been much used in connection with "simple" stimuli, such as pure tones or monochromatic lights. The results from these experiments in several sense modalities have led to the emergence of what Miller[14] has called "the magical number 7 plus or minus 2." This number represents the number of alternative stimuli that subjects can accurately identify as long as only one aspect ("dimension") of the stimulus is varied. This magical number thus corresponds more or less to the upper and lower bounds for the "span of absolute judgment." More-precise estimates of performance figures will need to take account—in addition to individual differences—of such experimental conditions as the range of stimulus variation, the spacing of stimuli over a given range, and the number of available response categories. Subjects seem also to perform better if knowledge of results is fed back to them after each response.

Sensory communication in everyday situations is, however, not restricted to making unidimensional judgments. The sounds, shapes, tastes, and smells upon whose successful recognition one's sensory commerce with the environment depends are basically "multidimensional displays." Laboratory experiments with such displays indicate that the span of absolute judgments increases in size as an increasing number of stimulus aspects are varied. Pollack and Ficks[15] obtained 7.2 bits per judgment when they presented to their subjects sounds that varied along six different acoustic "dimensions." This performance corresponds to correct identification of approximately 150 different categories. Comparison of the Pollack-Ficks data (1.2 bits/judgment/dimension) with the characteristic figure for unidimensional judgments (2.3 bits/judgment) shows that, while each new dimension helps to transmit more information, these increments tend to diminish as the dimensionality of the display increases. But it is not known where the asymptote lies for this relation between bits per judgment and stimulus dimensionality. Thus, organisms seem much better in absorbing information from the environment by making several crude distinctions simultaneously, instead of by making extremely precise discriminations of a single aspect of a sensory stimulus. This finding will not surprise those who are familiar with the facts of speech communication where the precise spectral composition of speech sounds is rather unimportant in conveying information. Instead, man's ability to recognize speech sounds seems to depend upon the detection of the presence or absence of "distinctive features"[16] that are thus rather analogous to the dimensions of the acoustic display.

PSYCHOPHYSICAL SCALING

Among all the attempts to establish orderly relations between verbal responses and sensory stimuli, Fechner's law is probably the best known. By the use of indirect methods in which he used the just-noticeable difference as his scale unit, Fechner concluded that psychological magnitude varied as the logarithm of stimulus magnitude. There has been much argument about the measurability of sensation, about the validity of Weber's law, about the legitimacy of the Fechnerian integration of Weber's law which Fechner used to derive his own law; and yet, by and large, Fechner has been correct in predicting that his psychophysical edifice would stand because his detractors would not be able to agree on how to tear it down. In recent years, S. S. Stevens,[17] whose concern with measurement and scaling had led him to investigate systematically many of the fundamental assumptions in psychophysics, has produced a series of painstaking and ingenious studies of how subjects order stimuli by *direct* methods. Stevens did not accept the assumption according to which the unit of resolving power§ is the natural unit for experiments in which observers are asked to order a stimulus continuum by assigning numbers to it and in which these numbers are to reflect the judged or subjective magnitude of the stimuli. Stevens[18] divides perceptual continua into two general classes: continua that have to do with *how much* are called prothetic; continua that deal with *what kind* and *where* (position) are called metathetic. Well-known examples of prothetic continua are loudness and brightness; pitch is an example of a metathetic continuum. On the basis of experiments involving more than a dozen prothetic continua, Stevens concludes: ". . . there is a general psychophysical law relating subjective magnitude to stimulus magnitude . . . this law is simply that equal stimulus ratios produce equal subjective ratios. On numerous perceptual continua, direct assessments of subjective magnitude seem to bear an orderly relation to the magnitude of the stimulus. To a fair first-order approximation the ratio scales constructed by "direct" methods (as opposed

§ This indirect derivation of the scale of psychological magnitude parallels in some sense the extrapolated number of distinguishable sounds or colors. In both instances, the just-noticeable difference is the key concept of quasi-theoretical deductions without regard for operational compatibility.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

to the indirect procedures of Fechner) are related to the stimulus by a power function of one degree or another."[18]

Figures 4 and 5[19,20] present two samples of the numerous results obtained. In Fig. 4 there are plotted the magnitude estimates of loudness made by listeners who had not been given standard sounds of fixed intensity for comparison purposes. The eight different intensities were presented irregularly, and the subject estimated the loudness by numbers of his own choosing. These numbers were multiplied by appropriate factors to make each subject's estimate at 80 db the same, namely, 10. The points represent the medians of these "normalized" judgments, and the vertical lines represent the interquartile range of the judgments. By plotting the estimated magnitudes on a logarithmic scale *versus* the logarithm of stimulus intensity, the slope of the straight line is the exponent of Stevens' power function

$$\Psi = kS^n. \qquad (3)$$

Here, Ψ is the psychological magnitude, S is the stimulus magnitude, and k and n are constants. For the stimuli that have been studied, the approximate value of n varies from 0.3 for loudness and brightness‖ to 4 to 5 for electric shocks. The exponent for vibratory stimulation applied to the finger has a value of approximately 1. It is interesting to speculate that these exponents stand in inverse order to the dynamic ranges for the relevant sense modalities. The dynamic range for hearing and vision spans approximately 12 logarithmic units, the range for tactile vibration spans perhaps 3 to 4 logarithmic units, and the range for electric shocks spans only about 1 logarithmic unit. Does the fact that

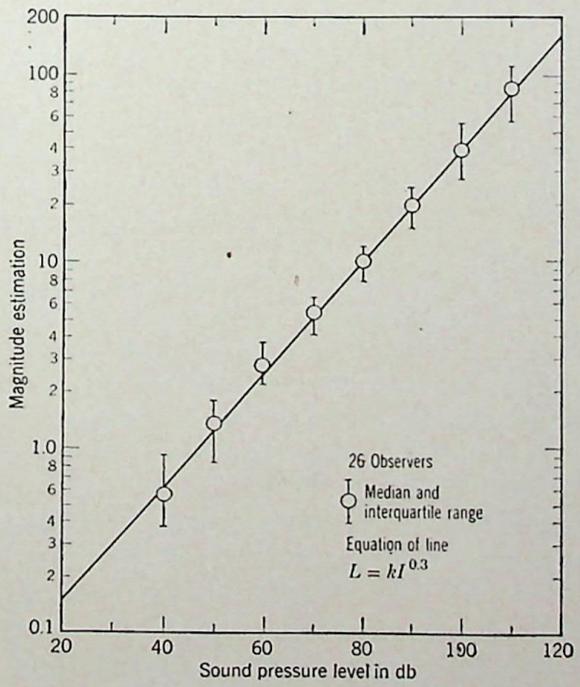

FIG. 4. Magnitude estimates of loudness made with no fixed standard.[19]

‖ The exponent is 0.6 if stimulus magnitude is expressed in terms of sound pressure instead of sound energy.

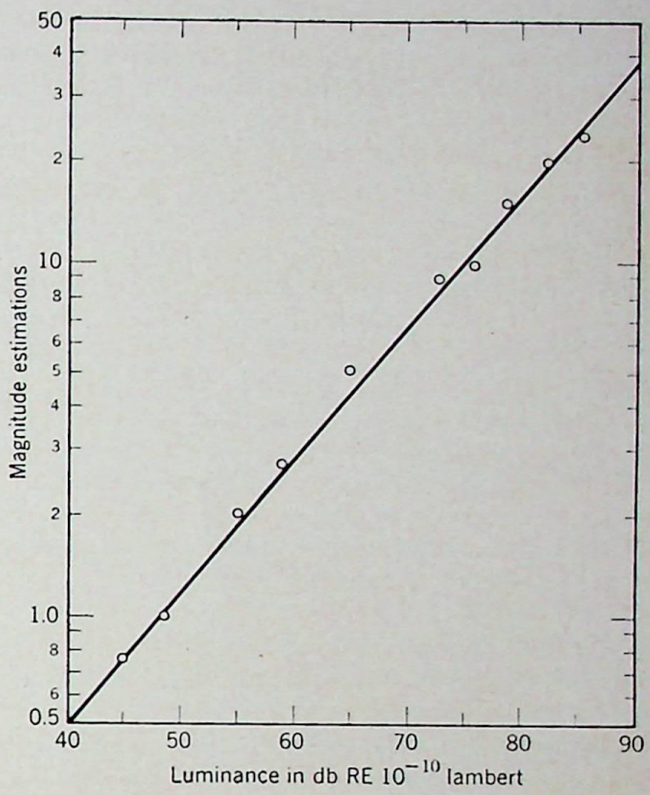

FIG. 5. Magnitude estimates of brightness of a luminous spot; the median estimates of ten observers are plotted.[20]

the product of the exponent multiplied by the dynamic range yields numbers of the same order of magnitude have any deeper significance? Does it reveal anything about the functioning of the sense organ, about the functioning of the nervous system, or does it rather reveal a certain constancy in verbal behavior—i.e., about the way in which people use numbers between the threshold of detection and the threshold of pain?

Another recent study by Stevens[21] deserves to be reported in this context. Once scales of subjective intensity have been established for several sensory continua, can these scales be used to predict what people will do when asked to match directly the loudness of a noise against the subjective intensity of a vibratory stimulus or an electric shock to the finger? Cross-modality matches were made between each modality and each of the other two. To a good approximation, the predicted functions were confirmed by direct experimentation, and the internal consistency of the direct approach to scaling has been further validated by this cross-modality study.

TEMPORAL CHARACTERISTICS OF SENSORY PERFORMANCE

Since Helmholtz's time, experiments on reaction time have been used to make inferences on the processing of sensory signals in the nervous system and on the duration of so-called mental processes such as discrimination, recognition, and choice. It was established that reaction times to sounds, electric shock, and touch were faster than reaction times to visual stimuli; also, that reaction

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

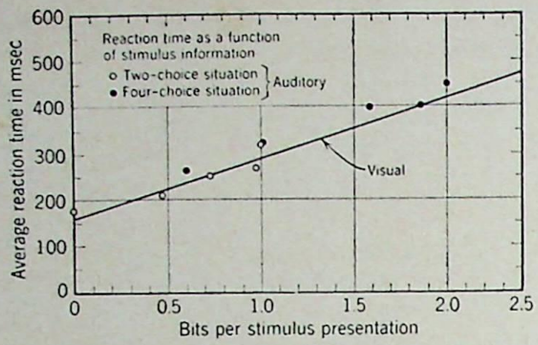

FIG. 6. The straight line represents the best fit to data obtained by Hyman[23] from one of his subjects in response to visual stimuli; the open and closed circles represent reaction-time data obtained by Albert[25] from one of his subjects in response to auditory stimuli; here, the stimulus set was composed of either two or four elements.

times decrease—at first rapidly and then more slowly—as the intensity of a sensory stimulus is raised above threshold (Fig. 2).

In addition to these data on simple reaction times, other experiments have attempted to assess the effect of task complexity on the speed of more discriminative reactions. It has been shown that reaction time increases as the stimulus ensemble increases in size and as its members become harder to distinguish from each other. This whole topic had lain more or less dormant for several decades until it became obvious that the application of certain concepts from information theory might make it possible to explore another aspect of man's capacity to handle information. A series of experiments[22–24] indicated that, at least over a certain range, choice time (or disjunctive reaction time) was proportional to the average amount of information transmitted per stimulus-response event. This finding applies equally well to visual as to auditory stimuli (see Fig. 6), and there is sufficient agreement between the data obtained by different experimenters that it is possible to talk about a characteristic figure for the "rate of gain of information" whose value lies near 6 bits per second. It is not possible to account for these time intervals in terms of delays on either the afferent or the motor sides of the nervous system. Enough is known about the latencies of evoked electric activity to permit one to say that these events consume only a fraction of the time involved in even the fastest reaction. The discrepancy becomes much greater, of course, upon considering sensory stimuli that are barely above the absolute or masked threshold or reaction times that involve complex discrimination. Thus, one must infer that a large fraction of the total reaction must be spent in "central information processing."

Recent experiments by Davis[26,27] and others throw some new light on these inferences. Davis presented to his observers two visual stimuli in succession and asked them to respond to each stimulus in turn. He then varied the interval between his two stimuli randomly between 50 and 500 msec. As long as the separation was more than 250 msec, the reaction time to either stimulus was approximately 200 msec; but when the time interval between the two stimuli fell below 250 msec, the second reaction time increased sharply. The second reaction time reaches its maximum value, approximately 400 msec, for an interval of 50 msec. The same phenomenon occurs when one stimulus is visual and the other is auditory, no matter what their order. Next, the subjects were instructed not to respond to the first of two lights. The results show little improvement over the delays that occurred when motor responses were made to both signals; the only difference was a slight shortening of the second reaction time, by about 20 to 30 msec. In a final experiment, the subjects were asked to make a "response" without a signal having occurred. Following the pressing of the key, a light came on (after an interval that was again randomly varied between 50 and 500 msec) to which the subjects were required to respond. This time there was no additional delay for any time interval. The subject was just as efficient in responding to a signal that came 50 msec after he pressed the first key as he was in dealing with a signal that came 500 msec afterwards. It would thus appear that the actual performance of the response does not contribute much to the delays that are observed, but that these delays are imputable to the processing of a signal that is still going on when the second signal is presented. There is further evidence that emphasizes the amount of time that central processes play in the handling of sensory information. In hearing and in vision, there is almost perfect integration of energy at the absolute threshold, as long as the stimulus is being presented for time intervals that are shorter than 200 msec. There is a whole class of phenomena in both hearing and vision in which a strong succeeding stimulus interferes with the "proper" analysis by the nervous system of a preceding weaker stimulus. The shorter the time interval between the two stimuli and the greater the discrepancy in intensity, the more severe is the interference. Since the delay times on the afferent side of the nervous system are longer for weak stimuli than for strong ones, the more intense stimulus has a chance to "catch up." However, the time intervals involved are sufficiently long that these differences in delay times along the ascending pathway are hardly the whole story. There is the further fact that interference with the more complex discrimination seems to be effective over longer time intervals than with more primitive tasks (such as simple detection of a preceding stimulus).

The preceding illustrations all point to the conclusion that the analysis of sensory information is a time-consuming task that occupies an organism's central nervous system in relation to the amount of information to be processed. This is hardly surprising; yet, it is often overlooked in practical situations.

The foregoing briefly reviews man's sensory performance as it appears when examined by the quantitative methods of contemporary psychophysics. Organisms

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

are able to deal with the sensory bombardment that impinges upon them by being satisfied to make crude discriminations, unless specifically instructed to make precise ones (at the cost of spending more time making them and of neglecting other sensory events than those under analysis). The flexibility of organisms in switching from one sense modality to another, from one aspect of sensory display to another, is bought at the expense of relatively low rates for the transmission of information. The mere existence of organisms seems to entail a high, internal noise level that prevents responses to environmental stimuli from being anything but statistical in character. As long as thresholds of tolerance are not approached, the more energy a sensory stimulus delivers to an organism, the higher is the probability that the signal will be processed in the central nervous system with both discrimination and dispatch. One may paraphrase this situation by saying that the higher the energy level of a sensory signal, the greater the redundancy with which the representation of this signal will be handled in the central nervous system. These are some of the considerations that led us to select certain aspects of the electrical activity of the nervous system for quantitative study.

Biological Transducers and Coding*

OTTO H. SCHMITT

Departments of Zoology and Physics (Biophysics), University of Minnesota, Minneapolis 14, Minnesota

IN this discussion of biological transducers and coding, no attempt is made to describe in detail the specific codes in which diverse animal (and plant) transducers operate, for this attractive topic in comparative physiology and biophysics is discussed at length in other sections of this book by Bullock, Hartline, Katz, and others. Nor is an attempt made here to correlate over-all organismic behavior with transducer functions for that is, to a large extent, the burden of the communication by Rosenblith. Instead, the niche between organismic behavior and detailed transducer codings is examined to determine whether or not it is possible to develop new and useful analytical tools by which one can better formalize the behavior of individual transducer elements and their interrelationships, so as to approach a deeper and more intuitive understanding of the resulting whole organism's stability, decision making, intelligent behavior, and homeostatic performance.

While it is impossible to develop the point of view adequately in a few pages of text, it is the firm conviction of the author that biophysical theory, where it has developed at all, has developed too closely in the footsteps of physical theory and has not yet evolved mathematical models and analytical techniques specifically tailored to fit biological phenomenology. Instead of adapting physical-science terminology and theoretical formulations to its needs, it has adopted them as though they were "true" rather than merely convenient approximate descriptions of experimental experience. This has been especially true in the studies of biological transductive processes where the biologist, armed only with experimental facts, has for the first time come up against the new and highly formalized jargon of information theory and automatic-control engineering. Through modesty or lack of mathematical dexterity, he usually tries to make-do with these mental tools as furnished him ready-made by physics and engineering. It is not the author's purpose to deny that one must start with available techniques, but rather to propose that one must quickly amend and supplement these with uniquely biophysical hypotheses and an appropriate calculus, if the problems of this field are to be reduced to a complexity where intuitive insight into them can readily be gained.

* Much of the original work reported in this section was supported by grants H513 from the National Institutes of Health, Public Health Service, U. S. Department of Health, Education, and Welfare, by contract N6onr-24609 with the Office of Naval Research, U. S. Department of the Navy, and by grants from the Minnesota Heart Association and the University of Minnesota Graduate School.

It is necessary, however, to set up some ground rules before launching into a discussion of biological transducers, their transfer functions and other possible means for studying their organization and coding. As there are no uniformly adopted definitions for transducers in biology and biophysics, an explanation is probably necessary for the term biological transducers. The usage of the author may be somewhat different from that of others in the biophysical field, and perhaps different even from that of other authors contributing to this volume.

What, then, is a biological transducer? The term transducer is borrowed from the engineering sciences, where it is usually defined so as to include those devices which "lead across" or transform energy from one form into another, and thus translate signals from one energy modality—such as sound—into another—such as a varying electrical current. While the physical-science definitions do not usually specifically exclude gross-energy converters such as steam boilers, storage batteries, and electric light bulbs from being considered as transducers, it is tacitly assumed that only devices which serve a communication or signal-converting function will be called transducers. Thus, a motor turning the rudder or shifting the ailerons of an airplane in response to instructions from the autopilot is clearly regarded as a transducer; one driving a washing machine is not. Similarly, a resistance-wire strain gauge is considered a transducer in its function of converting mechanical position changes into electrical-current variations, but its incidental function of converting electrical power into heat is not usually thought of as transduction.

Biological transducers, then, should logically be the biological counterparts of the physical sciences' transducers and should comprise all of those biological units and systems which perform transformations of energy modality within the context of a communication or informational transformation function. Thus, biological transducers should include not only the familiar sensory transducers such as the rods and cones of the retina, the thermal, olfactory, and gustatory receptors, the vestibular and cochlear receptors, and the many proprioceptive organs, but they should also include numerous synaptic and related intermediary units involved in biological-data processing and storage, and the output or motor transducers as well. Nor is there any reason to exclude humorally mediated transducers. The concept of a transducer fits the function of a cortical neuron or of the motor end plate at least as well as it does that of the muscle-spindle strain gauge.

It is convenient to use the terms afferent and efferent

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

in reference to biological transducers to distinguish incoming from outgoing transduction functions, and it seems desirable to adopt directly from engineering the terms "passive" and "active" transducers, to distinguish between those where the energy of an incoming signal provides directly the output energy and those transducers, very common in biological systems, where the incoming energy triggers or controls the release of locally supplied energy into an output modality.

Transducers that operate in one direction only are called unilateral transducers, while those that operate in either direction are called bilateral. The quite special transducers that not only operate in either direction, but also obey the reciprocity theorem, are called reciprocal transducers.

The linear transducer is one where the output can be related through linear-differential or algebraic equations to the input function. It is a type of transducer not often found in biological nature, but a form to which most experimental transducer results are approximated, as its behavior is easily formulated and understood mathematically. The linear transducer does deserve special mention, for it is out of the notion of a linear transducer that the transducer transfer-function idea arose.

The transfer function of a linear transducer is usually expressed simply as the ratio of its output to its input signal with frequency as a parameter. This ratio is usually a complex number which may be dimensionless in the case of a transduction between similar modalities, or may carry within it the ratio of the dimensions in which output and input are expressed. It is valuable to remember that, around any properly described, closed, biological control loop, transfer functions must cancel dimensionally. Thus, a mathematical description of a biological loop system can be tested much as elementary physics equations are tested dimensionally by cancellation of dimensions and by reduction to mass, length, and time units.

In studying biological transducers, it is often desirable to regard the transfer function as a much more general operator than merely a linear complex ratio, for many of the merits of transfer-function analysis remain even where the transfer operator is a very elaborate time- and pattern-dependent code.

It is evident from these definitions and the associated discussion that the foregoing concept of biological transduction is very inclusive. The term "biological transducer," is used here to include all of those organs and processes wherein the purpose of the reaction involved is to convey, store, or process information about the environment and organism for its preservation and effective operation. Included, therefore, are all of those processes whereby information is transduced or led across some kind of a transformative exchange, with no restriction, for example, to sensory receptor organs. In this definition, genetic determination, many processes of differentiation and growth, as well as reflex and higher level abstraction mechanisms, become specifiable in transductive terms. It may be felt that this is too inclusive a definition, for it obviously includes a great deal of biochemistry, hormonal control, enzyme dynamics, growth processes, and central nervous whole-organism behavior control. It can be limited, however, and made meaningful by adding the loose criterion that has entered into some European engineering literature to distinguish between what are called large energy processes and small energy processes, and by recognizing that this distinction is one of convenience rather than one of fundamental importance.

Behind this categorization is the idea that, while every energy turnover process, whether power-plant generation of electricity or ATP utilization in muscle, involves a certain amount of direction, and while every informational biological activity, even so explicitly directive as the axonal propagation of an impulse, requires the expenditure of energy, one can usually choose one of these as being of dominant importance in the particular process in question.

One often finds in complex control systems that up to about 10 or 15% of the total energy consumed will go into processes that may legitimately be considered as primarily informational. This fits reasonably well with biological systems where, if one considers the human as an example, something like 10 to 15 w of power goes into the total nervous-system maintenance and operation, whereas the total average power turnover for a normal-size person of average activity is somewhat over 100 w. It is sound economical biological design that one should put perhaps 10 to 20% of the available metabolic energy to work for learning about the environment, deciding what to do about it, and issuing proper instructions to do something appropriate.

Now, to turn to a different aspect of biological transducers and coding, it is rather hard to break from tradition to frame variables conforming to codes in which biological processes are described by the organism, as against those terms in which one is used to describing similar phenomena in the physical sciences. In engineering analysis, one very firmly separates time as a variable apart from space coordinates, whereas one is forced to conclude that the organism uses in almost every transducer a conveniently mixed code and pays very little attention to whether it separates out temporal and spatial aspects of pattern.

Figure 1 illustrates one of the classical sensory-receptor code patterns (that of the carotid-sinus pressure receptor) to show that these receptors do not slavishly report on the value of a function being transduced or on the time derivative of this function exclusively. Instead, they answer the biologically important questions: "What is the present state of affairs?" "What is changing?" and "What has been the recent past experience?" These reports correspond loosely to engineering transducer language in which function, time derivative, and integral transducers are involved, but in

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

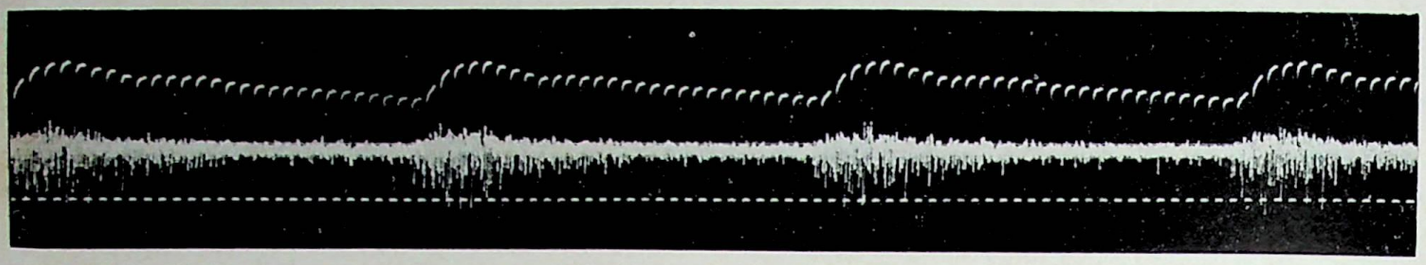

FIG. 1. Carotid sinus pressure transducer response (dog). Central record represents multifiber nerve response. Upper curve envelope is directly measured blood pressure referred to lower base line as zero. Mean blood pressure 150 mm Hg, interruption rate on pressure measuring trace 60/sec. Each pattern represents one heart beat (records by courtesy John W. Trank).

engineering transducers these factors usually are rather carefully separated out or very cautiously combined. Figure 1 is a record of the action potentials recorded from a few nerve fibers leading from the carotid-sinus end organs in a dog. This organ is concerned with reporting on the mean blood pressure in the animal and also on the details of pressure during the heartbeat. In this case, the average pressure is an important item and its absolute value remains important. Therefore, this must be a relatively nonaccommodating organ in the sense that it must continue to report the present state of affairs.

On a short time basis, it has a large "derivative" term, and thus is modulated from a high frequency almost to cutoff during each beat. Its steady-state response as reflected in the mean frequency, and especially in static records like those of Fig. 2 for a similar organ in a rabbit, is shown to convert static pressure almost linearly into pulse frequency. In this static sense, one might call this carotid-sinus organ a linear pulse frequency-modulation transducer. One must however, point out the danger of specifying a transducer as "linear" or "nonlinear" on this basis by referring to the two graphs accompanying Fig. 2 where data from the same impulse records are plotted in (a) as a frequency *vs* pressure-transfer relationship and in (b) as a pulse interval *vs* pressure graph. Note how the choice of variable determines "linearity" or "nonlinearity" in this casual sense. One must, therefore, define quite carefully on a theoretically sound basis what kind of nonlinearity is meant when that term is used.

This transducer an engineer might still consider reasonably well-behaved, but now consider the photoreceptors of Fig. 3 which use an amplitude, nonlinear heavily time-influenced code. These transducers operate on a pulse-code modulation characteristic much like that which would be anticipated for a leaky, resistance-condenser coupling decay characteristic. Frequency is very high initially and decays for constant illumination so that frequency increases, but not linearly, with intensity, and decays with time for any given intensity. In addition to this general pattern of response, some animal photoreceptors also give oppositely polarized responses so as to remark pointedly that the light is decreasing or going out; an event worthy of mention, even though in the negative sense. Some sensory transducers, such as those in the tongue concerned with measuring temperature, use their nerve frequency spectra doubly, once in an ascending sense, once in a descending, the range in use being determined by a separate signal.

It was only about fifteen years ago that it was discovered that "contrast" or accentuation of detailed changes in a one- or multi-dimensional field of transduced data could be greatly enhanced by systematic suppression in a readily specifiable manner by each region of every adjacent region. In fact, it was only in about 1945 that spatial, maximum, and minimum finding networks were first produced, temporal peak predictors having come only a little earlier.

Now it is found that a very similar system exists in optical, acoustic, and probably other sense-modality, biological transducer systems, so that much of the pattern finding is done before data reach the central nervous system.

Where there is ample signal energy to operate many transducers at substantial output, as in foveal bright-light vision, this detailed differential discrimination is common, while in threshold signal performance, adjacent units are often pooled to improve statistics. There is an interesting auditory case reported where noise heard in one ear can be used to subtract out coherent noise from noise plus signal in the other ear, to permit recognizing signal otherwise submerged below recognition. In this case, two ears cooperate in a field-subtractive type of selective filtering.

It is often stated that the sensory codes are essentially logarithmic in the sense that equal fractional increases in intensity of stimulation rather than absolute increases are required to evoke correspondingly detectable increases in response. While this generalization has been elevated to the status of a "law" and is often roughly true over a decade or two, it is usually noticeable that there is a threshold region where logarithmicity is not obeyed and that there is a bending over of even the logarithmically plotted line at extremely high intensities. In long-range senses, there will usually be one or more automatic-gain control systems operating to extend the working range. It will interest engineers and physicists to know that biological transducers often operate in pseudo-instability, much like that of the superregenerative radio receiver in the absence of signal, and share

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

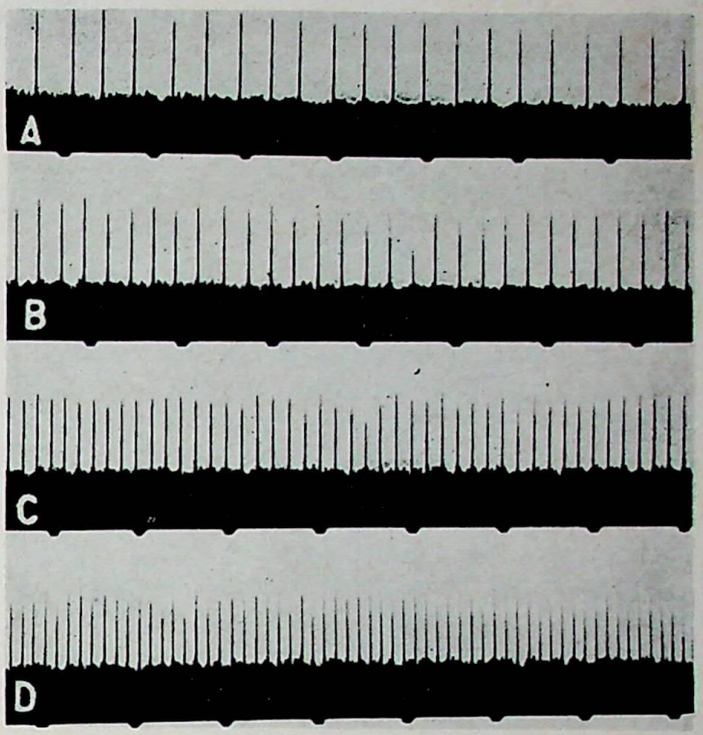

FIG. 2. Steady-state response of carotid sinus pressure transducer [from D. W. Bronk and G. Stella, Am. J. Physiol. **110**, 708 (1934)]. Data from original records of this figure are replotted in Fig. 2(a) as frequency *vs* pressure and in 2(b) as pulse interval *vs* pressure to emphazise importance of descriptive variable chosen in determining whether transducer is "linear" or "nonlinear."

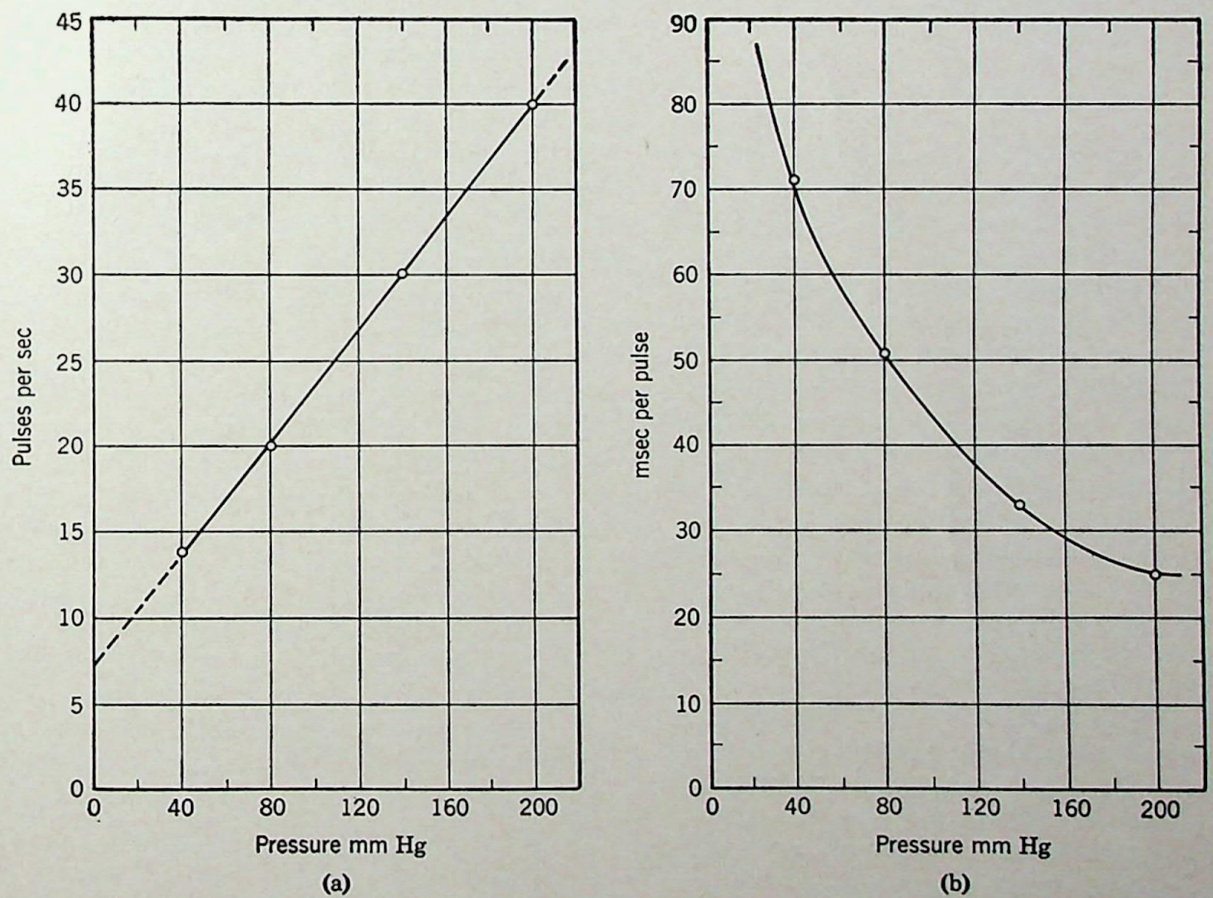

with the superregen, exceedingly high sensitivity near threshold and a tendency to lock onto any furnished rhythms. This point again deserves attention in connection with biological rhythmic processes, mentioned briefly in a later section.

It is perhaps safer to generalize that the sense-organ receptors which report in neural pulse-code modulations usually spread the available frequency band width roughly equally, in terms of importance, over the continuum of intensity time space in which they have to report, than it is to assume that they adhere to the Weber-Fechner ideal of true logarithmic response. The accuracy with which a sense organ can report over a given neural channel depends on the length of time in

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

FIG. 3. Record showing adaptation of a sense organ (photoreceptor). Stimulus was maintained at constant strength throughout, but interval between discharges steadily diminished. Signal indicates duration of stimulus application and time is in 0.2-sec intervals [record of H. K. Hartline cited from D. W. Bronk, Research Publs., Assoc. Research Nervous Mental Disease 15, 60–82 (1934)].

which it is allowed to report for a given discriminating mechanism. In general, the organism must have its report quickly, to avoid vacillatory behavior and sluggishness, yet reasonably accurately over a wide range. Thus, the neural codes turn out, for the narrow band width in frequency of pulses available, to be apt compromises between adequate and quick reporting.

One is familiar with the interestingly interchangeable way in which temporal and dimensional variables enter into the ordinary wave equation describing the progression of a pattern or wave of form f in space x and time t. Equations (1) show this relationship for one dimension:

$$\begin{aligned} F &= f(x-ut) \\ \partial F/\partial x &= f'(x-ut) \\ \partial F/\partial t &= -uf'(x-ut) \\ \partial V/\partial t &= -u\partial V/\partial x, \end{aligned} \qquad (1)$$

but it is easy to see how it can be generalized for more dimensions. There is a linear relationship between the position of a particular feature of the wave in space and the passage of time.

As a practical illustration of this equivalence, it is recognized that one frequently interchanges mentally the picture of a nerve action potential in the space-time world. Usually, one measures the potential variations at one place along the nerve as a function of time, but, without feeling any strain, one substitutes the picture of a wave of identical form progressing smoothly down the length of the nerve as a fixed pattern.

It will certainly be important to discover the mechanisms within neural net systems whereby such interchanges become easy and in which this kind of spatial-temporal pattern analysis can be accomplished with the available neuronal networks and fields. It must be expected in this seemingly messy and complicated situation that the usual biological optimization of representation will apply. One must expect near-logarithmic compression of past and future in this representation, and similarly one must expect that spatial features will be compressed in their representation as they become farther removed pattern-wise.

It is attractive to think of the neural net as a multi-dimensional analytical space in which distance along partially excited, short neuron extensions corresponds to temporal or spatial separation. Figure 4 shows how the phase velocity of an unpropagated nerve impulse goes on at near-normal speed in a passive axon, ready at any time to be reinforced into partial or full excitation by surrounding fields. A corresponding lower-velocity process easily can be anticipated for the short neuronal extensions in the central nervous system. In this connection, it is worth mentioning that application of readily available, distributed negative-resistance networks to *in vitro* nerve preparations allows exploration of this type of reinforcement.

Consider now some basic differences in approach to informational coding that must apply in biological studies as contrasted to the conventional engineering analysis of comparable systems. In an engineering system, the coding is generally superimposed from without by the machine design, so that there is real justification for dissociating the message from the code. In biological systems, the organism must create the complex of a code plus the messages in this code with which it will function.

It consequently becomes possible in the biological case to compare meaningfully the cost of a very elaborate code, in which a one- or two-bit message can tell one to record the complete contents of the *International Critical Tables* or of the *Encyclopedia Britannica*, with a very elaborate message in a simple code whereby one dictates one or the other of these works at length. In a genetic plus sensory-motor biological code complex, the organism seeks to minimize the combination of these two aspects.

Where there is to be very frequent repetition of similar messages, it becomes economical to devise fairly elaborate codes in which these messages can be shortened and sharpened in discrimination. For the very rare or

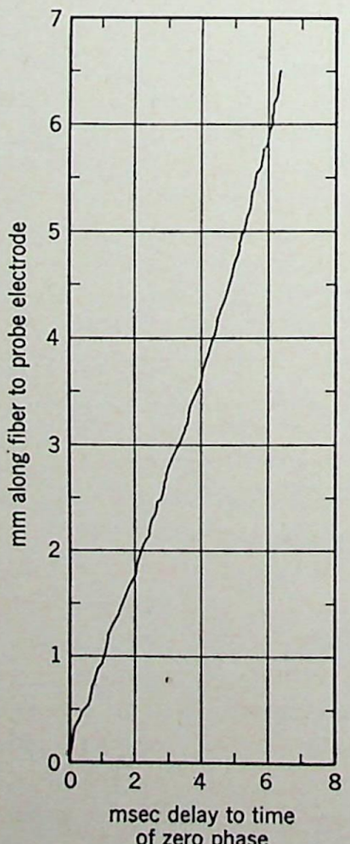

FIG. 4. Phase velocity of an unpropagated subthreshold sinusoidal wave in living axon. Data for squid axon, mean diameter 0.41 mm, 300 cps, 21°C. Phase velocity 10 meters/sec varying slightly with taper of fiber. Record is directly traced from machine drawn curve without smoothing.

one-time situations, it is economical to spell out the message in detailed, simple versatile code so long as it is not essential that the communication be completed in a very short time. Undoubtedly, some of the complex innate behavioral responses of lower and higher organisms have to be spelled out rather expensively in informational, genetic, and developmental symbols, as they are essential to survival and can be left only slightly sketchy.

It is an almost universal observation that, wherever a specific biological organic structure or organization functionally need not be built to a firm pattern, it will be left to grow as dictated by local circumstances. This relieves the informational system of that much superfluous burden. If it is necessary only that there be a substantial number of muscle fibers or connective-tissue units in a particular structure, it is very improbable that an exact number will be present, while it is equally certain that a nine-plus-two or a correspondingly important topological or chemically significant structure will be firmly designed-in. The informational design, once having been paid for genetically, will be used widely, thus minimizing the necessity for superfluous duplicate instruction. Biological organisms are probabilistic mechanisms, and their transducer codings reflect their willingness to take a statistical chance for survival in a risky world, especially if the odds are good. Where an item of information is especially important, it will usually be protected by replicate and nonreplicate redundancy. Such redundancy may become too expensive in some cases and may have to be sacrificed. This may be the case in some genetic transformations where cells and indeed the continuity of life for the organism become susceptible, briefly, to minor external mutational influences.

To avoid further digression from specific, experimentally accessible material, some of this free-wheeling thinking should be tied down to mechanisms and bits of analysis where there is a chance for specific solutions to specific problems. This set of analytical tools is still rather dull, but undoubtedly can be sharpened by use and extended to the effective analysis of the behavior of complex informational systems prevalent in animals.

As a starting point, consider some of the ways in which one can elaborate on the standard notion of a transfer function, which forms the usual stock-in-trade of the servo-engineer and electronic designer when he is trying to understand the behavior of control-communication and computer systems. The transfer function is usually represented as a black box into which a signal is put and out of which a related signal emerges. Normally, it is very tightly hemmed in with formal restrictions of allowable behavior not unrealistic, in most cases, for amplifiers and physical transducers, but usually very unbiological. As a result, many a biologist has been led down the garden path when he has attempted to use this concept, for, unlike the engineer, he is unable to make his system conform to the limitations of the model on which he bases his reasoning.

In the conventional cases, a transfer-function black box will be classed as either passive or active. If passive, it will require that there be put in as a signal all of the power required to actuate the box. It merely gives out a proportion of this power modified in some internally determined manner. Alternatively, it may have a local power source, as in an amplifier, and thus actively give an enlarged or otherwise modified more-powerful or effective output. In either case, the transfer box is usually assumed to be linear, except for special cases. The output is, thus, in terms of magnitude at any one frequency, a kind of phase-shifted, differently scaled replica of the input, although the relationship may be different at different frequencies. For the simple cases then, the performance of the box is adequately represented by describing the ratio of the output to the input as a function of frequency when driven by a sine-wave input variation. Output is presumed proportional to input, but is acknowledged to vary in relative magnitude and also to advance or retard in relative phase as a function of frequency. Consequently, for many purposes, a complex plane phase-amplitude plot of this transfer function is considered to convey adequately the behavior of the box.

Usually, the transfer-function box is used as a building block to construct functional block diagrams, often including loops like those in Fig. 5(a) to confer a measure of stability absent in a system that is not back-compared. Occasionally, a long, compound loop system like that of Fig. 5(b) will be used, because it has still greater stability than the simpler loop systems for a given available gain, but it is also more likely to become violently unstable if certain limits are exceeded.

Note that the feedahead loop illustrated in Fig. 5(c), while not intrinsically as stable as the feedback loop, has an advantage in being capable of introducing exactly compensatory control corrections without having infinite gain, whereas the feedback loop can only approach this ideal asymptotically. Feedahead can be combined with feedback to give a very desirable compound operation and is now gaining widespread acceptance in engineering applications.

Figure 6 illustrates a more typical, biological-transfer loop system which characteristically includes feedahead as well as feedback loops and almost always displays control parameter dependency upon signal. It should be emphasized that the traditional transfer-function box clearly carries with it the notion of signal pathways firmly fixed spatially; that is to say, there is some kind of a discrete-circuit-pathway diagram characteristic of the system. There may be switches, but these merely direct activities between alternative discrete pathways. Each transfer box is a point-to-point function; whatever enters, comes in from a source at a specifiable place in the diagrammatic model, and what comes out, comes out at a specified place or places. Such function dia-

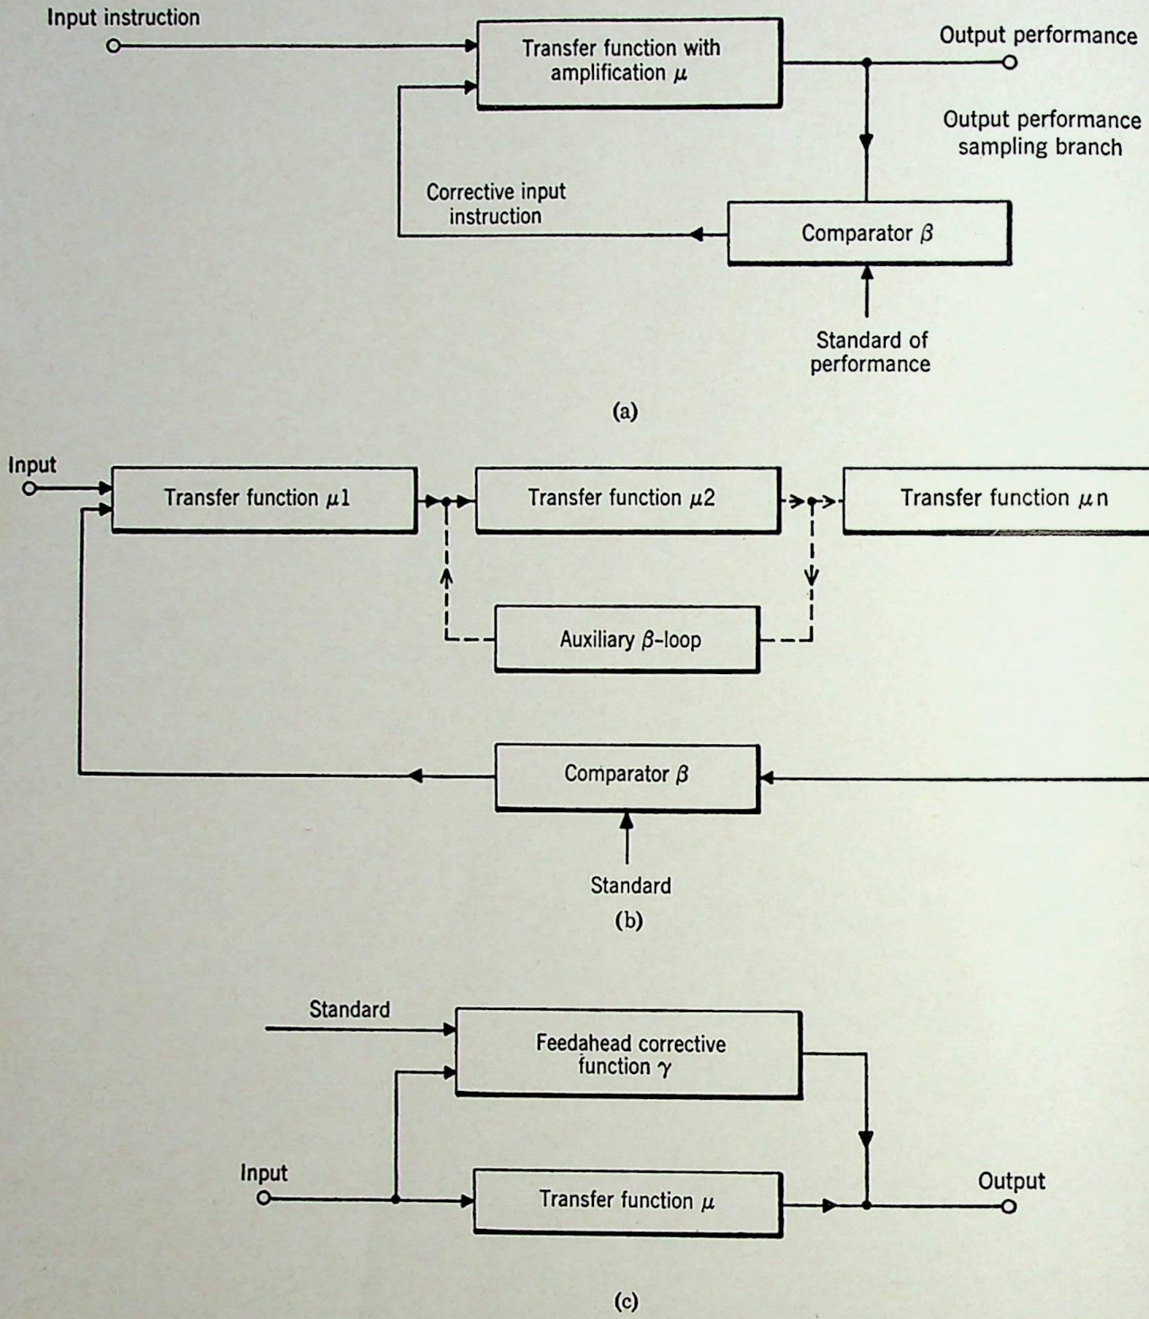

FIG. 5.

grams are hardly ever generalized to anything more complicated than a substantial interconnected block of such units, possibly with systems of switching arrayed in a logical, or occasionally in a statistically determined, pattern.

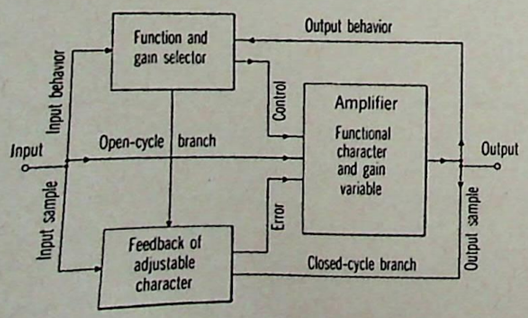

FIG. 6.

In all fairness, it should be pointed out that there is another and quite different set of packages, sometimes also called transfer functions, where the black box, instead of performing linear operations, now performs logical operations. These units, which figure prominently in digital-computer design, do something specific at an output when received signals in some predetermined logical set appear or fail to appear at its input. Typical signal sets might represent both, neither, or, *a* before *b*, time coincidence, equality, inequality, etc. These two quite different kinds of transfer-function black boxes can, in fact, be considered as epitomes, respectively, of

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

the functional organs of analogical-computer systems and of digital-computer systems.

Biology does not have *a priori* knowledge of a real difference between analogical and digital computers, and consequently is not hampered by this distinction. In fact, this difference is much more of the experimenter's making than it is an intrinsic property of the system being analyzed.

Digital systems are really those where enough probabilistic configurations of a system are lumped redundantly into a few significant categories to make the whole system approximate the all-or-nothing pattern characteristic of Aristotelian logical arguments. Analog systems are those where the available system configurations are dispersed over a significance range and, if numerous enough, resemble a value continuum. In the systems where energy redundancy is reduced to a minimum and nearly all of the available time band width of an information-handling system is utilized, the conventional thinking about digital and analog distinction becomes hazy and a new and more general type of analysis has to be substituted.

It is perhaps unfortunate that the term "analog system," which originally implied that one physical variable was being substituted for another for computational purposes, has come also to be used to describe any system utilizing a continuous range of variables in its operation. One is thus left with the anomaly that an analogical computer may be digital in makeup and that circuits performing quite direct control operations, and not particularly analogical physically to anything else, will be called analog-control systems.

It would be unfair to suggest that the modern engineer is not aware of the importance of nonlinear systems or to accuse him of thinking that digital and analogical systems are intrinsically different. He does, however, tend to build apparatus so as to conform essentially with one or the other of these because these analyses are familiar and easy, and he most likely has not been forced to cope with distributed transfer-function systems, particularly those that are highly re-entrant.

A little futher on, the behavior of two importantly different types of re-entrant systems is discussed, but first some places in biology where one can use fragments of available analyses are examined and embroidered on so as to make them more biological in their characteristics. In this way, they may be made applicable to the increasingly important cases where there are biological-transducer elements, particularly neural nets, which are simultaneously a continuum and a system of tight topological connectivities. This is a complicated way of saying that they are to an extent switchboard connected, but are simultaneously a system of diffuse field interactions. In this case, these field interactions mean simultaneously the chemical field, e.g., the hormonal or other chemical concentration-gradient field, and equally important, the electric field contributed by the surrounding active elements.

There will almost certainly be found in this complex an understanding of the efficient large-scale behavioral control of higher organisms, and mathematical techniques will have to be expanded to give facility and simplicity in handling systems which are hopelessly complex if treated as telephone exhanges gone berserk or soaked in electrically leaky saline.

One cannot offer more than an introduction to this kind of thinking at this time—first because it is complicated, and second because most of the answers are still unknown—but several extensions of ordinary field theory can be stated that are not presently being used in neural-net analysis.

There is one experimental and theoretical approach to this area that should be explored. This is the approach based on cardiac transfer-impedance theory, a technique used successfully in our laboratory in examining the superficially accessible action potentials of heart muscle, i.e., the spatial electrocardiogram. This theory, developed to handle biophysical heart data, will in all probability prove even more valuable in examining neural field interaction than it has in the purpose for which it was intended. Strangely enough, the key notion of reciprocity inherent in this theory was beautifully stated by Helmholtz, one of the early biophysicists, just about a century ago. It was not applied to biophysical problems until quite recently, and then it was introduced in another disguise.

The following demonstrates how the transfer-function notion can be spatialized. Consider Eq. (2), the definition of transfer impedance in its usual engineering form for a linear passive network:

$$\text{output voltage} \equiv \text{input current} \times \text{transfer impedance}. \tag{2}$$

Such a network may include any combination of capacitive, resistive, or inductive components that do not contribute external energy. For any combination of such linear components, one can determine the current applied between any two terminals in the system and the resulting potential difference developed between any other two terminals. The ratio of this voltage to the current will be dimensionally an impedance, and will have a constant value at any specific frequency if the system is linear.

Substitute for the passive circuit a biological tissue, nervous or otherwise, which is electrically at least approximately isotropic and linear although not necessarily homogeneous. These qualifications are included to avoid tensor notation with its complications when simple vector expressions are probably adequate for the present state of the art. In the low-frequency range which is of interest neurophysiologically, the brain approximates such a system of linear electrical components, except for microregions. Consequently, if any two points are picked as terminals through which to apply current, and any other two points are picked to

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

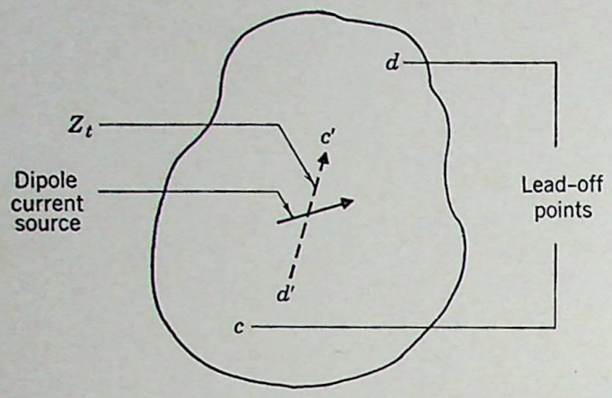

FIG. 7.

read off the potential difference, one finds that the voltage and current will be in a constant linear relationship which is formally described by their transfer-impedance ratio. If one now brings the two current points close together, they can be treated as a dipolar source-sink combination, and such a dipole is the kind of source that is encountered in biological tissue.

Because of the relatively short, length constants involved in muscle, nerve, and other biological current-generating systems, one can generally assume quite safely that source and sink are dipolar on a millimeter basis, and that macroscopic linearity prevails. In an isotropic medium, another generalization can be added. One can observe that, so long as the source dipole remains essentially in one region, it with its orientation becomes vectorial in the sense that the voltage transferred to a specified pair of terminals will obey a cosine relationship with respect to some specifiable preferred axis.

Thus, the dipole can be thought of as projecting itself, to a constant scale, on an effective axis not necessarily going through the recording points. In the diagram (Fig. 7), lead-off points c and d may be thought of as effectively represented by a vector on an axis $c'd'$ at the source. The magnitude of potential realized at the lead-off electrodes will be proportional to the magnitude of the current source times its distance of separation (i.e., its current dipole moment) multiplied by the cosine of the spatial angle between it and a reference line $c'd'$.

It is seen at once that this has become a vector dot product system and that the $c'd'$ reference has become a reference vector characteristic of a particular lead system. One, therefore, vectorializes Z in the alternating-current version of the Ohm's law relationship $E=IZ$. I becomes a dipole current moment (amperes times separation in centimeters). Z becomes a transfer impedance which is dimensionally ohms per centimeter in magnitude, but assumes the spatial attributes of a vector. Voltage, of course, remains a scalar quantity which is consistent with its representation as the scalar product of the transfer impedance with the current dipole moment.

$$V=\mathbf{I}_m\cdot\mathbf{Z}_t.$$

With Z vectorialized, one now has a function capable of being distributed spatially throughout a tissue system; that is to say, the transfer function has been successfully distributed in a neural field space. This function must necessarily be a vector-point function—that is, a quantity having specifiable magnitude and direction at every point throughout the space involved. By evaluating this function, one can characterize the interaction of a source anywhere in the field space with a receptive region anywhere else in the field, and can quantitatively predict their mutual electrical coupling.

It is at this point that Helmholtz's reciprocity theorem comes to bear. One must be rather careful in stating the theorem for a distributed medium, but it can be put in the following form. For any given system of lead-off electrodes, there is a spatial vector-point function which will relate the potential difference measured in this lead to the current dipole moment introduced anywhere in the medium in any orientation. The potential will be $V_t=\mathbf{I}_m\cdot\mathbf{Z}_t$ where V_t is the led-off voltage, $\mathbf{I}_m$ the dipole-source moment, and $\mathbf{Z}_t$ the transfer-impedance function. Upon applying an adaptation of the reciprocity relationship, it is found that the electric field or potential gradient $\mathbf{E}_t$ anywhere in the medium owing to introduction of current I into the former lead-off electrodes will be exactly $\mathbf{Z}_tI$, so that the spatial transfer-impedance function $\mathbf{Z}_t$ is identical in the two cases for any electrode or medium configuration.

What is the value of this $\mathbf{Z}_t$ function and its reciprocity property? In the first place, it permits one to predict, by applying currents to finite leads and measuring the resulting potential distribution with micro-electrodes, what potential will be set up as a field by microsources such as neurons. Model measurements and *in vivo* measurements of transfer impedances by the reciprocal method now become feasible and valuable. While these measurements have not yet been done to any great extent on brain tissues, it is possible to illustrate the kind of results to be expected by comparison with results obtained in the electrocardiographic field.

Figure 8 is an example of such an application where a set of orthogonal leads was developed experimentally by linear combination of partial derivatives of the transfer-impedance function. Knowing that transfer-impedance functions must obey the superposition theorem as well as the reciprocity rule, it was possible to develop leads sensitive, for practical purposes, *only* to sagittal, vertical, or horizontal sources of current irrespective of position within the heart tissue.

Inversely, it was possible to show theoretically and experimentally that fields from neurons in certain configurations can add up so as to be quite strongly concentrated at substantial distances from the sources, while in other cases they die out even more rapidly than the inverse cube law. Measurements of transfer-impedance fields via models give surprising insight into such complicated field patterns. The analysis indeed

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

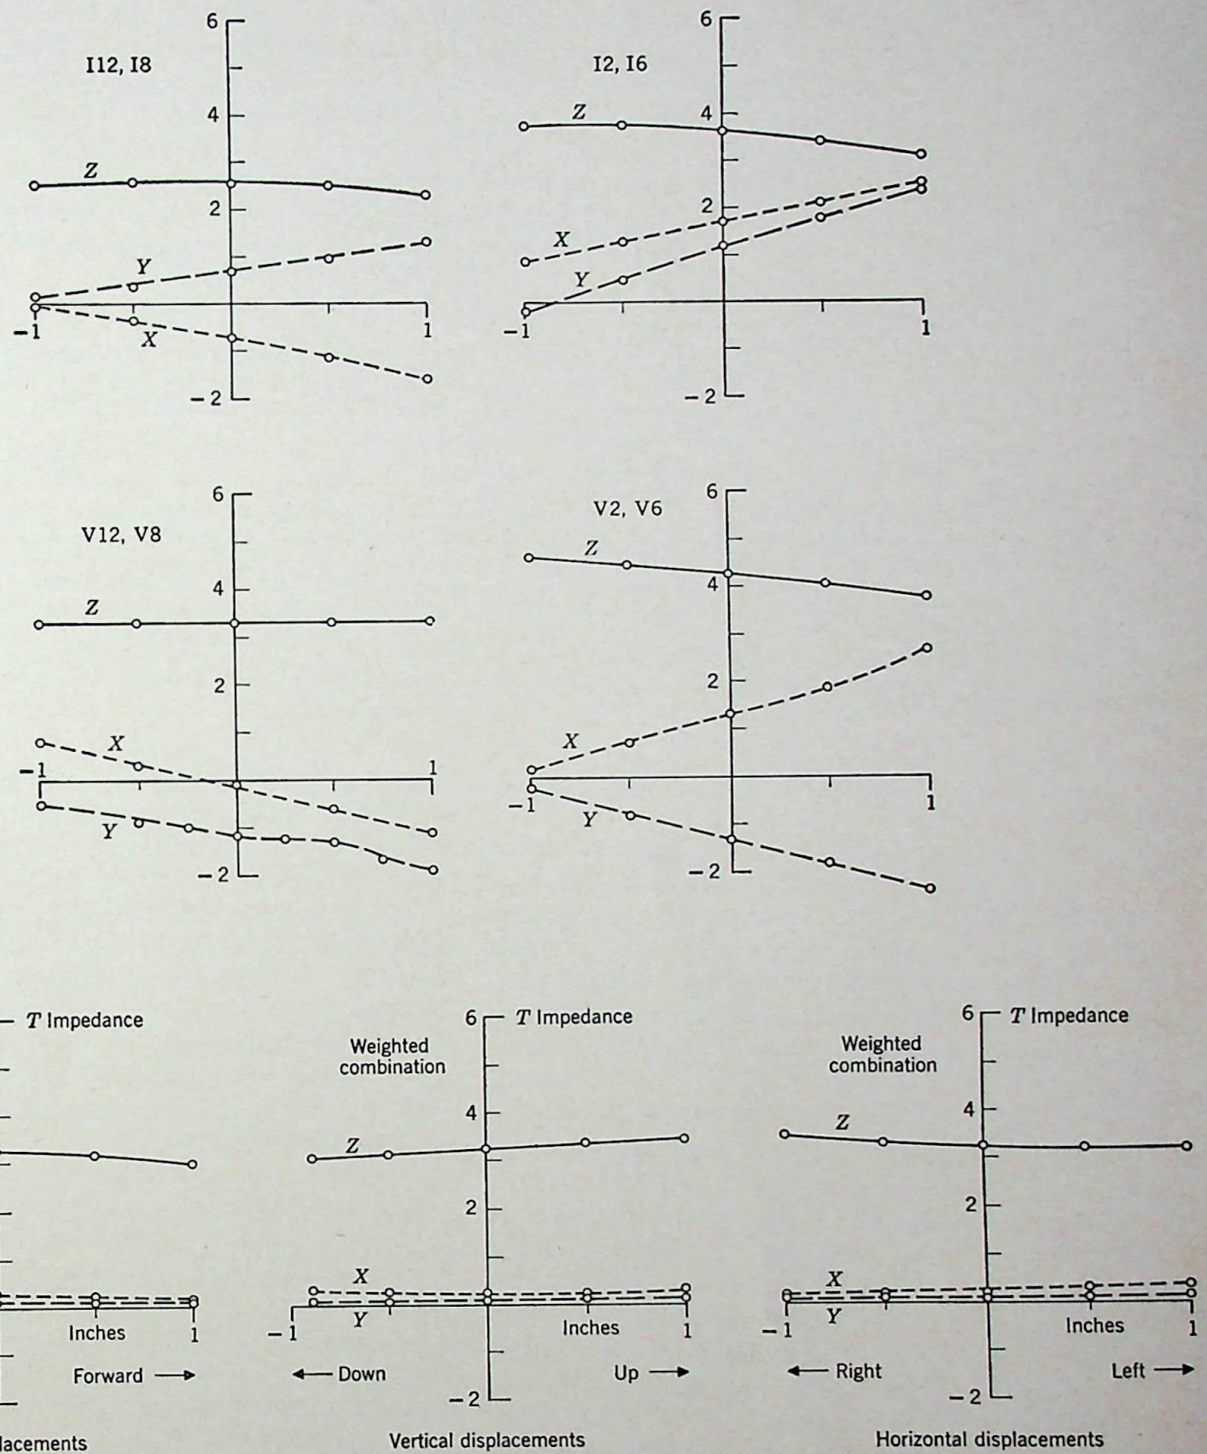

FIG. 8. Orthogonalization of transfer impedance fields. For any tissue system to which a specified lead system has been applied, there is a characteristic associated transfer-impedance field which takes the form of a continuous spatial vector-point function. By examining the principal partial derivatives of this vector function for several different lead systems applied to the same tissue, it is usually possible to devise weighted combinations of leads which yield nearly orthogonal functions in a finite source region so that potentials picked up from the combined leads report uniformly and orthogonally on sources in the corrected region, and stimuli applied through the leads stimulate the source region uniformly and in a constant known direction. Alternatively, highly distorting leads can be devised which will record and stimulate selectively. The patterns shown here as examples were developed to yield a uniform sagittal, or front to back, lead for the human chest to be used in electrocardiography. Ideally, the transfer impedance should be large and constant in Z and should have negligible X and Y contamination.

resembles a kind of degenerate directional antenna design procedure.

Spatial transfer-function analysis is very attractive in studying field stimulation of neurons, for it gives an intuitive insight into the remarkable time sensitivity of stimulation patterns. If one remembers that the conduction time at constant velocity is equivalent to distance, and that the inverse equivalence is also valid, then one has in a neural net a most interesting mechanism for the spatial-temporal localization of a pattern,

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

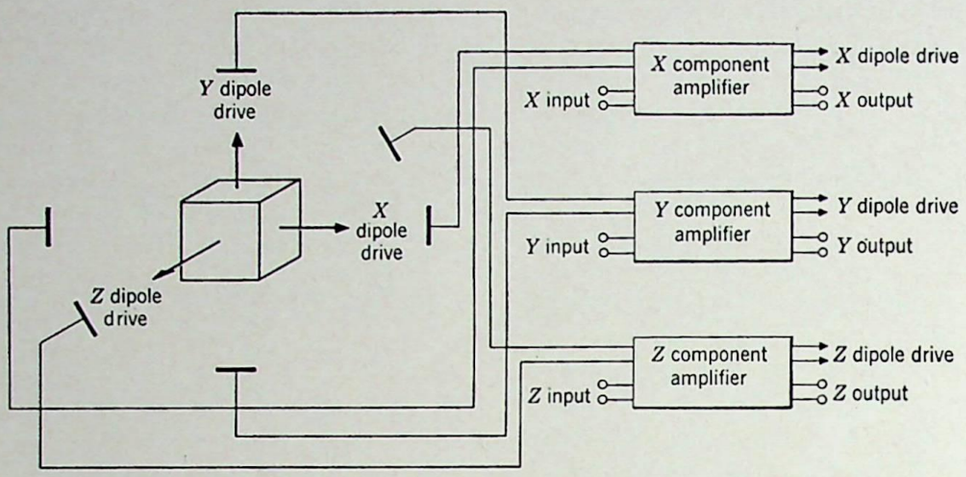

FIG. 9. System for automatic synthesis of equivalent concentrated dipole-current moment sources. A conductive model of the tissue system is fitted with a lead system equivalent to that on the experimental animal or person, and a vector dipole source is installed in the model at the chosen locus for which the equivalent vector source is to be calculated. A system of high gain amplifiers is looped around the model lead system to the dipole, and the amplified signal from the biological subject is inserted as a forcing function. In order to maintain all the amplifier inputs at near-zero potential simultaneously, the amplifier system must generate a dipole source which just cancels the complex of lead potentials and thus one which duplicates, in a negative sense, the desired source. The solution is, of course, unique only for a specified dipole source locus and electrode configuration as can be demonstrated by rearranging the electrodes on model and subject or by moving the dipole source about in the model and noting the continually altering resultant pattern of source dipole moment.

and hence an ideal medium for distributed probabilistic field effects.

Another closely related extension of transfer-function analysis was introduced by Burger in Holland a few years ago. In this approach, an image space is developed as a complementary space to the real field space. In the image space, vectorial summation of superimposed field ontributions becomes beautifully simple, even though orking out the shape of the image space is a more omplicated process.

There is a very interesting feedback method for synthesizing spatial excitation sources (Fig .9). If one builds a conductive three-dimensional scaled model of a tissue system and immerses in it an orthogonal, triple dipolar source at a place corresponding to a supposed bioelectric source, this artificial source will excite a transfer-impedance pattern similar to that of the original living system. If each component of the dipole is fed from a high-gain amplifier which is fed, in turn, from one of a set of three reasonably orthogonal lead sets corresponding to the dipole orientation, the system then becomes an automatic synthesizer of excitation sources in terms of the actual picked up potential. Explained in behavioristic terms, the feedback system tries constantly to null itself in all directions simultaneously and can do so only by creating a source equivalent to the real but inaccessible one. To what extent this general scheme can be extended beyond three loops to synthesize more complex sources, and to what extent noise can be used as a tracer to establish source localization, are not yet known, but this approach seems to be very promising.

Space does not permit amplification of many additional aspects of the biological-transducer function which are of great importance, but the transductive aspects of animal "orientation" behavior must not be totally omitted. Animal orientation includes especially the navigational processes whereby an organism "steers" itself toward a desirable goal literally as well as figuratively. It is well known that pigeons home, that fish almost unerringly find their native stream after months at sea, that birds migrate to very specific targets, and that bees communicate to their fellows the range and azimuth of food depots. Birds are even believed to utilize astronavigation, as suggested by recent experiments. All of these processes are biological-transducer problems at a higher level and ought to be investigated on this basis, as well as by the traditional types of experiment. If a moth knows which way to fly to find another moth a kilometer away, this is a transduction and coding problem, and one should seek not only the sensory transducers involved but also the transfer functions describing the reduction of massive sensory data to net decisive instructions for a flight plan.

Another set of biophysical phenomena classed as animal orientation is the family of rhythmic or oscillatory processes found in almost all biological organisms for which one has yet to discover a biophysical mechanism. It is well known that animals and plants exhibit strongly rhythmic properties with periods ranging from 1 or 2 msec in the case of some nerve processes to periods of a month, a year, or even several years in other cases. These rhythmic processes often have very nearly, but not exactly, a one-day period. Again, the period may coincide with the succession of high and low tides in a particular place, with the lunar month, or with the terrestrial year. While these periodicities are related to those of the normal environment, many of them persist for many cycles in experiments where the organism is carefully shielded from all known environmental clues to these periods.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Some of the simple biorhythms like the cricket chirping rate have a reasonable chemical-process temperature coefficient but others have an almost exactly zero temperature coefficient. Some of these temperature-independent periodicities can be shifted in phase by a systemic shock such as dunking in cold water. Others can be "pulled," as a crystal oscillator can be pulled slightly off frequency by coupling to another resonator of similar frequency. None of the basic oscillatory mechanisms has been identified nor has an adequate hypothetical master oscillator been devised which will conform with experimentally determined properties of these natural oscillations.

Crabs change color on a tidal-periodic basis; some bacteria luminesce periodically on the basis of when it should be day or night; some flies emerge from pupae on an integral diurnal but not fixed illumination-period basis; some poisons change toxicity on a diurnal basis; and cilia beat rhythmically. No one seems to have found the transducer mechanisms by which these rhythms are loosely but adequately coupled to the environment. Surely, there should be a search for mechanisms of periodicity hinted at by the three major classes of physical oscillating systems. In any case, one should be embarrassed to have failed completely in turning up even approximate explanations for these phenomena that are of undoubted prime biological importance at every level from the intracellular to that of the entire organism.

Finally, there are two items referred to earlier—bivalent codes and hierachical re-entrant control systems. It is evident that biological control systems are, in general, organized in a series of semi-autonomous hierarchically arranged levels where each subordinate system left to itself will achieve a more primitive, less flexible, but still effectual, type of homeostatic control. Single isolated cells get on somehow in tissue culture, and a heart will beat in parts if it fails to receive coordinating excitations from its pacemaker. What are the mechanisms and the general control principles whereby several, often contradictory, courses of motor behavior are coordinated so as to remain unified and influenced by the several operator controls, yet not uselessly vacillatory or indecisive in action? Evidently, whole patterns of feedback and feedahead control are coordinatedly included or excluded from taking dominance in effective control. What does an animal do when exposed to unfamiliar, conflicting sensory information such as might originate from a minor malfunction of one of its transducer mechanisms? Generally, it chooses one set of the feasible interpretations of the available data and ignores incompatible parts of the others. Sometimes, as in the case of Von Holst's fishes (where the fish, used to having 1*g* gravity downward and light from above, are experimentally exposed to light from the side and to a centrifugally increased apparent *g*), they seek a weighted compromise. Very seldom do they fail completely, as do our rockets, from some single small malfunction.

In summary, one may conclude that there is at present no unified, formally manipulable system in the biophysical sciences for examining and describing systematically the functional characteristics of biological transducers and for studying their aggregate behavior when combined into functional ensembles. There is ample mathematical experience in the engineering fields to permit a start in this direction, but existing techniques fall far short of adequacy, and it is certain that new, uniquely biological theory and techniques for transductive-function manipulation and code specification will have to be developed.

Initiation of Nerve Impulses in Receptor and Central Neurons

THEODORE HOLMES BULLOCK

Department of Zoology, University of California, Los Angeles 24, California

THE objective of this paper is twofold: to point out some of the problems which represent the present state of physiological analysis of some sense organs as detectors and transducers, and to point out a current view of the complex chain of events between transducing a stimulus and initiating a nerve impulse. It will be argued that this chain is similar in receptor and central neurons and that information about either one is relevant to the other.

Biophysicists long have been interested in sensory receptors, since they present in such a conspicuous form the conversion of physical events of the inanimate world into physiological events in the organism.[1] Some of the best-known achievements of biophysical science lie in this realm. Indeed, a vast literature exists on sensory capacities, analysis of the parameters of reception, and quantitative description of the subvarieties of unit receptors within modalities[2]. There continue to appear in the literature new kinds of receptors physiologically identified, and there remains a host of histologically known sense organs and diffuse receptors, differentiated visibly but not yet defined physiologically (e.g., pectines of scorpions, esthetes of chitons, osphradia of snails and clams, etc.).

This situation, virtually unique among organ systems, is not surprising if one thinks of behavior as the principal attribute in which the great wealth of animal types is differentiated, if one ascribes behavior to differentiation in the central nervous system and remembers the intimate and perhaps causal correlation between differentiation in the central nervous system and that in the sense organs. One has learned to expect startling discoveries in each new batch of journals—polarized-light detection, wind-speed indicators, gyroscopic-deflection sensing, infrared directional devices, olfactory separation of optical isomers, hydrostatic-pressure detection in supposedly gas-free organisms, ultrasound reception—not to speak of systems achieving a complex degree of analysis of signals such as the ultrasonic-pulse-reflection analysis in bats, the amplitude-modulation frequency analysis of the ears of crickets, the integration of proprioceptive information in the strike of a praying mantis, and of we do not know what information in many cases such as orientation of fish to turbulence and to other unseen fish. This list furthermore omits mention of eyes of various kinds and their fantastic achievements, of which Hartline writes (p. 515).

Since a systematic survey is patently impossible, I offer here only a small selection of some recent instances of progress in the *identification and characterization of receptors* with respect to their capacities and properties. A closer look is taken later at the *parameters of impulse initiation.*

ELECTRORECEPTORS

Recent work[3–6] has opened up a new sensory modality in the sensitivity to normally occurring electric fields, found in many species of fish of at least three unrelated families, the Gymnotidae, the Gymnarchidae, and the Mormyridae (Fig. 1). These fish have electric organs which emit pulses of low voltage—of the order of 1 v—in some species in brief, low-frequency bursts, and in other species continuously, hour after hour, with characteristic frequencies and pulse form and duration, diagnostic of the species (Fig. 2). The frequencies commonly lie between 60 and 400/sec, but in some cases exceed 1000/sec. The pulse duration—from the whole animal, representing activity of many electroplates—ranges from 10 msec to less than 0.2 msec. What is significant for us is that the behavioral evidence clearly shows in some species the use of these signals in orientation with respect to objects, apertures, and other emitting fish in the immediate environment. Clearly, the fish detects alterations in the pattern of the electric field in the water surrounding it (Fig. 3). Marked signs of agitation are elicited by a wire brought within range or by the discharges of other fish. Conditioned-reflex experiments show the ability to detect the presence of a stationary magnet outside the aquarium and to discriminate between conductors and nonconductors in the aquarium. The fish respond to the movement of a small electrostatic charge such as that produced by combing one's hair with a vulcanite comb. Sensitivity to imposed electric currents has been known, but what is of interest for us is the demonstration that a normally developed sensibility exists which is apparently used in nature to detect and to analyze in a complex way naturally occurring electric fields.

The sense organ is presumably the lateral line, heretofore regarded as a special form of mechanoreceptor. We will have to make room in our lists of modalities for a new category—electroreceptors. It is perhaps more curious that this modality is not more widespread. Muscle-action potentials can be recorded in the water at some distance from fish as well as from other animals, but so far the tests outlined in the foregoing, when applied to fish of other families than these three, have

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

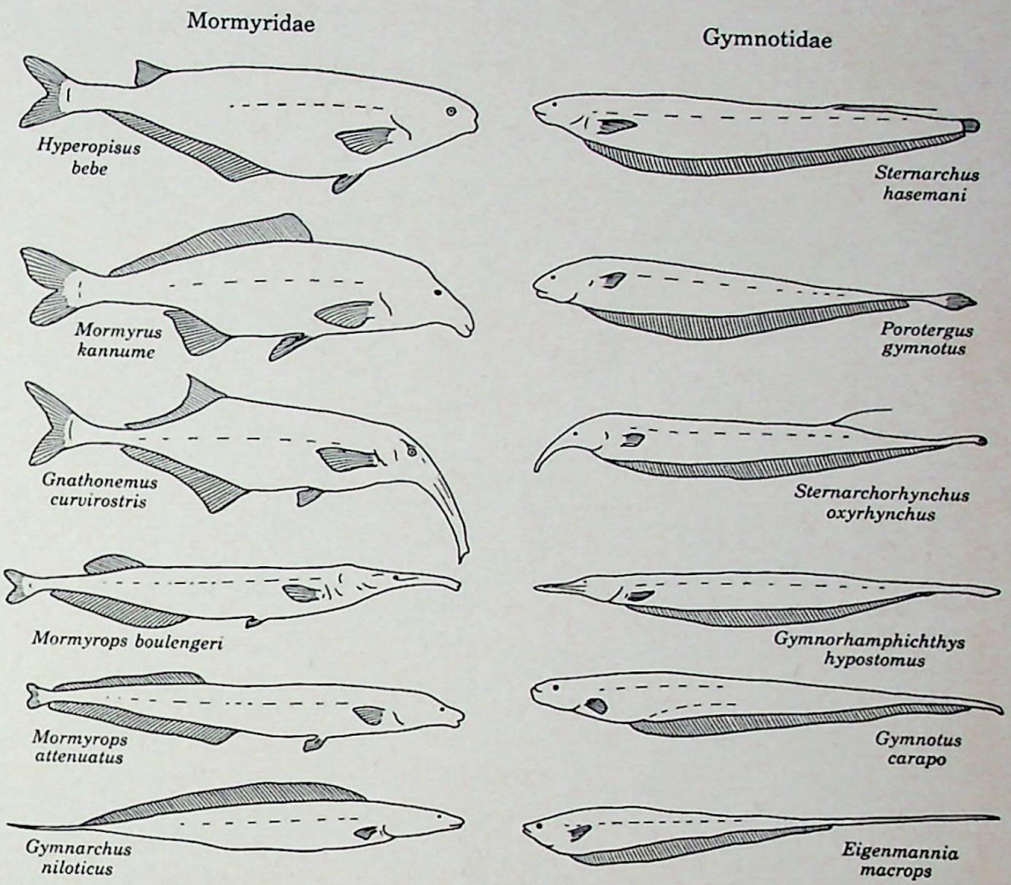

FIG. 1. Examples of continuously discharging, low-voltage electric fish. Representatives of the Mormyridae, Gymnotidae, and Gymnarchidae [from H. W. Lissman, J. Exptl. Biol. 35, 156 (1958)].

indicated no such sensitivity (with the possible exception of the *Siluridae*). One may conjecture that it is perhaps not so much the deficiency in peripheral sensibility as the lack of central apparatus for making use of the signals, which distinguishes the ordinary from the electric fish. All electric fish share, among other things, the enormous development of the valvulae cerebelli, the so-called mormyro-cerebellum.

The sensitivity of the receptor has not been measured directly but Lissman and Machin[3] have calculated the intensities of the electric fields which are effective in altering behavior, for example in conditioned response tests to electrostatic charges or magnets outside the aquarium. The field in the water around the fish must be changed by about 0.003 μv/mm at threshold, in *Gymnarchus niloticus*. This corresponds to a current through the fish of 2×10^{-5} μA/cm^2, some hundred thousand times smaller than a still subthreshold stimulus current density across the membrane of a squid axon (2 mv across 10^3 ohms/cm^2). The problem of the possible meaning of such high sensitivity to electrical events already has been raised by Terzuolo and Bullock.[7] Our evidence suggests that even in ordinary nerve cells the sensitivity, while not nearly as high as in these electroreceptors, is several orders of magnitude higher than the usually recognized threshold changes of 10 to 20 mv required to excite a silent nerve fiber. In the first place, this high sensitivity is manifested only as an alteration of frequency of an already discharging cell. In the next place, to be sensitive to minute changes in membrane potential, both the critical potential for spike initiation and the rate of rise of the prepotential must be extraordinarily stable—and must be localized in a limited part of the cell. The basic problem of high electrical field sensitivity—of special interest because it may be the one case where one does not need to search for a transducing mechanism as we do in photoreceptors, mechanoreceptors, etc.,—is the matter of *stability*. What are the requirements in terms of stability of the threshold and of the prepotential such that a given channel can provide a useful signal within a reasonable time

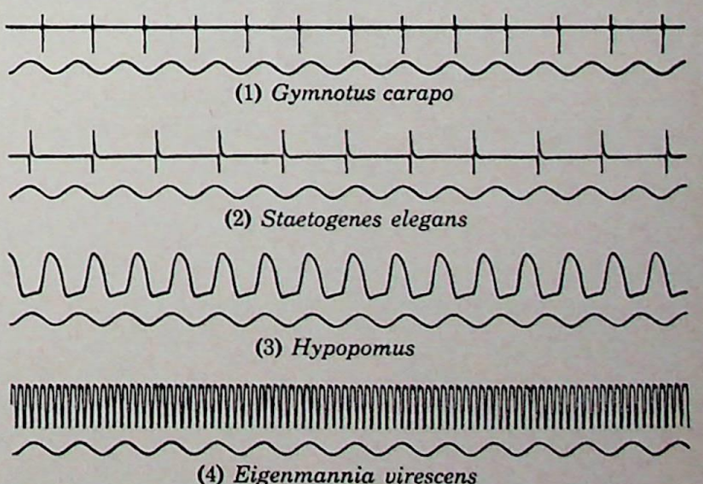

FIG. 2. Examples of types of electric pulses produced by four species of the Gymnotidae. Both pulse duration and pulse frequency are different and characteristic for each species. The fish are continuously discharging day and night. Time marker 50 cps [from H. W. Lissman, J. Exptl. Biol. 35, 156 (1958)].

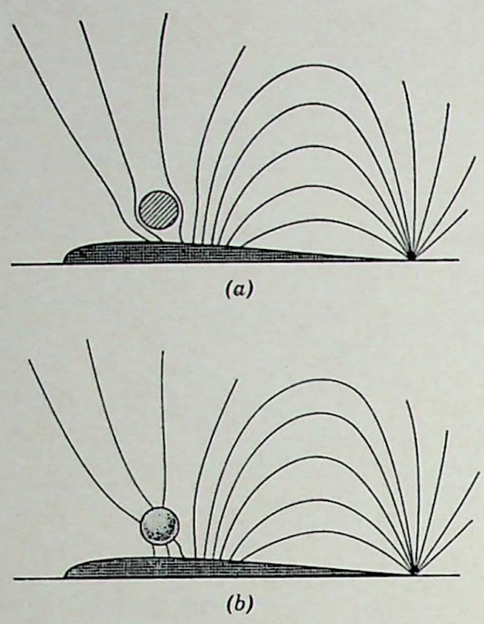

FIG. 3. The influence of objects upon the electric field around a fish. (a) An object of low conductivity, and (b) one of high conductivity. The fish detects the distortion of the field and reacts to both classes of objects [from H. W. Lissman and K. E. Machin, J. Exptl. Biol. 35, 451 (1958)].

(e.g., 1 sec)? At another level is the important problem of whether or not the high electric field sensitivity in the modulation of ongoing discharge plays a role in normal situations in the nervous system. If so, it permits effects not only of changes in electric fields normally present but also of changes in the chemical milieu which may act through the same mechanism, by changing the frequency of the spontaneous discharge for a given membrane potential at the critical locus.

MECHANORECEPTORS

Turning to the realm of mechanoreceptors, an attractive problem exists in the wide variety of arthropod hair-like exoskeletal projections (Fig. 4), each of which receives a single distal process of a primary sensory neuron and is specialized for signaling deflection of the hair in a certain direction.[8–10] In the lobster statocyst (an equilibrium sense organ where this is especially clear and for which recent analyses have been made), there are several specific types of hairs, differentiated for sensitivity to movement in one or another direction, or for sensitivity to a maintained position in one or another plane, or for sensitivity to vibration. Since the stimulus seems likely to be limited to a very restricted region—namely, the point of articulation of the hair near its base—one is faced with the general problem of transducing a mechanical event into a physiological one in perhaps a more simple and discrete form than in the more familiar mechanoreceptors such as stretch, touch, and auditory organs. Although the sensitivity must be high in terms of displacement, it cannot be estimated accurately, owing to the fact that, at the base of the long hair, where the relative movement that must act as a stimulus occurs, the mechanical disadvantage is

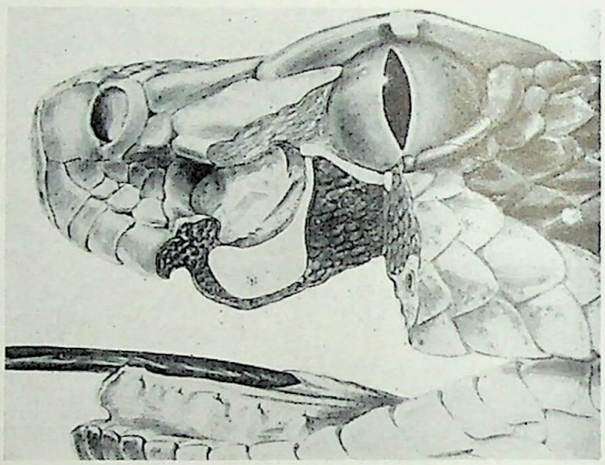

FIG. 5. The infrared sensitive facial-pit organ of rattlesnakes, *Crotalus*. Here, a wedge has been removed to show the deep pit and the sensitive surface—the thin membrane at its back (shown crinkled but normally smooth), with an air chamber both in front and behind it. This membrane, 10 to 15 μ thick, is heavily innervated and vascular [from T. H. Bullock and F. P. J. Diecke, J. Physiol. 134, 47 (1956)].

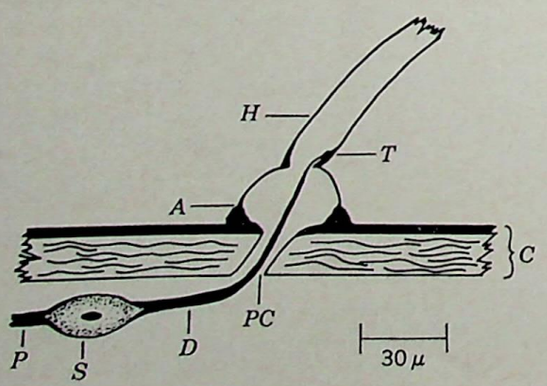

FIG. 4. Diagram of arthropod sensory exoskeletal hair of the type innervated by a single primary sensory neuron. The distal process of the sense cell ends near the region of articulation of the hair [from M. J. Cohen and S. Dijkgraaf in *The Physiology of Crustacea*, T. H. Waterman, editor (Academic Press, Inc., New York) (to be published)].

maximal and the small threshold movements of the tip of the hair must be reduced enormously in absolute magnitude. Fundamental questions remain, regarding the *ultrastructure and the local events* in the region of the mechanical deformation of the sensory nerve ending.

As an example of the specialization of which arthropod mechanoreceptors are capable, Burkhardt and Schneider[11] have found that units in the Johnston organ of the antenna of flies (*Calliphora*) are hardly less sensitive than the human ear to sound frequencies between 150 and 250 cps, the range of the wing-beat frequency. Even beyond this range the units follow the sound frequency faithfully, giving the animal sensory information corresponding to each wing beat with a delay of only about 1 msec. The speed of flight is controlled by this sense organ. For some other recent studies in this area, see references 12–17.

FIG. 6. The sensory endings in the pit-membrane of a rattlesnake. This is a faithful drawing from a silver-stained whole mount of the 10 to 15 μ membrane. The nerve fibers end freely in palmate expansions with branching processes. 500 to 1500 such expanded endings occur per mm^2. Apparently all are of one functional type—so-called warm receptors. Width of picture, 150 μ [from T. H. Bullock and S. W. Fox, Quart. J. Microscop. Sci. 98, 219 (1957)].

TEMPERATURE RECEPTORS

Referring briefly to temperature receptors, there is some information regarding the extraordinarily developed long-infrared-radiation detectors found in rattlesnakes and other pit vipers in the thin membrane at the base of the facial pit (Figs. 5 and 6)[18,19]. This structure, richly provided with a special form of free nerve ending and specialized in other ways—such as, for the directional estimation of radiant sources—responds to very small doses, of the order of 10^{-11} small calories in $\frac{1}{10}$ sec on the area of the terminal ramification of one nerve fiber (2000 μ^2). The evidence indicates that this response is due to the change in temperature of the tissue, which both by indirect and direct methods is estimated to be of the order of 0.001°C, close to the value already found for the human.[20] Expressed as Q_{10}, the frequency of nerve impulses in a single fiber increases with temperature with a Q_{10} of about 10^{30}, a figure which offers considerable room for speculation about *high amplification with preservation of reasonable stability* (Fig. 7). Much more could be said about each of these cases with respect to physiological properties and characteristics of response. It is the purpose here only to call attention to the variety of opportunities and problems presented by a few recently studied receptors.

CHEMORECEPTORS

In the area of chemoreceptors, I choose only two recent reports. Hodgson and Roeder[21] have discovered labellar hairs in various flies in which two primary sensory neurons send distal processes to the chemoreceptive area at the tip of the hair. These two neurons have different modes of sensitivity: one responds only to sugars; the other to salts, acids, and alcohols. Not only is this preparation of interest because of the opportunity for the physiological *study of unit receptors of different chemical specificity*, but also, because of its additional sensitivity to mechanical stimuli and to tem-

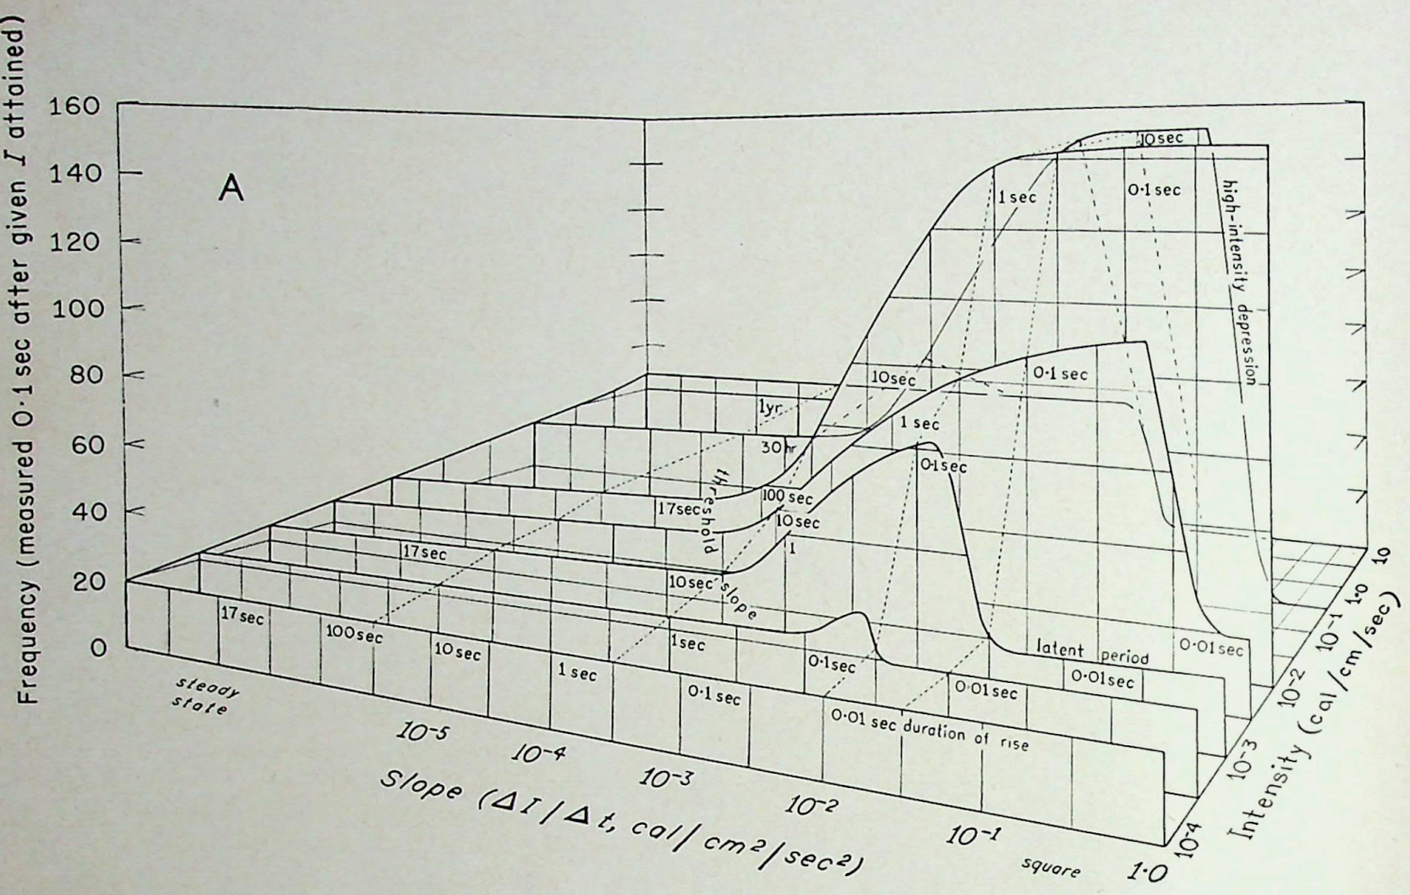

FIG. 7. Response of typical receptor unit of rattlesnake infrared sense organ, measured as nerve impulse frequency at different rates of increase of radiation and at different flux levels [from T. H. Bullock and F. P. J. Diecke, J. Physiol. 134, 47 (1956)].

perature changes as small as $\frac{1}{10}$°C, it presents in a clear form the general *problem of analyzing the world through receptors which are not unambiguously* detecting one aspect of the environment only. Furthermore, these labellar hairs are remarkable, as shown by Dethier,[22] in that complete behavioral rejection or acceptance responses of the intact animal occur to stimulation by a microdrop which can reach only one single sensory neuron. Schneider[23] has discovered an electrophysiological response in the antennae of silk moths (*Bombyx mori*) in the males only, which is highly specific apparently to the naturally occurring odorous material produced by the female. This odorous material attracts the males from great distances. In microelectrode records from the isolated antenna, picked up extracellularly from many units, Schneider finds a slow wave of several millivolts which is negative for some substances and positive for others. Spikes are superimposed preferentially on the negative phase of the electroantennogram. As in the preceding case, there is here an apparently peripheral filtering of the normally specific stimulus, which filtering is achieved by a *specific chemical sensitivity* of a receptor and again one is faced with high sensitivity. de Vries[24] has calculated that at threshold there are far fewer stimulating molecules impinging upon the sensory epithelium in man than there are olfactory receptor cells in the same area.

ABSOLUTE RECEPTION

Extending the remarks by Rosenblith (p. 485), it is highly desirable that further attention be given the problems raised by the sensory reception of absolute stimulus values as opposed to reception where comparison can be made by the receptors with a status in the recent past. Besides body temperature, blood pressure, and the like in man, there are many other indications of reception of values which may be called absolute, e.g., preferred temperatures in cold blooded animals, levels of light which day after day induce a given response, CO_2 concentration reactions, and pitch recognition. Even in many humans lacking phenomenal ability, the cross-modality subjective-intensity matching and many psychophysical phenomena illustrate scales not dependent upon relative stimulation as measured against a just-preceding level. One faces here the problem of stability and drift correction—not only the control loops, intra- or inter-cellular, but the standard of reference for detecting error.

SEQUENCE OF LABILE COUPLINGS LEADING TO IMPULSE INITIATION

Consider now what makes a neuron fire—namely, the specification of the distinguishable processes within the neuron leading to an explosive firing of a propagated all-or-none nerve impulse. The interesting conclusion

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

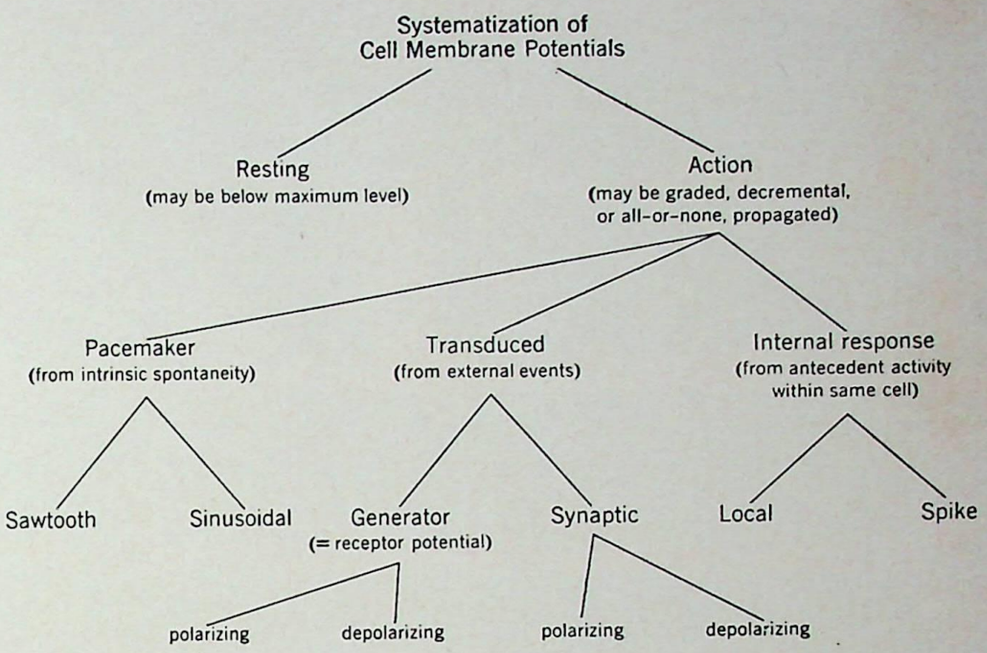

FIG. 8. The types of nerve cell membrane potentials.

permitted by current evidence is that *the determination of firing is not merely the build-up of an adequate stimulus* or its transduced and amplified resultant to a critical level, the threshold, but rather it is a sequence of labile couplings between graded (analog) events, each occurring in a limited fraction of the neuron. Normal firing is preceded by a series of steps, with alternative pathways. The several processes are separate, partly in space and partly in time, but causally are interconnected. Some of these processes are reflected in membrane-potential changes and some are not.

The *processes reflected in the membrane potential* include slow shifts of the average membrane potential, synaptic, generator, local, and pacemaker potentials. Figure 8 makes it clear that generator and synaptic potentials are parallel types of transduced potentials representing amplified response to external events whether from a presynaptic cell, from a non-nervous sense cell, or from the external environment. It also points out that both of these classes of response may occur either in polarizing or depolarizing directions. Depolarizing responses are commonly called excitatory because they are likely to increase the probability of firing. Polarizing, or as they are sometimes called, hyperpolarizing, responses generally decrease the probability of firing and are called inhibitory.

First among the processes which determine the initiation of impulses in receptor and central neurons, we should list what is actually no doubt a whole class of different and complex processes by which the level of the so-called *resting potential* is under the influence of the milieu and nonspecific agents (nonspecific to a given cell, though possibly specific to a cell type). Hormones, inorganic and organic constituents of the medium, deformation of the cell (even in neurons other than specific mechanoreceptors), and other factors are known to have some effects, although in most cases their importance in normal physiology cannot be assessed yet. In addition to these, we now can recognize as an important class the general shift in membrane-potential level accomplished through specific nervous pathways. For example, Otani and Bullock[25] found in certain cells of the 9-celled cardiac ganglion of lobsters that certain presynaptic fibers exert an influence, but without any discrete synaptic potentials. With repetitive stimulation they cause a slow, smooth shift of membrane potential (Fig. 9) as seen by an intracellular electrode in the soma. Terzuolo[26] has shown that certain neurons in the spinal cord of the cat similarly respond to stimulation of certain parts of the cerebellum by a shift of membrane potential level. This absence of discrete synaptic potentials even with a small number of incoming pathways possibly means that the main factor in determining the slow, smooth shift of potential is the distance of the synapses from the soma. If the distance is considerable, individual deflections would be smoothed out by the spread through leaky cables. But, if one believes that the membrane potential level at the basis of the axon or some such limited locus is crucial to the determination of cell firing, any such properties of the dendrites and soma—such as the electrotonic conduction of slow potential changes, the smoothing out of potential changes, or the discrimination against rapid deflections—would be of decisive importance in spreading the influence of the decrementally propagating activity of the much-branched dendritic processes to the region in which the spike originates. This may be one reason for having long dendrites. Among sensory neurons, there are many whose distal process divides to supply a considerable number of receptor regions of the periphery (Fig. 10, from the work of Meyer[27]) and in which the histology is suggestive that these loci are not alternative sources of full-fledged impulses but may, in some cases, make graded contributions to the probability of an impulse arising at some

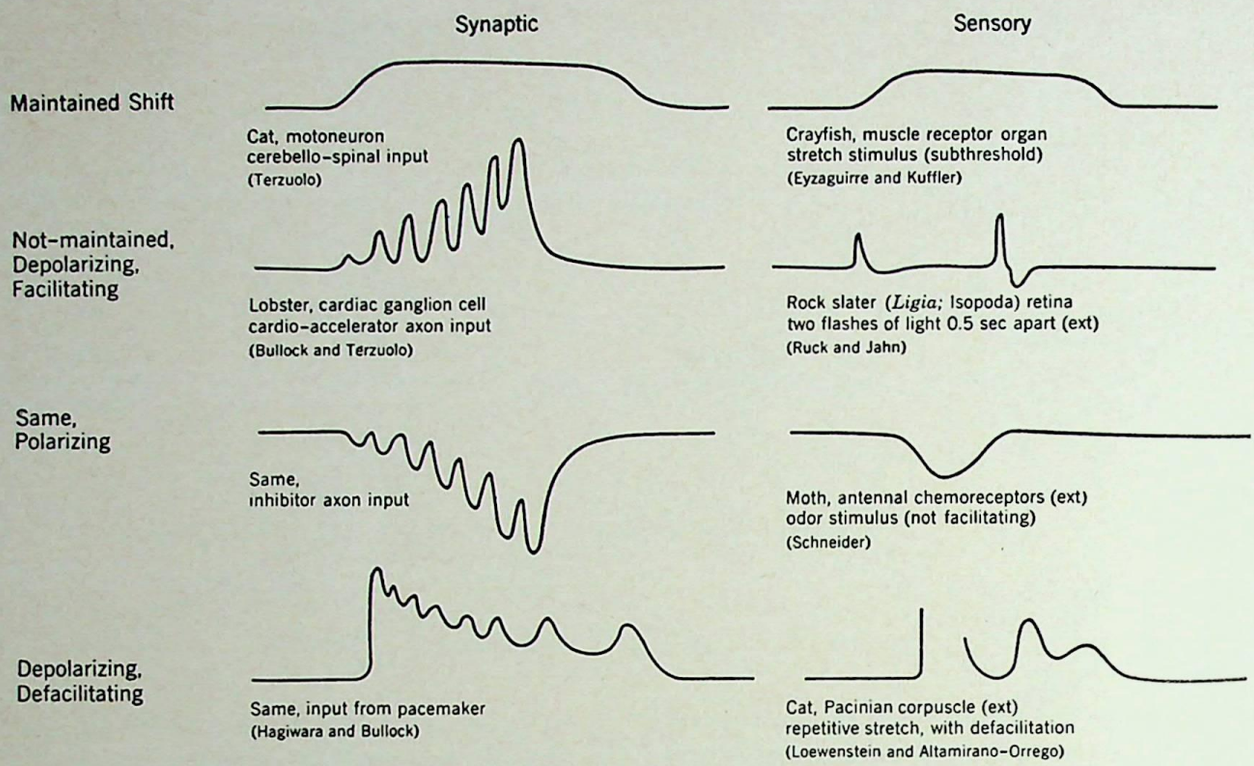

FIG. 9. Some of the types of subthreshold potentials, to show the correspondence between synaptic and sensory types. Hand-drawn approximations of original records, intracellular (except when marked ext = external); time scale is not uniform; upward deflection is depolarization or, in external recording, negativity of closer electrode.

point, such as a confluence of main branches of the distal process. So much for the processes that act upon the spike probability through the so-called resting potential.

More typically, or at least more familiarly, *the response to an external event is the transient deflection*, called a synaptic potential or a generator potential according to whether the external event is presynaptic or whether it is a sensory stimulus (Fig. 9). These responses arise in restricted portions of the neurons and have their significance in the effects they produce in other regions after nonregenerative spread—with decrement and phase delay. They may be polarizing or depolarizing, and this alternative may be decided by the nature of the external event or, in certain circumstances by the level of the membrane potential obtaining at the moment. Some normally polarizing, hence inhibiting, events are reversed readily to a depolarizing response which can be shown to increase the probability of firing and are thus at least in a measure excitatory. Such change in the response to a given input owing to different levels of membrane potential is not purely a laboratory phenomenon resulting from experimentally imposed polarization, but occurs normally, for example, in the aforementioned situation where Terzuolo found the membrane level of spinal motoneurons shifted by cerebello-spinal pathways, thereby altering the response to dorsal-root inputs. (In some accounts, emphasis has been laid on the fact that an inhibitory input drives the membrane potential from either side toward a certain equilibrium value and does not cause any synaptic potential if the membrane is already at that level. Even under the latter condition inhibition can result, because the lowered impedance tends to clamp the membrane. But this can inhibit only in the near vicinity. Upon spike-initiating regions or synaptic regions at some distance, the sign and magnitude of the potential change will determine the sign and magnitude of the effect.)

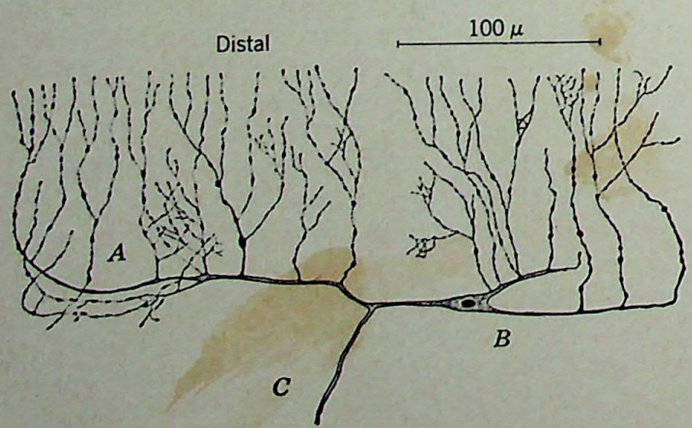

FIG. 10. Sensory nerve cell from the leg of a centipede, *Lithobius*; methylene blue. *A*—lattice of fine terminal fibers, *B*—cell body, *C*—axon [from G. F. Meyer, Zool. Jahrb. Anat. 74, 381 (1955)].

In at least some cases, there intervenes between the synaptic or generator potential and the critical level at the spike-initiating locus (which is a very restricted part of the neuron at some distance from the principal synaptic and generator loci) *an intermediate graded potential* which is usually called the *local potential* (Fig. 11, from the work of Bullock and Terzuolo[28]). This is presumed to arise in an electrically excitable membrane adjacent

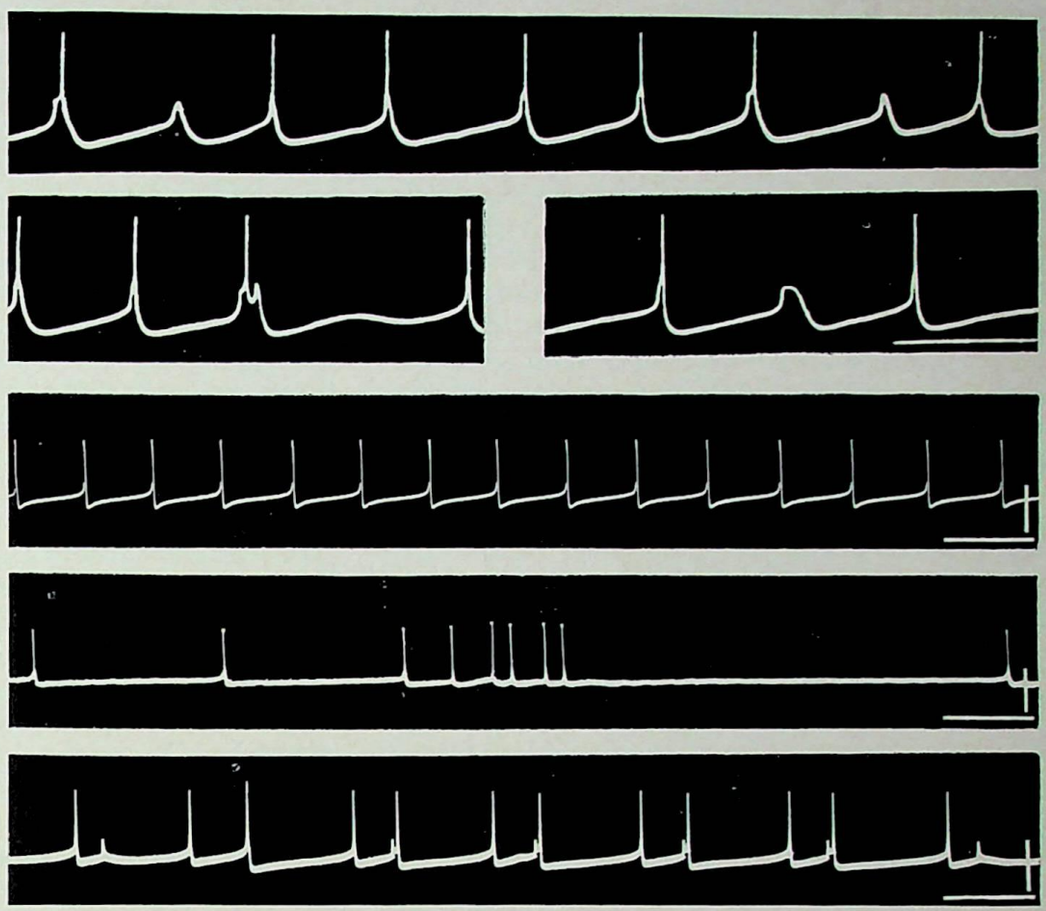

FIG. 11. Examples of true spontaneous activity as seen by an electrode inside a nerve cell. Cardiac ganglion cell of the lobster, *Panulirus* [(a) and (b)] or the crab, *Cancer* [(c) (d) (e)]. (a) and (b) show a large pacemaker potential, presumably arising nearby, and another prepotential, regarded as a local potential, before the spike. The local potential may fail to elicit a spike and then can alone cause repolarization. Note the failure of the local potential to arise following the third spike in (b) with instead an undulation leading to a new cycle. (c), (d), and (e) show different forms and permutations of pacemaker potential and repolarization. Scales: (a) and (b)—500 msec; (c), (d), and (e)—50 mv, 200 msec [from T. H. Bullock and C. A. Terzuolo, J. Physiol. 138, 341 (1957)].

to the synaptic or generator membrane, but distinct from it, and as a consequence of the local circuits from antecedent activity of the same cell. In this respect, the local potential is like the spike potential, which also arises by electrical excitation from the local circuits in neighboring regions of the same neuron. Indeed, local potentials can be made to have graded amplitudes all the way to the full amplitude of the spike potentials, and they differ only in being nonregenerative and, therefore, in spreading decrementally for distances of the order of a millimeter only. In some sensory neurons, we may conjecture that such local potentials occur in different branches of the distal process and sum in the stem process to determine the initiation of a spike. The experiments of Katz[29] on the summating subthreshold deflections in sensory terminals of muscle spindles may be so interpreted. Situations where distal sensory processes branch over a considerable area are quite common.

The nonregenerative property of some neuronal membranes is important in those cases where it results in the *inability of spike potentials, once initiated, to invade* those regions of the neuron. This preserves these regions from explosive depolarization and from subsequent strong repolarization, and thus enhances their integrative capacity. For example, the soma of the large cardiac ganglion cells in the lobster and perhaps the dendrites on some other types of neurons never experience an explosive all-or-none event. This characteristic is very likely true of most neuronal membranes, that is to say, of the vast forests of fine branching processes making up neuropiles. If this is so, one must think of all-or-none spike potentials as a peculiar development of a limited portion of the neuron whose function is the faithful propagation of signals over long distances rather than integration.

The familiar local and spike potentials are depolarizing in direction, but there are a few instances indicating that membranes are capable of equivalent *regenerative potentials in the opposite direction.* For example, during the plateau of an essentially completely-depolarized potential in the Purkinje tissue of the mammalian heart, during a heart beat, a threshold stimulus in the polarizing direction sets up a regenerative repolarization which grows explosively and restores a resting potential [Weidmann[30]]. Hisada[31] has recorded action potentials of the same polarity—that is, increasing polarization across the cell membrane of the protozoan *Noctiluca.*

Finally, we have *spontaneous activity* manifested in *pacemaker potentials* in some neurons including many sensory neurons. A background of continuous spike discharge in the absence of known stimulation or under steady-state stimulation may be called spontaneity. Of course, such activity depends upon permissive conditions of the metabolism and of the milieu of the cell. If these conditions are normal ones, however, steady-state firing is spontaneous in the sense that the origin of the intermittent activity lies within the neuron, rather than

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

in the environmental mechanisms. Such activity has been explored in several cases (Fig. 11), and the significant finding from the present point of view is the *localization of the pacemaker process to a limited portion of the neuron* different from that in which spikes arise, and perhaps also different from that in which synaptic or generator activity occurs primarily. Of course, these regions must be within shouting distance of each other, for their normal significance lies in the summing of their effects to produce a threshold change in the membrane potential at the spike-initiating region. In lobster cardiac ganglion cells, evidence of more than one pacemaker locus is seen in the same neuron. This is possible because these loci apparently occur in different major processes of the cell, each of which has its own spike-initiating region; two different rhythms of spikes arise and can be seen in the same soma without interfering one with another since they cannot invade the soma. What this says is that the absolute dimensions of neurons are not accidental but are fixed by engineering requirements specified by the electrotonic parameters of the membrane.

There are very likely at least *two distinct types of spontaneous potential* change. The rarer is approximately sinusoidal. Spikes tend to occur during the phase of maximum depolarization. Several spikes may occur during this phase, but they are not necessary for and do not accelerate the repolarizing phase. In contrast, the more common type is similar to a relaxation oscillation, in that the pacemaker potential itself is a steadily depolarizing potential which must be interrupted by some new process with a threshold whose net result is to repolarize, thereby starting a new cycle. This threshold process is typically the spike potential, but it may be preceded by and indeed may be substituted by a local potential which is capable of repolarizing the membrane during its recovery phase, thus setting the stage for another pacemaker potential to begin.

There are other *permutations and complexities in the processes of spontaneous impulse initiation* as is suggested by the high rhythmicity of some receptors and the low rhythmicity of others. In fact, it may be characteristic that, in one and the same unit, rhythmicity is relatively high at high frequencies of discharge and low at low frequencies. Tokizane and Eldred[32] have found two distinct populations of stretch receptor fibers in the dorsal roots of cats. One population is consistently more rhythmic at any given average frequency than the other; that is, the standard deviation of intervals is smaller for a given average interval. They believe that the more-regular units come from flower-spray endings in the muscle spindles and that the less-regular units belong to annulo-spiral endings.

The various possibilities for understanding the *origin of nonrhythmicity* or randomness-within-limits of successive intervals cannot be discussed here. Nor can one discuss the interesting question of the central problem created by nonrhythmicity, the *distinction of signals from noise*—that is, of weak true stimuli from random changes in the frequency of firing. These problems have been discussed elsewhere (see references 33–35).

These separate processes reflected in membrane potential shifts, in synaptic, generator, local, pacemaker, and spike potentials are *sequentially coupled* in complex ways: partly because there are several alternative sequences; partly because much depends on the particular microanatomy of a given neuron, the spatial relations of the separate loci, and the possibilities of spread of the respective potentials; and partly because of the labile character of the coupling constants. The constants or transfer functions well may be nonlinear.

However, these do not exhaust the processes of which there is evidence that determine the initiation of impulses within the cell. Turning to *processes not manifested by membrane potential* changes—at least by changes detectable with the same methods used for measuring the just-discussed events—we are faced mainly with indications of excitability changes. These are brought to attention only by responses to subsequent stimuli. One is called *facilitation* (Fig. 9). The cell can be initially at a certain membrane potential and respond to a given arriving impulse (in this case, a single presynaptic fiber) with a small synaptic potential. After repetition, the response to the same presynaptic impulse is much greater even when the membrane potential is allowed to return to the initial value between stimulations. Another type, which may be seen in the same neuron may be called *defacilitating*; the response is less to successive presynaptic impulses the closer together they come. Here also, at the same membrane potential level, the cell or presynaptic terminals are altered in response or excitability according to the recent history. This is not a laboratory artifact but is an essential part of the normal mechanism of burst formation in the 9-celled cardiac ganglion of the lobster. Here, the large follower neurons, driven by a burst of arriving presynaptic impulses from the pacemakers, characteristically give the form of synaptic potential response shown in Fig. 9. A large, initial synaptic potential is followed by a series of small ones during the high-frequency portion of the burst and then by growing amplitude responses as the frequency of the arriving presynaptic impulses declines.

Here we have to deal with the *time course of excitability of graded, subthreshold events*. There must be a separate curve for each of the subthreshold events previously discussed and for each locus and type of synapse. The last two instances, of facilitation and defacilitation, recorded in the same neuron were both excitatory synaptic potentials, from different presynaptic pathways (one from the pacemaker in the cardiac ganglion, and the other from the cardioacceleratory nerve from the central nervous system). The same neuron also has facilitating inhibitory synapses. Each of these synaptic

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

responses must have its own dependence of response upon input and of this relation (response per input) upon time after preceding activity. The local potentials also may have a separate time dependence of excitability and so may the spike-initiating locus where the excitability is measured by a sharp threshold. We note that the classical spike threshold, so easily measured any place in the axon, is normally a significant parameter at a very limited region only in the whole neuron. Beyond this region, the safety factor is normally sufficiently high that the spike threshold is without great significance.

Another degree of freedom not predicted by the membrane potential is the presence or absence of after-effects —either persistent response after the input ceases or of overshooting rebound (post-excitatory inhibition or post-inhibitory excitation). Cases of each kind are known for receptors and for central neurons.

Still another line of evidence for processes determining spike initiation, which cannot be seen in the usual membrane potential measurements, is that of significant *alteration of the frequency of already-active neurons by weak electric fields* in the surrounding medium, already mentioned. In a preliminary analysis, Terzuolo and Bullock[7] estimated the intensity of the voltage gradient in the saline surrounding a neuron (stretch receptor of the crayfish) when an imposed polarization was of a magnitude just sufficient to cause a noticeable change in the maintained frequency of firing. The results, as already mentioned, were that very weak fields (of the order of 1 $\mu v/\mu$ in the external medium around the cell) were sufficient. There will be a potential change in a given direction (for example, an excitatory direction) in certain parts only of the neuron, and since this will be graded in magnitude geographically, there must be a very limited region only wherein the imposed field actually exerts its effect. It can be concluded, therefore, that, even in the absence of average change in membrane potential, very localized regions may be critical in determining the firing frequency and may have an extremely high sensitivity to small voltage gradients. Thus, old ideas are confirmed in a certain sense that, among other things, the neuron is to a significant degree under the influence of differences of potential between one part and another of the surface of the neuron.

The general picture then is quite different from that of the axon. Grundfest[36] has given arguments for believing that adjacent patches of neuronal membrane are, respectively, electrically excitable and electrically inexcitable in a certain meaning of these terms. It may be emphasized that the evidence cited here is also strongly indicative of a *neuronal membrane consisting of a patchwork* of different kinds of subthreshold-response capacities. The responsiveness or the excitability—these two are different, but ordinarily are not easy to distinguish experimentally—vary separately one from another; some are manifest by electrical events, others are not.

One more degree of complexity must be added: the separate processes do not simply sum algebraically to determine the level of probability of impulse initiation, but at least some of them apparently interact: the presence of an increased magnitude of one subthreshold process may alter the magnitude of one of the others. For example, in the presence of a large generator potential, excitatory synaptic potentials may not simply add but will themselves be altered in size. The same may be true for inhibitory and pacemaker potentials. These interactions have been little studied, but there is no doubt that they will be found, in some cases, to contribute importantly to the integration of input to determine output (see, for example, the evidence of multiplicative neural events adduced by Hassenstein and Reichardt[37]).

SUMMARY

A selection of sense organs upon which recent progress has been made is reviewed in order to point out problems and opportunities of biophysical interest. The electroreceptors in electric fish, mechanoreceptor hairs in arthropods, infrared receptors in pit vipers, and specific chemoreceptors in flies and moths are the examples presented.

The general problem of absolute reception as opposed to reception of change is emphasized in terms of stability, drift correction, and reference standard.

The long series of subthreshold events which may intervene between transducing a stimulus and initiating a spike is reviewed. These include events which are reflected in the membrane potential and others which are not. Specific shifts of membrane potential, pacemaker, generator, synaptic, local and spike potentials, and some subvarieties are sequentially coupled in labile and perhaps nonlinear ways. They occur, in general, in restricted regions of the neuron which interact in complex ways not only because of the complex coupling constants between successive steps but also because of the profound influence of the anatomical distribution of the differently responding types of membranes.

Events not reflected in the membrane potential are the excitability cycles and the presence or absence of aftereffects. In addition to the spike threshold, each graded process preceding the spike has a curve of response against input and of this relation against time after preceding activity.

It is probably important that these several processes not only are sequentially related but that they interact —the amplitude of one may alter the responsiveness of another. Spike initiation is, therefore, potentially a highly derived and integrative result.

Receptor Mechanisms and the Integration of Sensory Information in the Eye

H. K. HARTLINE

The Rockefeller Institute, New York 21, New York

THE processing of sensory information begins in the sense organs themselves. It is in them that the first steps take place in the transformation of external influences into the patterns of nervous action that regulate the activity of an animal in its complex environment. The fundamental nature of the receptors and the design of the accessory structures in which the receptors are deployed determine how external information flows into the organism. Thus, sense organ and receptor mechanisms determine the character of the neural activity that is passed on to higher neural centers. In addition, the first steps in neural integration take place within the sense organs, for in many of them the receptors interact with one another. As a result of both of these actions, patterns of sensory nerve fiber activity transmitted to the higher centers are more than mere replicas of the temporal and spatial patterns of external stimuli. Certain significant features of the stimulus patterns are accentuated at the expense of less important fidelity of representation. This can be clearly illustrated in the analysis of the first steps of the visual process, with which this paper deals.

One of the great contributions of biophysics in the last century was the precise description of the human eye as an optical instrument. The high degree of perfection of our eyes enables us to exploit many of the peculiar advantages of luminous energy as a source of information; their shortcomings set limits to our visual performance. The vertebrate scheme of optical imagery by a lens system is not the only one that is used by animals; compound eyes also have been evolved—made up of small optical units, each having a narrow entrance angle and each pointed in a different direction so that all cover the entire field of view. They too have both advantages and disadvantages, one of the advantages being that short wavelengths can penetrate to their receptors. In either case, retinal receptors arranged in a mosaic receive light in varying amounts from the various parts of the animal's surroundings. The mechanism of the visual receptor units that compose the retinal mosaic determines many of the properties of vision.

The photoreceptor offers certain advantages over many other receptors in the study of sensory mechanisms, for in it the very first step in the transducer mechanism for translating the stimulus into nervous action is beginning to be well understood. This is a consequence of the general principle that electromagnetic radiation, to produce a permanent effect on a material system, must yield some of its energy to the system. Consequently, the action spectrum of the visual apparatus is simply the manifestation of the absorption spectrum, or a portion of it, of the primary photosensitive material in the visual receptors. It is the absorption spectrum of the primary visual pigment that sets the rather indistinct limits to the extent of the visible region within the electromagnetic spectrum and that determines quantitatively the relative effectiveness of different wavelengths of visible light. There is now very good agreement between the measurements of the absorption spectrum of photolabile pigments extracted from the retina and the "action spectrum" of vision for several animal forms, especially for man.[1,2]

The fact that one can identify the photosensitive material of the visual receptor makes it possible to say whereabouts in the receptor cell the first act of the visual process takes place. In the vertebrate eye, the visual pigment "rhodopsin" is known to be concentrated entirely in the outer segments of the retinal rods. This identifies the outer segments as the locus of the initial step in the visual receptor process. Rhodopsin can be extracted from suspensions of the outer segments of retinal rods, and its absorption spectrum, after appropriate correction, agrees well with the distribution of spectral sensitivity of rod vision. It is clearly the primary photosensitive substance of the rods. A number of visual pigments related to rhodopsin are now known. One of them, iodopsin, is the corresponding photosensitive substance of the retinal cones.[3] The biochemistry of the visual pigments constitutes an extensive and elegant chapter of modern biochemistry that cannot be discussed in detail in this paper (cf. Wald[4]).

Rhodopsins are known to be conjugated proteins, the prosthetic group being a carotenoid called retinine. Retinine is an aldehyde, the corresponding alcohol being vitamin A, and is known in a number of isomeric forms. The first act of light apparently is to produce an isomerization of the carotenoid group while it is still attached to the protein.[5] Retinine is then split off the protein molecule by subsequent reactions that are independent of light, and may be converted reversibly into vitamin A.

After photolysis, visual pigments can regenerate. Otherwise, one would have one look at the world and then be forever blind. The kinetics of photolysis and regeneration of visual pigments has been studied extensively, both *in vitro* and recently in the living retinas of experimental animals and human subjects.[6] Many

receptor properties, such as the loss of sensitivity in the light and its recovery during dark adaptation, can be explained qualitatively by these elementary biochemical processes in the visual receptors. Moreover, a simple model of the photochemical system of the receptor was used by Hecht to explain quantitatively many psychophysical measurements of vision.[7] His formulations remain the most comprehensive and successful theoretical treatment of visual-receptor physiology, although his model is oversimplified and the theory needs reworking in light of recent developments in biochemistry and physiology.

The primary photosensitive pigment of the visual receptor is present in a structured system. Electron-microscope studies show a profusion of osmium-staining membranes in visual receptors. Sjöstrand[8] has shown that the outer segments of the receptors of the vertebrate retina have a lamellar structure. The rod outer segment is thus a stack of thin plates crowded with rhodopsin. In the arthropods, instead of a lamellar system, the part of the receptor cell (the rhabdom) that presumably contains the visual pigment is composed of myriads of microvilli densely packed to form a honeycomb-like structure. Figure 1 is an electron micrograph of the rhabdom of an ommatidium of an arthropod compound eye.[9] In the vertebrates, the outer segments of the retinal rods and cones have been shown to be derivatives of cilia.[10,11] In the arthropods, where cilia are extremely rare, there is no evidence of a ciliary derivation. In some mollusks, however, there is a different system of membranes and again the structures are derived from cilia.[12] Exactly how the visual pigment is arranged within any of these membranous structures is not known, though there have been speculations on this point.

Visual receptors have evolved into light detectors that are so sensitive that they work at the limit set by the quantum nature of light. A human observer is able to see a flash of light that contains only about 100 quanta, measured at the cornea of the eye. After correction for losses in transmission through the ocular media and failure of the visual purple to be present in sufficient amount in the retina to absorb all of the quanta that fall on it, this figure comes down to something of the order of 10 quanta.[13] This aspect of visual physiology has been extensively studied and is well reviewed in a recent article by Pirenne.[14] Obviously, it is of great significance to visual performance, especially at low

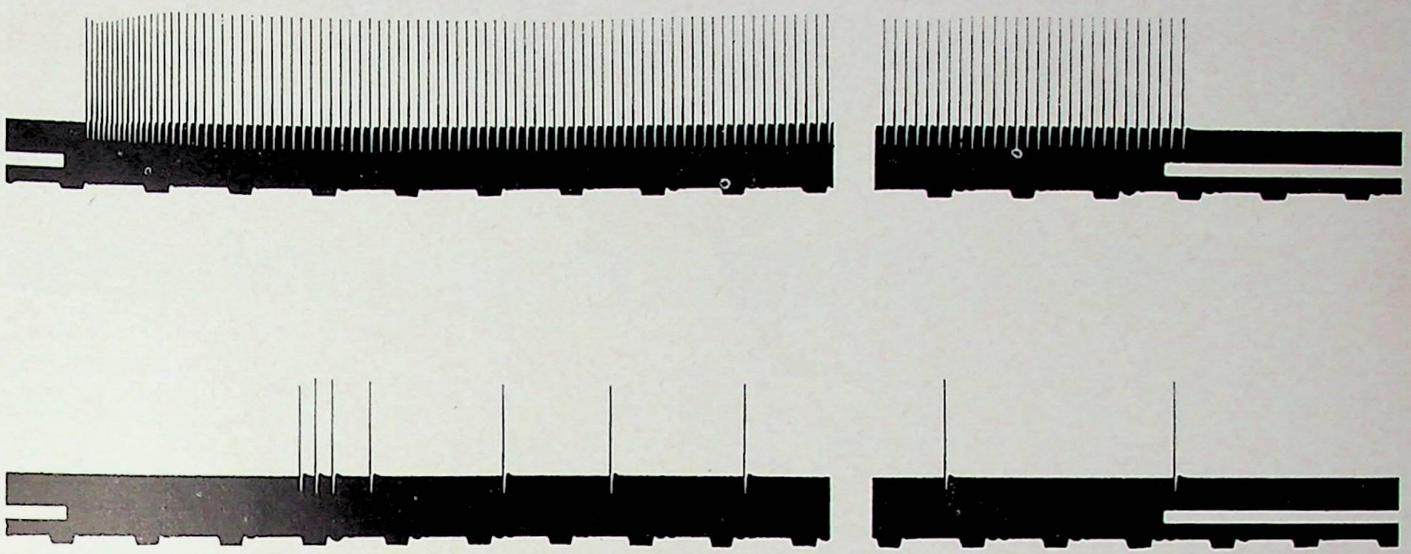

FIG. 2. Oscillograms of the electrical activity in a single optic-nerve fiber (eye of *Limulus*) in response to prolonged steady illumination of the facet of the eye innervated by the fiber.[15] Each spike is the "action potential" associated with the passage of a nerve impulse in the fiber. For the top record, the intensity of stimulating light was 10^1 times that used for the bottom record. Signal of exposure to light blackens out the white line above the time marks. Time marked in $\frac{1}{5}$ sec.

illuminations. In the short "action time" of the retina, so few quanta are needed that the retinal image, though visible, is too "grainy" to be seen with high resolution. Also, at threshold, seeing is uncertain. Indeed, the statistical uncertainty at threshold can be explained almost entirely by the fact that a very few quanta suffice to excite a response. Nevertheless, the visual threshold is sharp enough so that it is quite certain that a human observer cannot see just one quantum, although exactly how many are needed is still a matter of controversy. The small amount of light that is just visible can be seen if it is spread over a retinal area containing about five hundred rods. This must mean that near threshold there is almost no chance of any one rod receiving more than one quantum, and that the cooperative activity of several rods is necessary to reach the threshold of vision. Thus, a single quantum of light absorbed within the stack of plates comprising the outer segment of a rod is sufficient to excite that rod, causing it to transmit some kind of nervous influence that can sum with similar influences from several other rods to reach the threshold for a behavioral response. In this retinal summation, one has an example of the simplest kind of neural integrative action, exerted at the very threshold of vision.

The end result of receptor excitation is the generation of nervous influences in its attached nerve fiber. It has not yet been possible to record the neural activity of the receptors (rods and cones) of the vertebrate retina, but some invertebrate eyes afford an opportunity to record optic activity that appears to be very close to the action of the primary receptors. The eye of the common horseshoe crab, *Limulus*, is particularly favorable for the study of the action of single receptor units. This eye is a coarsely facetted compound eye. Individual receptor units corresponding to each facet (ommatidia) can be separately illuminated, and the electrical activity of the optic nerve fiber from such a unit can be recorded.[15]

The neural activity recorded from one of the receptor units of the eye of *Limulus* consists of trains of uniform nerve impulses similar in all respects to the sensory discharges observed in nerve fibers in all of the higher animal forms (Fig. 2). As in all receptors, the higher the intensity of the stimulus, the higher the frequency of the impulses with which the receptor responds. In the visual receptor, it is noteworthy that frequency changes over a relatively small range for a large range of light intensity: the dynamic range of a single receptor is five or six orders of magnitude. Roughly, the relation between frequency of discharge and intensity of light is a logarithmic one (Fechner's Law). Thus, the transducer mechanism of the visual receptor covers a large range and is adapted to signal the ratios of stimulus values. In our own visual experience, values of light and shade stay more or less fixed, no matter what the ambient level of illumination, over a large range. In such situations, stimulus ratios stay constant and the visual receptors yield approximately a fixed difference in the frequency for a given ratio of stimulus values, even though the absolute differences may vary widely.

Another important receptor property is illustrated in Fig. 2. The discharge of nerve impulses begins at a high frequency when the light is turned on, but the frequency of the discharge subsides in a fraction of a second to a considerably lower level, which is then maintained with only slight diminution as long as light continues to shine on the receptor. This sensory adaptation is manifested by all other receptors, some to a far greater extent than others. As a result of sensory adaptation, receptors provide a somewhat distorted report of the stimulus events, such as to accentuate any sudden change. Sensory trans-

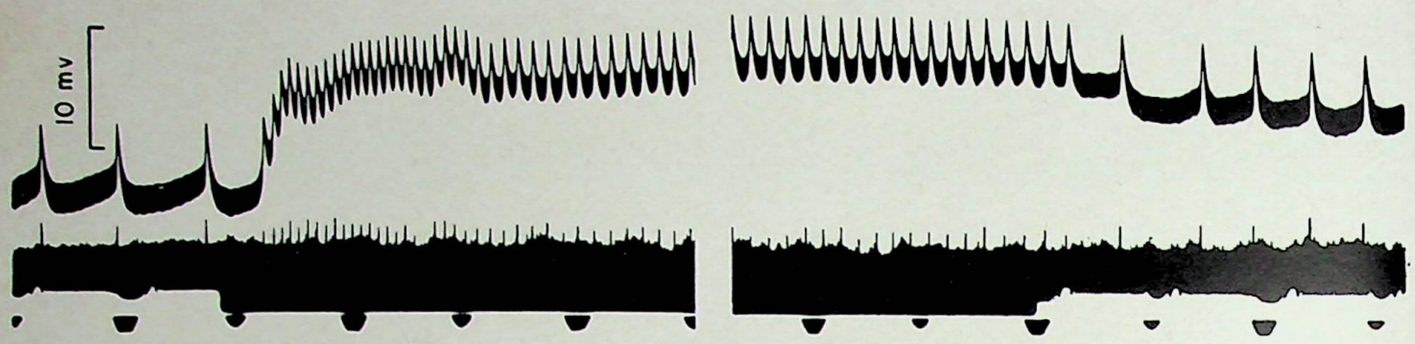

FIG. 3. Electrical responses to illumination of a single receptor unit (ommatidium) in the eye of *Limulus*.[15] Recorded (upper trace) by a micropipette electrode (tip diam 1 μ) in the neuron of the ommatidium, and simultaneously (black edge just below upper trace) by a pair of wire electrodes over which was slung the nerve bundle from the ommatidium containing the neuron's axon. At the beginning of the record, the microelectrode base line records the resting level of the electrical polarization of the cell membrane, at a potential about 50 mv negative to the solution bathing the outside of the cell. When the ommatidium was illuminated (black band above the time marks), there was a partial depolarization of the neuron (potential becoming less negative: rise in the base line) accompanied by an increase in the frequency of the spike-like deflections, each one of which was synchronous with the discharge of an impulse in the nerve bundle (small spikes on the black edge). Time marked in $\frac{1}{5}$ sec.

ducers are not concerned so much with a faithful representation of the world as with a useful one, and it is especially useful to the organism to accentuate the *changes* that occur in external conditions. If the illumination on a visual receptor unit is given a small increment, the receptor response consists of a modulation of the discharge of impulses in which there is an exaggeration of frequency changes at the onset and again when the increment is turned off. This permits the receptor to signal small changes, and still possess a large dynamic range. But what may be even more important, the suddenness of the changes enhances their stimulating effectiveness. Thus, the inherent properties of the sensory receptors determine how the patterns of neural activity they generate will represent the stimulus events. This is a first step in the processing of information for use by the organism.

As yet not much is known about the nature of the excitatory processes following the initial photochemical reaction in visual receptors until one comes near the end of the receptor process. In the eye of *Limulus*, it has been possible to learn a little about the actual production of nerve impulses in the axon of the excited neuron in the receptor unit. By the use of a micropipette electrode penetrating the sensory structure of the ommatidium, changes in the electrical polarization of the cell membrane of the neuron in the ommatidium have been recorded.[15–17] These changes are associated with the trains of impulses initiated by this cell when the receptor unit is illuminated (Fig. 3). When light is turned on, the cell membrane becomes somewhat depolarized, and simultaneously there is a speeding up of the discharge of impulses in its axon. Such depolarization is referred to as a "generator potential,"[18] in the belief that the nerve impulses are generated by local electric currents flowing as a result of the difference in potential between the axon and the depolarized cell body (or more probably, in the present case, the depolarized dendritic process of the cell which penetrates the rhabdom of the ommatidium). The degree of depolarization depends on the intensity of the stimulating light and in turn determines the frequency of the relaxation oscillations of the membrane of the initial segment of axon in the region where it leaves the cell body and from which the propagated impulses take off. The discharge of trains of impulses by depolarized neurons is a familar process in neurophysiology. For the photoreceptor, the question is how the initial photochemical reaction produces the depolarization and the ensuing "generator potential." About this, almost nothing is known.

As discussed in the foregoing, the receptor itself by its inherent properties does a certain amount of processing of the information from the outside world. It is concerned with the report only of certain aspects of the physical stimulus that acts on it, and it is not necessarily a high-fidelity recording device. Built as it is, it selects certain features of the stimulus pattern for accentuation. The next step in the processing of sensory information in the visual system concerns the distribution of light over the entire population of visual receptors. A retina, whether in a vertebrate or an arthropod, is more than a mosaic of independent detecting elements. In the vertebrates, it is well known that the retina is a highly organized nervous center. It is really a part of the brain closely applied to a mosaic of sensory receptors. The first step in the neural analysis of the pattern of the retinal image requires the intercomparison of what happens in the various differently stimulated receptors, and a modification of the pattern of neural activity to accentuate important features of the spatial distribution of light over the receptor mosaic. Evidently, it is profitable to do this close to the point where the information is being picked up. In the vertebrate retina, the early neurons in the visual pathway are spread out in correspondence with their associated receptors, and many of the processes in the first step of neural integration apparaently can be done most effectively in the retina itself. This is not a simple process; patterns of activity observed in the optic-nerve fibers in the verte-

brate retina are very complex, and their analysis is difficult. In simpler visual systems, integrative processes can be more readily analyzed. The eye of *Limulus* again affords a good oportunity for such studies.

The neural structure of the compound eye of *Limulus* is much simpler than that of the vertebrate retina or the eyes of more highly developed arthropods, but it is nevertheless a retina: the units of the receptor mosaic are interconnected by a network of nerve fibers [Fig. 4(a)]. The nerve fibers from the ommatidia branch profusely on their way out of the eye to form the optic nerve. Festoons of these branches connect each receptor unit with its neighbors. There are no nerve-cell bodies in this plexus of interconnections, as in more complex retinas, but there are numerous knots composed of a felt-work of very fine branchlets closely intertwined. The fibers in these clumps of "neuropile" are packed with "vesicles" typically present in synapses [Fig. 4(b)]. Evidently, the clumps of neuropile are synaptic regions, where influences are transmitted from one set of

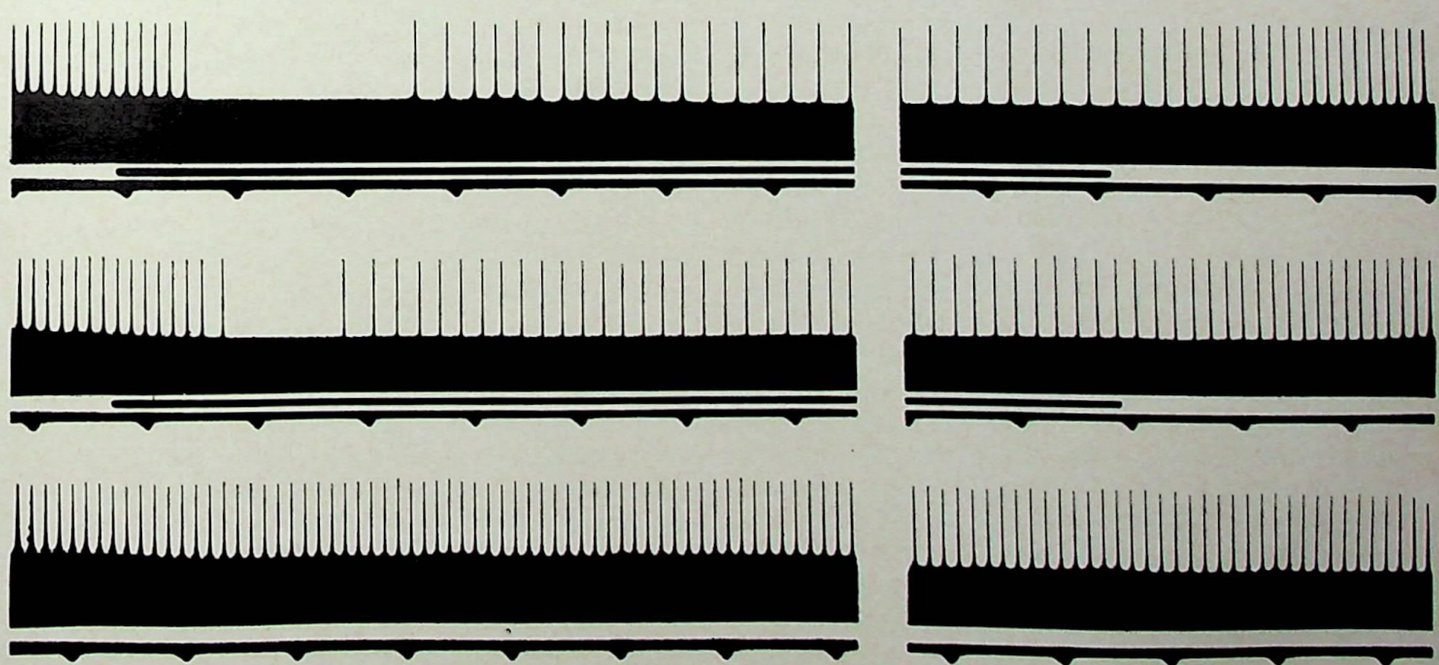

FIG. 5. Oscillograms of nerve action potentials, showing inhibition of the impulses in a single optic-nerve fiber of *Limulus*. The ommatidium of the eye from which the fiber arose was illuminated steadily at a fixed intensity, beginning 3 sec before the start of each of the records; adjacent ommatidium were illuminated during the interval signalled by the blackening out of the white line above the time marks, in the upper two records. In the top record, the intensity of the illumination of adjacent receptors was ten times that used in the middle record. Bottom record is a control (no adjacent illumination). Time in $\frac{1}{3}$ sec. Experimental arrangement as in Fig. 6(a).

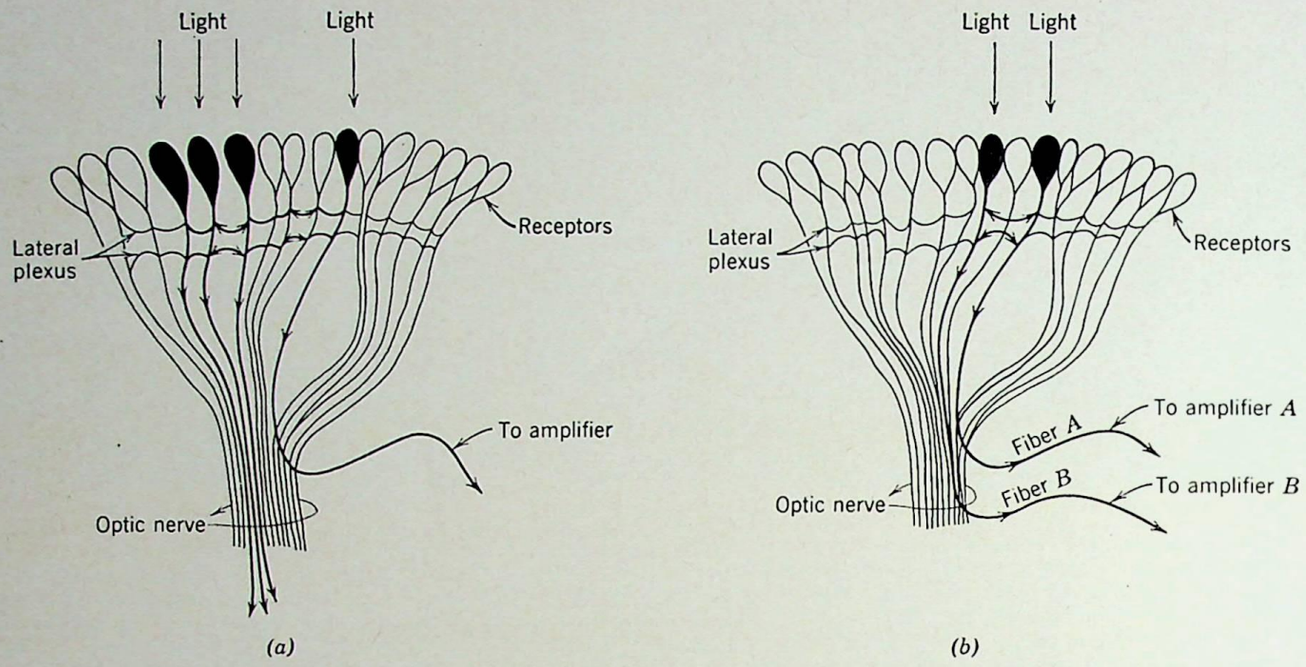

FIG. 6. Schematic diagrams of experimental arrangements used. (a) Experiment of Fig. 5 (inhibition of test ommatidium by illumination of nearby ommatidia). (b) Experiments of Figs. 7 and 8 (mutual inhibition of two ommatidia that were close to one another).

branches to another.[19] Based on this structural organization is a simple functional organization: each ommatidium tends to inhibit the activity of its neighbors. This influence is indeed exerted over the plexus of nerve fibers, for, by cutting the interconnecting branches to an ommatidium, the influence of its neighbors on it can be abolished.

The inhibition that is exerted on an ommatidium by its neighbors is illustrated in Fig. 5. In the experiment from which these records were taken, the discharge of impulses was recorded in a single optic nerve fiber in response to illumination, by a small spot of light, of the facet of the ommatidium from which that fiber arose [Fig. 6(a)]. During steady illumination of that one ommatidium alone, a steady discharge of impulses resulted (bottom record). When, during steady and continuous illumination of this "test" ommatidium, light was caused to shine also on other ommatidia in neighboring regions of the eye (top and middle records of Fig. 5), the frequency at which the test ommatidium discharged impulses was reduced.

Figure 5 also shows that strong illumination of the adjacent region produced a greater depression of frequency than weak illumination. It has also been shown that the magnitude of the inhibition exerted on an ommatidium is greater the larger the number of neighboring ommatidium that are stimulated. Thus, the inhibitory influences from many neighbors can combine to increase the net effect they produce. Also, the inhibition exerted on an ommatidium by its neighbors is greater the closer they are to it. Ommatidia that are separated by a distance exceeding 4 or 5 mm have no effect on one another.

Inhibition in the eye of Limulus is exerted mutually by the receptor units.[20] Each ommatidium, being a neighbor of its neighbors, inhibits them as well as being inhibited by them. This is shown in Fig. 7, obtained by recording activity simultaneously in the optic nerve fibers from two independently illuminated ommatidia, close to each other in the eye [Fig. 6(b)]. The frequency of each receptor unit was lower when both were illuminated together than when each was illuminated by itself. When this experiment is performed using various intensities on the two receptors in various combinations, it has been shown that the amount by which the steady frequency of discharge of each receptor unit is lowered depends on the degree of concurrent activity in the other, and is indeed a linear function of the frequency of its discharge (Fig. 8). Thus, the response of one receptor unit is determined by the excitation furnished by the stimulating light shining on it, diminished by the inhibitory influence from the second receptor, which in turn depends on the resultant of the excitation furnished by its own stimulus and the inhibition exerted on it by the first. This mutual interdependence of any two neighboring receptor units may be described by a pair of simultaneous equations, linear in the frequencies of the discharges.

When more than two interacting receptors are illuminated simultaneously, each is subject to the combined inhibitory influences from all of the others. The law that determines how the inhibitory influences from several active receptor units combine in affecting the activity of a neighboring unit has been found by experiment: if the influences on a given unit are measured by the reduction they produce in its frequency of nerve impulse discharge, the combined effect of all of the other units is simply given by the sum of the influences

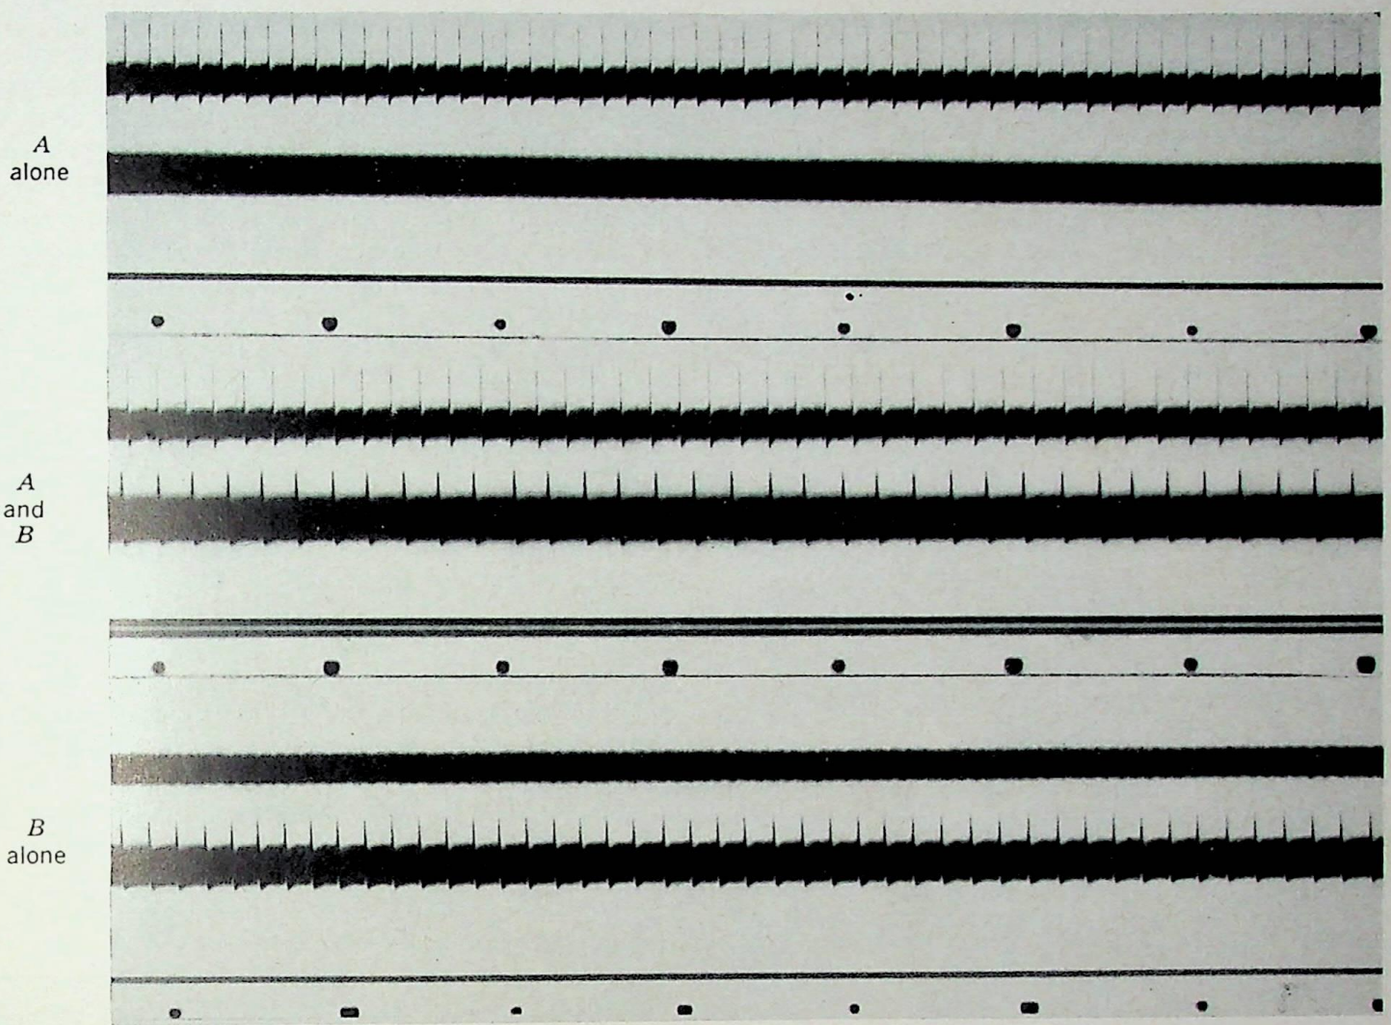

FIG. 7. Mutual inhibition of two ommatidia close to one another in the eye of *Limulus*, steadily illuminated at fixed intensity on each. Experimental arrangement as in Fig. 6(b). Time (black dots) in $\frac{1}{5}$ sec.

exerted by each.[21] The responses of a set of n interacting receptor units, measured by the frequencies of their optic nerve discharges, are therefore expressed by a set of n simultaneous linear equations,

$$r_p = e_p - \sum_{j=1}^{n} K_{pj}(r_j - r_{pj}^0) \quad p = 1, 2 \cdots n.$$

In these equations, r_p stands for the response of the pth unit (measured by its steady frequency of impulse discharge) when it is illuminated steadily together with the other units. Its excitation, e_p, is measured by the response it has when it is illuminated alone. Each constant K_{pj} is the coefficient of the inhibitory action of the jth receptor on the pth (usually less than 0.2) and each constant r_{pj}^0 is the threshold of that action. Terms for which $j = p$ are usually omitted. The equations as written apply only to those units and that range of activity for which r_j is not less than r_{pj}^0. As a rule, the closer the interacting elements are to one another, the larger the K's and the smaller the r^0's. Exceptions are often found, however, and it is not yet possible to state the statistical law governing the effects of distance on the inhibitory interaction.

If N small groups of receptors are considered, each group uniformly illuminated and assumed to consist of receptors with similar properties exerting equal actions, the foregoing set of equations may be reduced to N simultaneous equations with lumped coefficients representing the group interactions. Applied to three interacting receptors or receptor groups, the theory outlined in the foregoing can account quantitatively for a number of effects that have been observed with various experimental configurations of retinal illumination. Thus, if a test receptor is located midway between two groups of receptors that are themselves too far apart to interact, the combined inhibitory action of these two on the test receptor is equal to the sum of the separate actions of each, unless the test receptor itself has an appreciable effect upon them. If the two groups are close together and both are near the test receptor, their combined inhibitory effect will be less than the sum of their separate effects since they inhibit one another mutually when both are active. If a group of receptors is too far from a test receptor to influence it directly, it may nevertheless affect its response by inhibiting a second group located close to the test receptor, thereby releas-

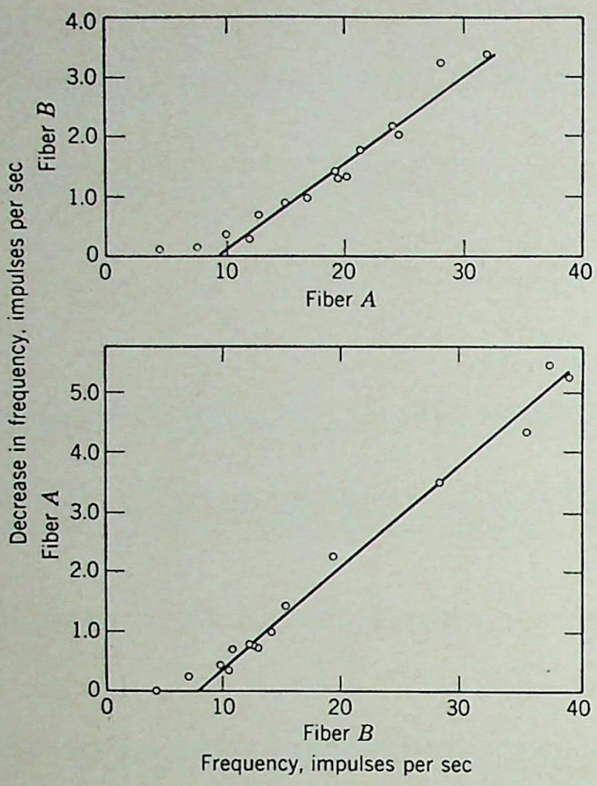

FIG. 8. Mutual inhibition of two ommatidia close to one another in the eye of *Limulus*, illuminated independently at various levels of intensity in various combinations. Amount of inhibition (decrease in frequency) of each ommatidium plotted as a function of concurrent level of response (frequency) of the other. From an experiment similar to that of Fig. 7, experimental arrangement as in Fig. 6(b).

ing the test receptor from the inhibition exerted by the second group. Such "disinhibition" illustrates how indirect effects may be exerted beyond the limits of direct influence and, in principle at least, extend over the entire mosaic of interdependent receptor units.

The inhibitory interaction just described may be considered a simple integrative mechanism that takes place at or close to the level of the receptors themselves. Because of it, patterns of optic nerve fiber activity yield a distorted representation of the patterns of incident illumination. This distortion, however, serves a useful function, for it is clear that inhibitory interaction must enhance contrast: brightly lighted elements in the receptor mosaic inhibit the dimly lighted ones more than the latter inhibit the former. If, as in the eye of *Limulus*, mutual inhibition is greater between close neighbors than distant ones, contrast will be greatest near regions of steep intensity gradients and borders and edges in the retinal image will be "crispened." Phenomena of border contrast are illustrated in our own vision by the light and dark bands bordering a penumbra (Mach bands), and by the fluted appearance of an optical step-wedge or of shadows cast by multiple light sources. Inhibitory interaction is probably one of the mechanisms in our own visual systems that gives rise to these phenomena.[22]

Direct experimental demonstration of the "crispening" of the contours by inhibitory interaction can be made, using the eye of *Limulus*.[23] The discharge of impulses is recorded from a "test" receptor near the center of the eye as the eye is caused to scan slowly a pattern of illumination containing a gradient of intensity. When all of the receptors are masked except for the one from which activity is being recorded, a faithful representation is obtained of the distribution of intensity in the image viewed. But when the mask is removed, so that all of the receptors view the pattern, maxima and minima in the frequency of the test receptor discharge occur, corresponding to the regions bordering the gradient. These resemble in form and location the "Mach bands" seen by a human observer viewing the same pattern.

Interaction is known to take place in other sense organs. In the ear, von Békésy[24] has suggested that inhibitory interaction may be important in increasing pitch discrimination. Indeed, Galambos and Davis[25] have demonstrated inhibition of the activity of single auditory nerve fibers by tones differing in frequency from those used to excite the fibers. Also, von Békésy[26] has demonstrated "contrast" effects in the tactile stimulation of the skin, suggesting inhibitory interaction over considerable distances over the surface of the body.

In the higher nervous centers, integrative processes of great complexity take place. In the retina of the vertebrate eye, which—even though located in the peripheral sense organ itself—is nevertheless a nervous center of high order, there is an intricate interplay of excitatory and inhibitory interactions.[27] As a result, diverse and labile patterns of optical nerve fiber activity are generated.[28,29] In the vertebrate retina, to a much greater degree than in the primitive retina of *Limulus*, the patterns of afferent nervous activity are greatly modified to accentuate significant features of information about the environment. The process of neural integration is well begun by the time the afferent messages are transmitted to still higher centers in the brain.

Mechanisms of Synaptic Transmission

BERNARD KATZ

Department of Biophysics, University College, London, W. C. 1, England

INTRODUCTION

THE propagation of an impulse along a nerve or muscle fiber is brought about by two coupled processes: (i) cable transmission, which allows an electric potential change to spread along a short distance, but with rapid attenuation, and (ii) a boosting mechanism by which the full signal strength is regenerated at each point. If either of these processes is interfered with, the signal will be blocked and will fade out locally. The cable mechanism depends upon the continuity of the fiber structure, with a relatively low-resistance core and high-impedance surface layer. During the impulse, sufficient current must be able to flow forward along the inside of the axon and outward through the resting membrane to stimulate it. If one were to close the core with a high-resistant transverse membrane, or to place a low-resistance shunt across the fiber surface, transmission would be impaired and probably would fail at that point. The very reason why thousands of axons packed together within one nerve bundle can conduct their messages independently, without mutual interference, rests on the absence of structural continuity, and lo of an effective cable connection between them.

The purpose of this paper is to consider what happens at "synapses," the points of contact between one nerve cell and the next, or between nerve and muscle fiber. There is no sign of cytoplasmic continuity between the different cell units. Electron-microscope evidence shows that the membranes of the synapsing cells are arranged in close proximity, though in general they do not seem to fuse or to come into intimate contact. The electron micrographs, however, do not reveal anything about the electrical properties of the contacting surfaces; and one has no means of guessing intuitively whether or not an effective cable linkage exists across the synapse.

ELECTRICAL AND CHEMICAL TRANSMISSION

There are, in principle, two basically different modes of synaptic transmission, electrical and chemical. *Electric* transmission implies that in spite of apparent morphological complexities, an effective local-circuit connection exists which allows sufficient current to pass from one cell to the next to restimulate it. In other words, the transmission is one continuous process without any essential change at the synapse. There must, of course, be *some* difference; for all synapses have the property of functioning only in one direction unlike nerve fibers which can conduct impulses with equal facility in either direction despite the fact that in normal life, because of their terminal synaptic connections, they are used for one-way traffic only.

Chemical transmission implies the intervention of an entirely different process specific for the synaptic area. It presupposes that the ordinary cable-connection is interrupted at the contact point between the cells, and replaced by the agency of a chemical mediator. A specific chemical stimulant which is synthetized and stored inside the nerve terminal is liberated by the nerve impulse. When the substance is released, it attaches itself to special receptor molecules in the surface of the contacting postsynaptic (or effector) cell. This chemical combination leads to a membrane change which gives rise to a local depolarization of the effector cell. When the depolarization exceeds the threshold level, a new action potential is set up which then travels along the cell in the manner previously described. Thus one has, interposed between two separate waves of propagated electric activity, a secretion of a specific substance from one cell, and a chemoreceptor reaction in the surface of the next cell.

Now, it is not possible to predict without thorough experimental examination which of these two modes of transmission occurs at a particular type of synapse. Various attempts have been made to generalize by drawing analogies from the few cases which have been explored; and in recent years the view has become prevalent that transmission is llkely to be chemical at all synapses, but that a variety of substances are being employed in different cases, and only a few of them, like acetycholine and noradrenaline, have so far been identified. This view, however, seems a little too sweeping, and the discussion is begun, therefore, by quoting an example of electric transmission which has just been brought to light by the work of Furshpan and Potter.[1] This may well be an exception to the rule, but it provides a definite warning against too much generalization in this field.

Furshpan and Potter used a "giant" synapse in an abdominal ganglion of the crayfish cord. This is a contact point between a very large nerve fiber which runs through the central nervous system of the crayfish and a somewhat smaller motor axon which emerges from the cord to supply the flexor muscles of the "tail." This synapse was chosen for two reasons: (a) because the large size of the two contacting cells made it possible for a pair of microelectrodes (one to pass current and one to measure membrane potential) to be introduced into each of them; (b) it seemed *a priori* that electric transmission might be feasible at this synapse, more so than at other types where minute nerve endings usually

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

terminate in contact with a huge cell (which implies, from the electrical point of view, a poor mismatch, very little current being available from the high-impedance terminals to discharge the large surface of the postsynaptic cell). Furshpan and Potter were able to show that the membrane contact of this special synapse acts as a good electric rectifier, allowing current to pass relatively easily from the presynaptic to the postsynaptic cell, but not in the reverse direction. In other words, at this particular synapse, an adequate cable connection exists between the interior of the two cells, in the *normal* direction of impulse travel alone. Provided the internal potential of the prefiber was *higher* than that of the postfiber, electric current could flow across and influence the membrane potential of the adjoining cell. The result is that a depolarization such as occurs during the impulse can be transmitted in the normal *orthodromic* direction, but not the other way. And, conversely, a local hyperpolarization, produced experimentally by passing a current inward through the fiber membrane was found to be transmitted only in the *antidromic* direction (from postfiber to prefiber) but not the other way. Thus, at the giant synapse of the crayfish, one has a case—so far, the only known example—of electric transmission, in which the action current generated by the arrival of an impulse in the presynaptic cell is passed on without finite delay and can directly depolarize and thereby excite the postfiber. One-way transmission is owing to the valve-like one-way resistance of the synaptic contact membranes.

There are only a few giant synapses available in nature allowing such a direct experimental approach to both sides of the junctional region. In most cases, the presynaptic nerve endings are too small to be tackled with intracellular electrodes and their electrical behavior has to be inferred from a more indirect approach. It is of great interest, however, that at another giant synapse, in the stellate ganglion of the squid, Bullock and Tasaki and Hagiwara[2,3] obtained evidence of a different kind; they observed a definite local delay in the propagation of the electrical change, indicating a stoppage of the local-circuit transmission at the junction; there was no detectable transfer of subthreshold cable signals in either direction. These observations provide another fair warning against attempts to generalize about synaptic mechanisms.

If one now takes an entirely different case—namely, the skeletal neuromuscular junction—one finds here one of the few examples of a synapse where chemical transmission has been firmly established. It was shown by Dale and his colleagues that a specific cholinester, almost certainly identical with acetylcholine, is released from the active motor-nerve endings. This substance is a very potent local stimulant and, provided it is applied rapidly to the junctional end-plate region of a muscle fiber, causes a local depolarization of the cell membrane and sets up propagated impulses and contraction in the fiber. The chemical effect is localized to the synaptic area of the muscle surface; it is at these points exclusively that a number of chemical blocking agents, like curare, act (apparently by a competitive attachment to the acetylcholine receptors). By histochemical methods, a high local concentration of a specific enzyme, acetylcholinesterase, has been found at the same point; the apparent purpose is to hydrolyze the transmitter substance within a very short time after it has exerted its action. Electrical studies have shown that there is an irreducible delay of 0.5 to 1 msec between the arriving nerve impulse and the start of the so-called end-plate potential (which is the local depolarization in the muscle fiber produced by the transmitter substance). There is no cable transfer of electric current, of either polarity, directly from the nerve axon to the muscle fiber. When potential changes are imposed on the terminal portion of the motor nerve, these changes do not spread beyond the nerve terminal, but can be shown to increase the rate at which acetylcholine is being released from the nerve endings and so, indirectly, to influence the membrane potential of the muscle fiber.

The most direct way of establishing chemical transmission by nerve impulses would be to show that a substance is released, on nerve stimulation, into the circulating fluid, and when applied to a remote effector cell produces the same, excitatory or inhibitory, action. This has been achieved in a few cases, notably the classical experiment of Otto Loewi in which he demonstrated the role of acetylcholine as the transmitter of nervous inhibition of the heart beat. Usually, such a direct demonstration is not feasible because of the enormous dilution of the transmitter agent, on the way from its primary point of release and action to the assaying tissue. Indeed, this discrepancy between (i) the amount of acetylcholine (ACh) which has to be applied artificially to stimulate a muscle, and (ii) the much smaller quantities which are released into the perfusion fluid from stimulated nerve endings, has been used as an argument against the validity of the chemical-transmitter theory. By a method of microscopic ionophoresis, much more effective applications have been made recently, and it has been possible to show that as little as 10^{-16} g equiv of ACh can give rise to an effective, superthreshold, depolarization of the muscle fiber. This is still a few hundred times more than the amount per impulse recovered in the earlier perfusion experiments, but it must be remembered that even with the best micropipettes one cannot reduce the average diffusion distance to that of the natural synaptic contact. The remaining quantitative discrepancy is entirely within the range to be expected and hardly can be used as a theoretical counterargument. The ionophoretic microtechnique has shown a number of other interesting results; it has confirmed the extremely critical localization of the chemoreceptors at and within

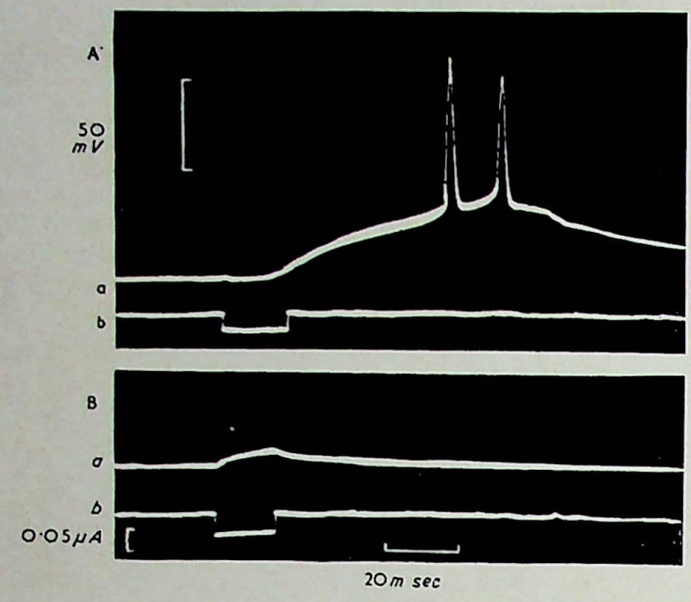

FIG. 1. External and intracellular application of acetylcholine to a motor end plate [from J. del Castillo and B. Katz, J. Physiol. 128, 157 (1955)]. Intracellular recording of membrane-potential changes from the junctional region of a frog muscle fiber. In *A*, an ACh-filled micropipette was placed on the outside of the end plate, and a quantity of ACh was released by passing a brief outward-directed current pulse through the pipette (registered in *b*). It produced the effect shown in trace *a*: a depolarization developing after a diffusion delay and culminating in two spikes. Between records *A* and *B*, the ACh-pipette entered the muscle fiber. An outward pulse produces now a small, direct potential change, owing to the passage of current through the fiber membrane. (If, for comparison, a KCl-filled micropipette is used, no potential change is produced by the pulse until the pipette has entered the fiber, when the effect is identical with that recorded in *B*, a.)

the neuromuscular junction. Moving the tip of the pipette by several microns can substantially reduce the effect of a given dose. Furthermore, it has been possible (Fig. 1) to insert the tip into the interior of the muscle cell, and so apply the acetylcholine alternatively to the external and internal side of the postsynaptic end-plate membrane.[4] The result showed that a depolarization was produced only by external, not by intracellular application; and this was observed with acetylcholine as well as carbamylcholine (a substance of similar action, but not destroyed by the local cholinesterase), and the same result was found for the blocking action of curarine. It seems that the first chemical attachment on to the receptor molecules must take place at the external surface of the end-plate membrane, which is, of course, the side facing the nerve endings from which the acetylcholine emerges under normal conditions.

Before discussing other peculiarities of the neuromuscular junction, the principal features and problems inherent in chemical transmission in general may be considered briefly.

There are two main steps interposed between the arrival of a presynaptic and the departure of a postsynaptic impulse: (i) the process by which the arriving impulse releases the transmitter substance, from its storage place inside the terminal into the narrow cleft between the contacting cells—this is a special case of what has been called "neuro-secretion"; (ii) there is the process by which the transmitter substance becomes attached to specific molecules in the postsynaptic cell surface and causes its electric membrane properties to change—this is a special example of *chemoreceptor* action, that is a process analogous to that occurring in our various chemical sense organs where a minute concentration change of some specific substance is registered in the form of sensory nerve impulses. As an intermediate step, one should consider also the mechanism by which transmitter molecules are transported across the small synaptic gap; however, the path length is only a fraction of a micron, and the time taken up by simple diffusion over such a short distance is well within the range of the observed synaptic latency.

EXCITATORY AND INHIBITORY CHEMORECEPTOR ACTION

To begin with, consider the second step, that is, the chemoreceptive mechanism. How do transmitter substances alter the membrane potential? Only a very incomplete answer to this question can be given. In general, the primary action leads to the opening of some ionic permeability channel in the membrane. Depending upon the size or specificity of this ionic channel, the membrane potential either tends to *fall* toward a low level, well beyond the firing threshold of an impulse, or it may become stabilized in the vicinity of the resting level or even tend to rise somewhat (hyperpolarize). In the first case, excitation ensues; in the last cases, one obtains an opposite, inhibitory, action (see Eccles[5]). But it may be noted that, underlying all of these changes, there is a common primary effect—namely, an increase of some ionic conductance.

For example, at the motor end plate there is evidence that acetylcholine causes the membrane permeability to increase, simultaneously, to several monovalent cations (e.g., sodium, potassium, ammonium) and possibly opens up an indiscriminate aqueous channel to all small ions on either side of the membrane. The result is a depolarization which has a "null point" at about 10 to 20 mv, negative inside, which corresponds to the level of a free-diffusion or liquid-junction potential between cytoplasm and external fluid. The effect is to short-circuit and depolarize the surrounding muscle membrane beyond the level at which a new impulse arises which then travels rapidly along the whole length of the muscle fiber. The methods by which these conclusions were reached have been described elsewhere;[6,7] briefly, they consisted in measuring the current/voltage relation across the end-plate membrane, and observing the particular level of the membrane potential at which the electromotive effects of ACh reversed, with normal as well as with altered composition of the ionic environment.

While ACh has a depolarizing and excitatory effect at the end plate, it produces the opposite action, that is

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

hyperpolarization or stabilization of the resting potential, in the regions of the heart muscle onto which it is released by impulses in the vagus nerve. Here also, the basic effect is an increase of ionic conductance, but the channel which is being opened is restricted to potassium, and does not include sodium. As a result the membrane tends to move towards, or to be held at, the potassium equilibrium potential which is usually somewhat greater than the existing resting potential (hence, a hyperpolarization).

Somewhat similar changes appear to be associated with the excitatory and inhibitory synapses in the motor neurons of the spinal cord.[5] At these junctions, the transmitter substances are unknown, but the "null points" of the potential changes which they produce have been determined and correlated with the existing ionic concentration gradients. Here also, an inhibitory hyperpolarization occurs which appears to be associated with an increase of membrane conductance to various small ions but excluding sodium; while excitation apparently arises from an indiscriminate "short circuit" in which sodium as well as the other small ions are allowed to pass.

Although the transmitter effects are fairly well understood in terms of ionic conductance changes, and the subsequent steps leading to excitation or inhibition present no special problem, the molecular mechanism by which the chemical attachment, e.g., of acetylcholine, to the receptive sites of the membrane alters its permeability is still far from understood. At one time it was thought possible that ACh^+ ions might produce a local depolarization without permeability change, simply by being able to move very rapidly through specific channels into the interior of the muscle fiber. This idea had to be abandoned when it became clear that the transfer of Coulombs during the end-plate depolarization exceeds the charge on the available ACh ions by several orders of magnitude. The observation shown in Fig. 1—namely, that a positive quantity of charge applied directly into the interior of the cell is much less effective in depolarizing the fiber membrane than an equivalent charge of ACh ions applied on the outside—illustrates this point rather clearly: most of the externally released ACh ions will diffuse away and have no chance of penetrating, or even colliding with, the end-plate surface. Yet under its influence much more positive charge enters the fiber than with the direct intracellular discharge. The conclusion is that the relatively few ACh ions released from the nerve terminal cause a vastly greater quantity of other, ambient, ions to flow through the end-plate membrane, and so achieve the great amplification of local current which is needed to transmit an impulse from the minute nerve endings to the much larger muscle cell.

Regarding the molecular combination between ACh and receptors and the subsequent chain of events, all that can be said at present is that a study of various chemical inhibitors (e.g., del Castillo and Katz[8]) suggests the presence of a 2- or 3-stage process whose kinetics resemble those of many enzyme-substrate reactions. Substances like tubo-curarine appear to act as competitive inhibitors, by interfering with the initial site of attachment, without themselves leading to the next phase which involves a change in the physical membrane properties.

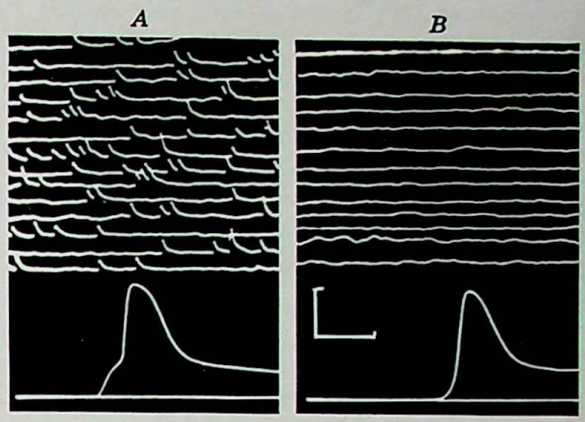

FIG. 2. Spontaneous miniature end-plate potentials. *A:* A recording microelectrode was placed inside a frog muscle fiber at the nerve-muscle junction. *B:* The electrode was placed 2 mm away into the same muscle fiber. The upper portions were recorded with slow speed and high amplification and show the occurrence of spontaneous small potential changes, restricted to the junctional region (calibrations: 3.6 mv and 47 msec). The lower portions show the response to a nerve impulse with fast-speed and low-gain recording (calibrations: 50 mv and 2 msec). The stimulus was applied to the nerve at the beginning of the trace; response *A* (at the end plate) shows the step-like initial end-plate potential which leads up to the propagating wave; response *B* shows only the propagated action potential, delayed by conduction over a distance of 2 mm [from P. Fatt and B. Katz, J. Physiol. 117, 109 (1952)].

Quantal Nature of Acetylcholine Release

An interesting feature which has emerged during a detailed study of the vertebrate nerve-muscle junction is that the release of ACh from the motor nerve terminals occurs in discrete packets or quanta each containing a large number of molecules. Even in the absence of a nerve impulse, such packets are released "spontaneously" at infrequent random intervals (Fig. 2). The arrival of an impulse at a cell junction apparently causes a few hundred events to be synchronized within a fraction of a millisecond instead of going on at a leisurely average rate of about 1/sec.[9]

The evidence for this state of affairs was obtained soon after it became possible to apply intracellular recording electrodes to the motor end plate. If a recording electrode is inserted into a resting muscle fiber well away from its junctional region, one observes a steady resting potential of about 90 mv, negative inside. But as one approaches the end plate with the recording probe, a characteristic form of spontaneous activity shows up which consists of an intermittent random

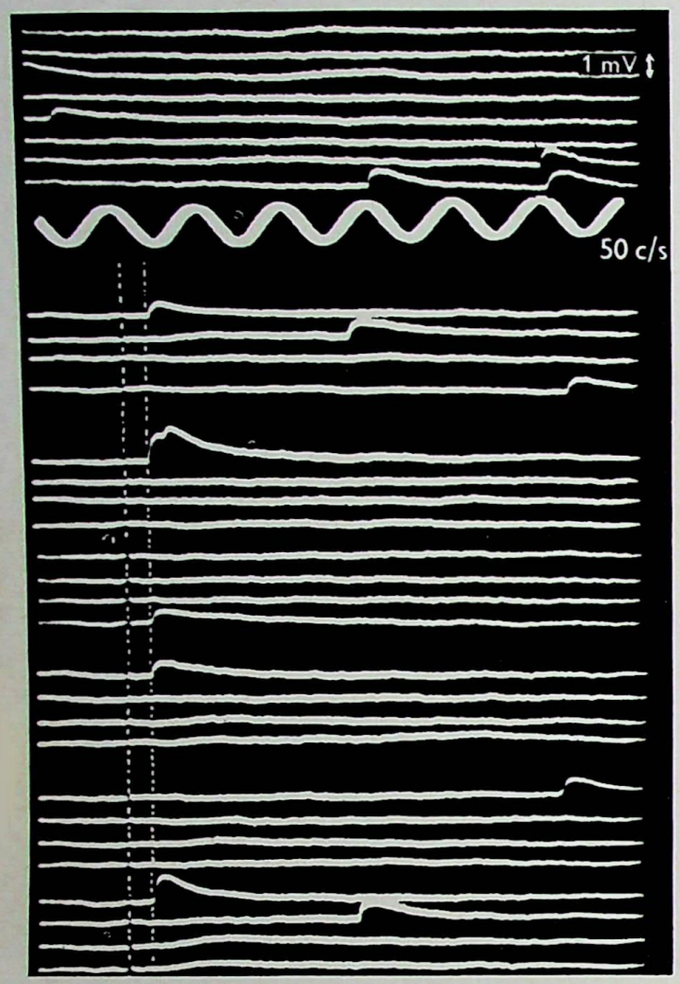

FIG. 3. Quantal units of end-plate response, recorded intracellularly from a muscle fiber in a calcium-deficient and magnesium-rich medium. The top portion shows a few spontaneous potentials. The lower part (below the 50-cps time signal) shows, in addition, the responses to single nerve impulses. Stimulus and response latency are indicated by a pair of dotted lines. There was a high proportion of failures, and only 5 single unit-responses to twenty-four impulses [from J. del Castillo and B. Katz, J. Physiol. 124, 560 (1954)].

discharge of minute potential changes of standard size and time course. Each deflection is a transient depolarization of the order of 0.5 mv, with a rapid (1 msec) rise and a slower decay, lasting altogether about 20 msec. It resembles in many respects the end-plate potential (e.p.p.)—that is, the immediate depolarization of the end plate produced after the arrival of a nerve impulse, but differs from it in its much smaller size (about 1%) and its spontaneous random occurrence. Fatt and I called it the miniature end-plate potential. It resembles the e.p.p. in its time course, its restricted localization to the innervated region of the muscle fiber, and its pharmacological reactions. It is reduced in size by curare, and its amplitude and duration increases when the local hydrolysis of ACh is prevented by a potent anti-esterase. In both respects, the miniature potential behaves exactly like the depolarizations produced by an applied dose of ACh, and we believe, therefore, that the spontaneous discharges arise from local random impacts of ACh on to the end-plate receptors. The source of these impacts is evidently a spontaneous release or leakage of ACh from the motor-nerve terminal where the substance is stored, for the miniature potentials vanish in the course of experimental nerve degeneration, at a time when neuromuscular transmission fails.

We considered the possibility that random molecular diffusion of ACh from the motor-nerve ending might be responsible for the minature e.p.p.'s. If this were true, then the same type of discharge ought to be elicited, at vastly increased frequency, by applying ACh to the fluid surrounding the end plate. This, however, is not the case: the depolarization which one then observes is continuously graded in size and time course, depending upon the dose and length of the diffusion path. It is clear that the effects of single molecular impacts of ACh must be far below the resolving power of our re-

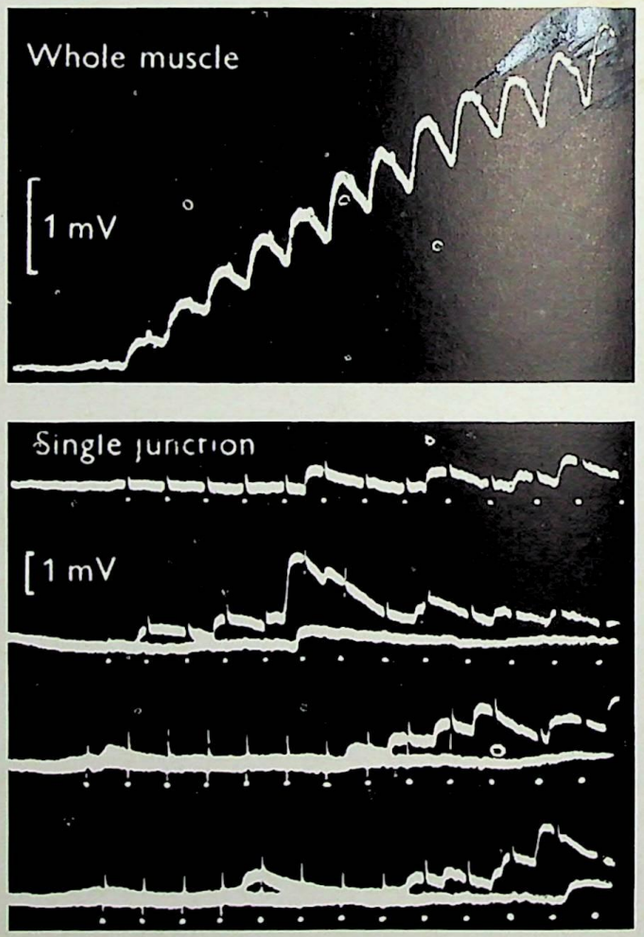

FIG. 4. Statistical properties of the end-plate response. The nerve-muscle preparations were blocked by a high magnesium- and calcium-deficient medium. The nerve was stimulated at 100 shocks per sec which produces a progressively increasing end-plate response. The upper record was obtained from the surface of a sartorius muscle showing the "smooth" average population response of a few hundred end plates. In the lower part, the response of a single end plate is recorded intracellularly, showing the quantal fluctuations of the response. Stimuli indicated by dots. Note spontaneous potentials on the superimposed "base lines" [from J. del Castillo and B. Katz, J. Physiol. 124, 574 (1954)].

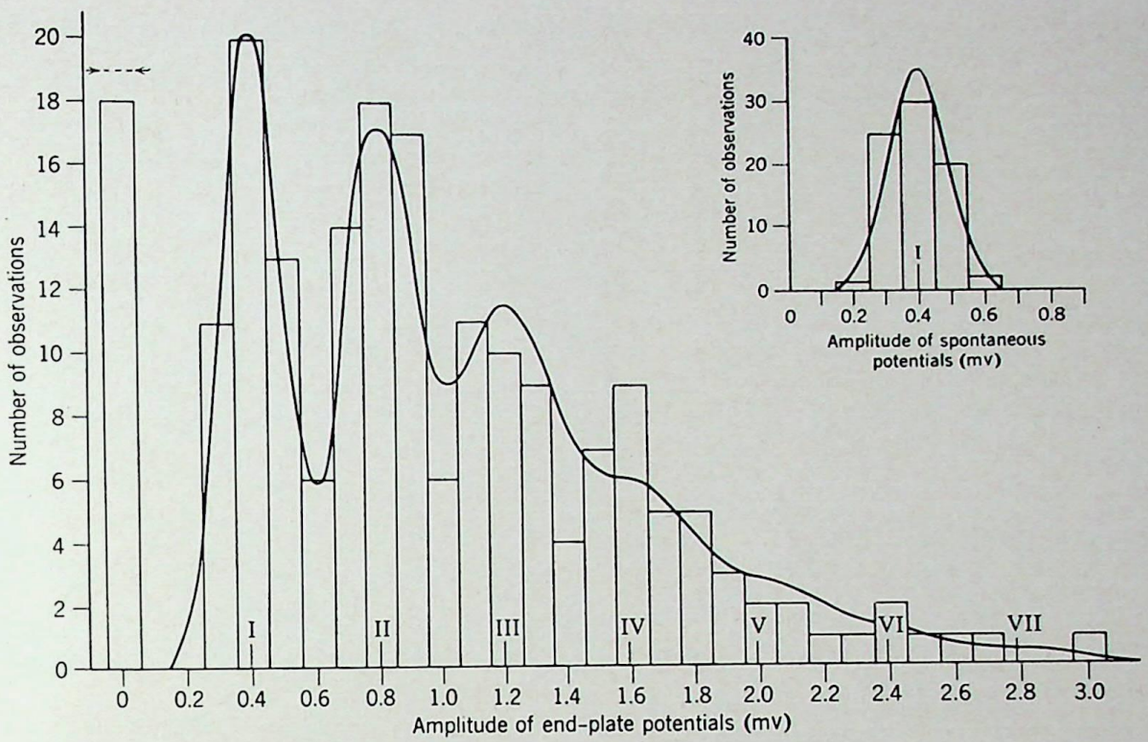

FIG. 5. Histograms of e.p.p. and spontaneous potential amplitudes (inset), from a mammalian end plate blocked by magnesium. Peaks of e.p.p. amplitude distribution occur at 1, 2, 3, and 4 times the mean amplitude of the spontaneous miniature potentials. A Gaussian curve has been fitted to the latter and used to calculate the theoretical distribution of e.p.p. amplitudes (continuous curve). Arrows indicate expected number of failures (zero amplitude) [from I. A. Boyd and A. R. Martin, J. Physiol. **132**, 74 (1956)].

cording equipment, and conversely that a discrete miniature e.p.p., with its standard size and brief time course, must be due to a synchronous package of ACh molecules, may be hundreds or thousands, discharged in the immediate vicinity of our end-plate receptors.

That this packet is the basic coin in which the trans-

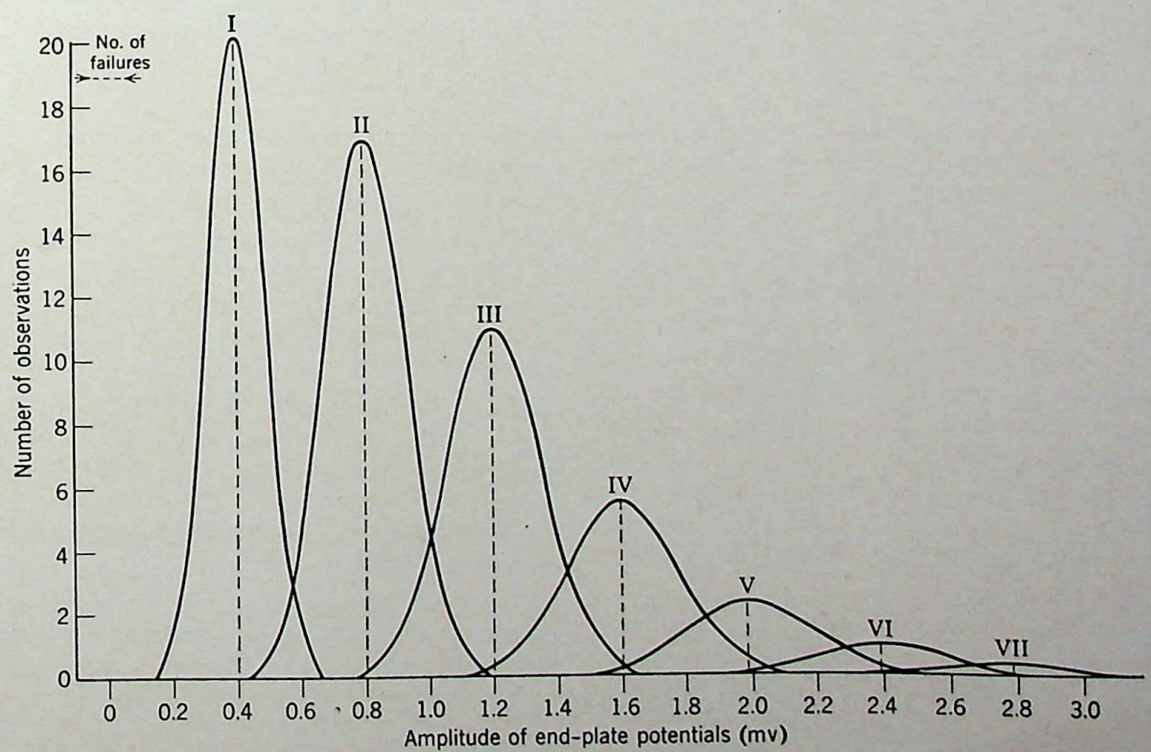

FIG. 6. Method of obtaining the continuous theoretical curve in Fig. 5. A Poisson distribution was calculated, for a mean value m = mean amplitude of e.p.p. responses/mean amplitude of spontaneous potentials. The calculated numbers of each Poisson class have been distributed along Gaussian curves, corresponding to multiples of the spontaneous potentials (see Fig. 5). Algebraic summation of ordinates gives the continuous curve of Fig. 5 [from I. A. Boyd and A. R. Martin, J. Physiol. **132**, 74 (1956)].

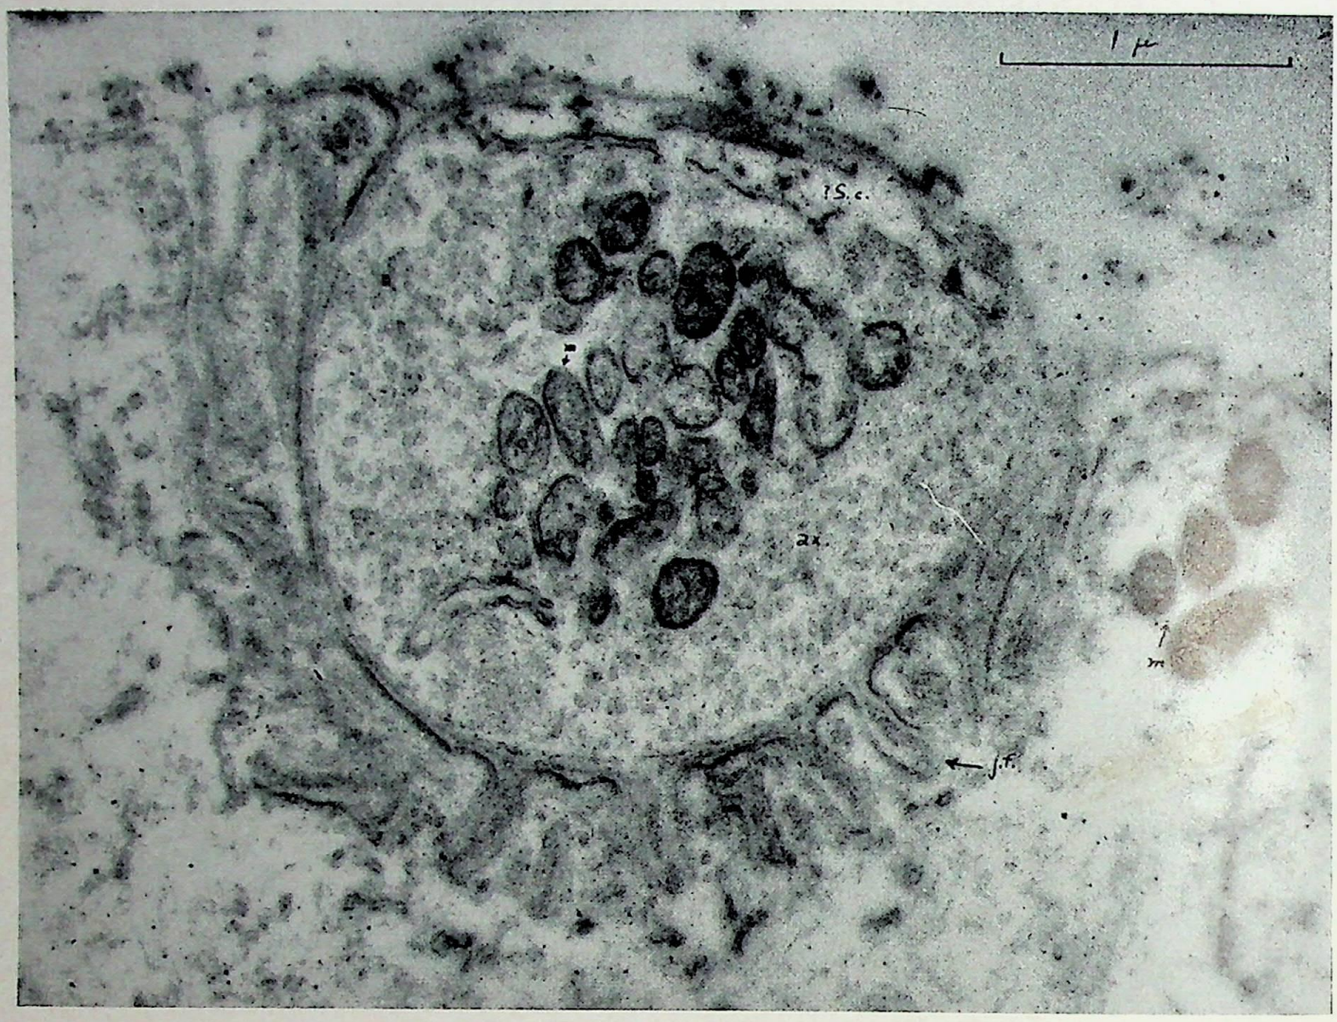

FIG. 7. Electron micrograph of a reptilian neuromuscular junction. Diameter of the motor-nerve ending is approx 2.5 μ; it contains, in addition to mitochondria (large dark particles), many small vesicles of a few hundred A units diameter [from J. D. Robertson, J. Biophys. Biochem. Cytol. 2, 381 (1956)].

mitter is normally delivered from the nerve endings, has been shown in several kinds of experiments. The release of ACh by an impulse depends upon a number of "co-factors" which can be varied experimentally: among these perhaps the most important are the concentrations of calcium and magnesium in the surrounding fluid. Calcium is an essential adjuvant, magnesium an inhibitor of the release mechanism. By lowering the calcium and raising the magnesium concentrations, the quantity of ACh liberated during an impulse, and the size of the resulting e.p.p., can be progressively reduced towards zero. The point of interest is that, during such an experiment, the e.p.p. at each individual end plate is found to be diminished in discrete steps, which correspond to the dropping out of individual miniature potentials, one by one. With a suitable ratio of Ca/Mg concentrations the liberation can be reduced to a small number of ACh packets;[10] in this condition, the size of the end-plate potential during successive nerve impulses has been found to fluctuate in a characteristic stepwise manner, corresponding to a Poisson-wise distribution of the number of units released in each instance.[11,12] The unit-step is identical with the spontaneously occurring miniature potential. Examples are shown in Figs. 3–5, Fig. 6 showing the method whereby Fig. 5 is obtained; detailed studies of this effect on a variety of vertebrate nerve-muscle junctions have made it certain that transmission is brought about by a summation of many of these quantal units of activity.

A further point of interest is that the size of the unit parcel of ACh which is delivered from the nerve endings, spontaneously or in response to an impulse, is relatively constant at all cell junctions and apparently quite unaffected by the many changes which may be imposed on the system in the course of an experiment. On the other hand, the probability of release of any one parcel in a given time interval—that is, the frequency of the miniature potentials—can be altered by several orders of magnitude, for example, by electrically depolarizing the nerve ending with a steady current, or by changing the chemical composition of the environment. The action of the nerve impulse itself can be described as causing a momentary enormous increase in the frequency of the miniature potentials (by a factor of nearly 10^6, provided a high Ca/Mg ratio exists in the surrounding medium).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

The basis of this multimolecular quantum of ACh release is not yet known; an attractive suggestion is that the transmitter substance is stored, within the nerve endings, in minute intracellular corpuscles from which it is discharged at the surface in an all-or-none manner.[6,7] Electron micrographs[13,14] have revealed a mass of fairly densely packed so-called vesicles inside the nerve terminals, and it is conceivable that these are the intracellular bags in which ACh is being stored prior to its release (Fig. 7). It is possible to imagine mechanisms by which a collision between such particles and certain critical spots in the nerve membrane could bring about sudden liberation of the vesicular contents straight into the synaptic cleft. But while it is easy to present speculations which are compatible with the existing evidence, to put them on a firm experimental basis will be a much more difficult task.

Some Quantifiable Aspects of the Electrical Activity of the Nervous System (with Emphasis upon Responses to Sensory Stimuli)*

WALTER A. ROSENBLITH

Department of Electrical Engineering and Research Laboratory of Electronics, Massachusetts Institute of Technology, Cambridge 39, Massachusetts

IN assessing the sensory performance of higher organisms (Rosenblith, p. 485), a certain number of characteristics emerge that suggest problems for a quantitative study of the electrical activity of the nervous system. In considering organisms engaged in communication tasks, it has been seen (a) that their performance is statistical in character; (b) that they need more time to handle more information; (c) that their capacity to discriminate and their speed of reaction depend on stimulus intensity; and (d) that their repertory of absolute identifications ("span of absolute judgment") is relatively small and seemingly based upon the ability to make several rather crude discriminations simultaneously, i.e., to classify environmental sensory inflow into some rather gross categories. One is thus led to examine the electrical phenomena in the nervous system in their statistical aspects and to look for over-all, i.e., relatively gross patterns of electrical behavior such as those exhibited by populations of neurons at various levels of a sensory system, rather than to attach disproportionate significance to the behavior of isolated members of such populations. By choosing this quasi-thermodynamic approach, it is not intended to deprecate the complementary view that derives its inspiration from statistical mechanics. But, it must be emphasized that we do not know how to sample a population of neural units adequately (it is far from easy to define a "typical" unit when experimenting with a single microelectrode), and that there is much to be learned of the laws of interaction between units that presumably belong to a population.

It is from this viewpoint that data are presented in this article on (a) electrical responses evoked by sensory stimuli and on (b) so-called on-going activity; the latter may be thought of as reflecting an organism's "state" as it reacts selectively to sensory stimulation.

SCHEMATIC FLOW CHART OF A MODEL SENSORY SYSTEM

It is obviously impossible to deal here realistically with the neuroanatomy of those structures in the nervous system that become involved when a sensory stimulus is presented. It may, therefore, be expedient to start the discussion by presenting, in Fig. 1, a highly oversimplified view of a model sensory system. *Pour fixer les idées*, consider the auditory system, which is perhaps the one for which the greatest amount of quantitative data is available.

A stimulus impinges upon the organism: The appropriate transducer (here located in the inner ear) is activated, and electrical activity is generated in the region of the hair-cell-neural junction.[3] If the stimulus is a "transient," certain subsequent electrical phenomena at the various higher levels of the nervous system are comparatively easy to follow, and both amplitude and temporal characteristics of responses at various locations can be measured with accuracy.

Once the electric signal has entered the organism's nervous system, it is possible for it to ascend the classical afferent pathway to the cortex. The route can be represented schematically by straight segments in the nature of nerve tracts; these alternate with circles that symbolize the main relay stations of the pathway. Along the axons of the longitudinal tracts, the transmission of signals is predominantly in the form of conducted nerve impulses (all-or-none activity or "spikes"). Transmission is one-to-one in the sense that a given axon exhibits identical patterns of "spikes" along its entire length. The relay stations exhibit activity that has both "discrete" and "continuously graded" aspects. It is in these regions that both excitatory and inhibitory synaptic junctions play an important integrative role by permitting interactions of the many-to-one and perhaps also one-to-many type.

One of the more significant features of the flow chart of Fig. 1 is that it depicts, in parallel with the classical afferent pathway, another route that leads—via the brain-stem reticular formation—to the cortex. In his recent book,[4] Magoun characterizes the reticular system as follows:

"From recent study of the brain stem . . . the concept has developed of a major non-specific or transactional mechanism in the brain, paralleling the specific sensory and motor systems of classical neurology and richly interconnected with them. This non-specific neu-

* This work was supported in part by the U. S. Army (Signal Corps), the U. S. Air Force (Office of Scientific Research, Air Research and Development Command), and the U. S. Navy (Office of Naval Research).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

ral system is distributed through much of the central core of the brain stem and, as spokes radiate from the hub of a wheel to its peripheral working rim, so functional influences of this central system can be exerted in a number of directions: caudally upon spinal levels to influence both reflex and other spinal activity; rostrally and ventrally upon hypothalamic and pituitary mechanisms through which influences can be exerted upon visceral and endocrine functions; cephalically upon the diencephalic and rhinencephalic brain, where affect and emotion now reign instead of in the heart; and, more cephalically and dorsally still, upon the neocortex of the cerebral hemispheres which, with its interconnected thalamic and basal ganglionic masses, subserves higher sensory motor and intellectual performance. The influences of this non-specific system in the brain stem are thus brought to bear upon most other portions and functions of the central nervous system, either to diminish or to raise the level of their activity, or to interrelate or integrate their several performances." . . . "It does this as a reflexion of its own internal excitability, in turn a consequence of both afferent and corticifugal neural influences, as well as of the titer of circulating humors and hormones which affect and modify reticular activity."

Relatively few of these properties are depicted in Fig. 1. Yet there can be seen collaterals that branch off from the afferent pathway to furnish the reticular system with information regarding the signals that are being processed along the more direct and specific route. There is also an indication that this system receives impulses from all sensory modalities, i.e., both from the *milieu extérieur* and the *milieu intérieur*. And there are indications that the flow of neural signals for even a single sensory modality is not just one-way in the reticular system, i.e., directed toward the cortex; there are important descending pathways whose functional significance is just beginning to be understood.

It is perhaps somewhat surprising to learn that neuroanatomists have given descriptions of the reticular system before the beginning of the twentieth century, but that it was only after Bremer's experiments of the midthirties, and in particular after the now classical Moruzzi-Magoun experiments[5] on the "Brain stem reticular formation and activation of the EEG" (1949), that this system began suddenly to loom large in the understanding of all integrated behavior. Previous to that period (and even in a large number of experiments performed since then, in the fifties), the use of centrally acting anesthetics has resulted in differential interference with reticular activity. Under these circumstances, most explanations of the role which the nervous system plays in perception or in the handling of sensory information are based on evidence from, neurophysiologically and behaviorally speaking, badly distorted preparations.

Among the more dramatic findings that have forced one to give up oversimplified views of the organization

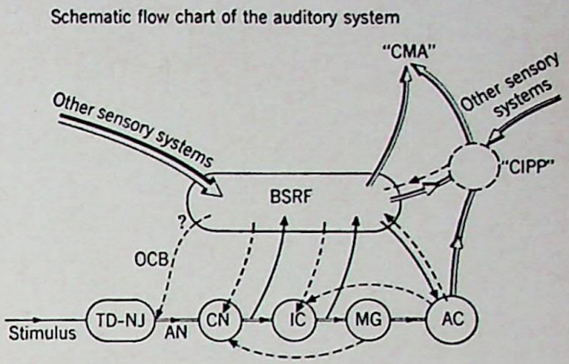

FIG. 1. For the sake of simplicity, this diagram presents only a gross outline of the neuroanatomy of the auditory system. Such important way stations as the cerebellum, the superior olive, the lateral lemniscus, and other regions of the brain from which responses to acoustic stimuli have been recorded have been left out; the still incompletely known and complex organization of the brain-stem reticular formation (BSRF) has not even been suggested. Furthermore, no attempt has been made to indicate connections that correspond to acoustic reflexes of short latency: middle ear muscles contract about 10 msec after stimulus delivery, while eye blinks occur about 35 to 40 msec after delivery of a strong click; such reflexes represent simple forms of integrated behavior that do not necessarily involve the higher levels of the auditory system.

In order to appreciate the number of neural elements present along the afferent pathway, Chow's[1] numerical estimates of the auditory system of rhesus monkey are reproduced here. There are about 10^5 cells in the cochlear nucleus (CN), about 4×10^5 cells in the inferior colliculus (IC) and also in the medial geniculate (MG); the auditory cortex (AC) is estimated to contain about 10^7 cells; these numbers, which represent orders of magnitudes only, may be compared with the 3×10^4 fibers in the auditory nerve (AN) and the 2.5×10^4 hair cells in the inner ear, i.e., at the transducer neural junction (TD-NJ). The foregoing data are the results of histological investigations; hence, they do not permit any direct inference concerning the number of neural units that will be either directly excited or inhibited in the presence of a stimulus of given intensity.

The remaining symbols are to be identified as follows: OCB stands for the olivo-cochlear bundle (depicted in dashed lines like the other descending pathways) whose influence upon the activity of the auditory nerve has been investigated by Galambos,[2] CIPP stands for the central information-processing pool of neurones, whose existence, though neither neuroanatomically nor neurophysiologically established, is conceptually useful. The relations of this hypothetical construct to the sensory-projection areas and association areas remain to be worked out to give a more realistic account of the role that the brain and its various components play in the organism's handling of sensory information. CMA stands for the inferred control unit of the motor activity that takes place in connection with the stimulus-related response.

and functioning of sensory systems have been the following: (a) sectioning of the classical auditory ascending pathway was shown to leave intact an animal's ability to be aroused by sound; (b) animals whose auditory cortex had been ablated were shown to be capable of simple frequency and intensity discriminations, though they were not capable of distinguishing more-complex patterns such as simple melodies. Experiments of this sort should, however, not be interpreted to mean that the anatomical structures that can be removed or interfered with play no role in the normal performance of sensory tasks. There are certainly different ways of assessing impairment of performance, and the mere statement that an animal is still capable of carrying out a given task, after ablation, does not force the conclu-

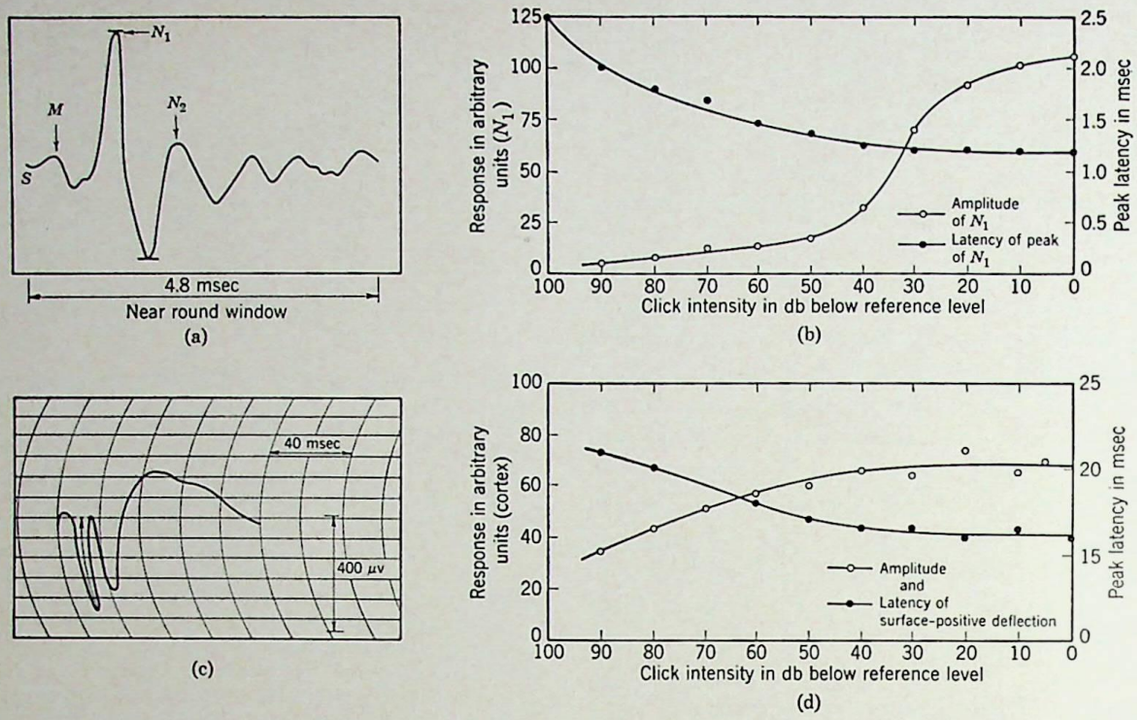

FIG. 2. (a) A typical response to a click of medium intensity recorded near the cat's round window of the inner ear. M is a so-called microphonic potential which is non-neural in origin. N_1 is the earliest and most prominent neural component that can be recorded at this location. It represents the summated action potentials from the auditory nerve. S indicates the occurence of the electrical pulse that generates the acoustic click. (b) An example of how the amplitude and latency of N_1 vary as the intensity of the click is varied. The latency values include a delay of approximately 0.5 msec that corresponds to the time that it takes for the sound to travel from the earphone diaphragm to the eardrum. (c) An average response to a click recorded from a location on the auditory cortex of an unanesthetized cat. The averaging operation was carried out by an electronic computing device.[14] Surface positive deflections are plotted downward. (d) Intensity functions for the baseline-to-peak amplitude and the peak latency of the surface positive component of the cortical response to clicks in an anesthetized cat.

sion that there is no sensory deficit. More generally, one is impressed with the fact that the nervous system of higher animals seems to be characterized by enough flexibility (which some people have metaphorically referred to as a "safety factor" or "redundancy") so as to permit the performance of certain rather basic discriminations in a variety of ways.

For a long time students of the nervous system have wondered how its flexibility manages to deal with sensory stimuli, when they are in the focus of the organism's attention in contrast to situations in which they seem to be of no importance. Adrian formulated this question most incisively at the 1954 Symposium on *Brain Mechanisms and Consciousness*[6]:

"The operations of the brain seem to be related to particular fields of sensory information which vary from moment to moment with the shifts of our attention. The signals from the sense organs must be treated differently when we attend to them and when we do not, and if we could decide how and where the divergence arises, we should be nearer to understanding how the level of consicousness is reached. The question is whether the afferent messages that evoke sensations are allowed at all times to reach the cerebral cortex or are sometimes blocked at a lower level. Clearly we can reduce the inflow from the sense organs as we do by closing the eyes and relaxing the muscles when we wish to sleep and it is quite probable that the sensitivity of some of the sense organs can be directly influenced by the central nervous system. But even in deep sleep or coma there is no reason to believe that sensory messages no longer reach the central nervous system. At some state therefore on their passage to consciousness the messages meet with barriers that are sometimes open and sometimes closed. Where are these barriers, in the cortex, the brainstem, or elsewhere?"

The schematic flow diagram of Fig. 1 suggests, in agreement with the beautiful experiments that have been carried out since 1954, that the barriers that Adrian refers to are at no single place in the nervous system, but that they are multiple. This is clearly not the place to review in detail the experiments carried out by Hernández-Peón[7] and many others.[8–13] Suffice it to report that all of these experiments indicate that the descending pathways exercise powerful gating, screening, and regulating influences. This central or centrifugal control of the afferent sensory inflow has been demonstrated to be effective across sense modalities (for example, the presence of a mouse or of fish odors reduces the response to a click at the level of the cat's cochlear nucleus) or during "habituation" (which presents itself as a reduction in the amplitude of evoked responses for stimuli that have been repeated over and over again). This effect of habituation can, however, be suddenly abolished by pairing the "boring" stimulus judiciously with a few electric shocks. From the available evidence

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

(these dramatic effects of attention and habituation are, for instance, not found in anesthetized animals), one is led to conclude that the selective processing of the sensory inflow is under the control of the brain stem or of descending pathways that are structurally or functionally closely related to the reticular system. Much remains to be learned about the precise ways in which the informational aspects of a sensory signal affect its progress in the nervous system, but it is already clear that sensory systems cannot be characterized by invariant sensitivity and invariant "tuning."

EVOKED RESPONSES ALONG THE AFFERENT PATHWAY

Having discussed the schematic flow chart and some of the phenomena that led to its formulation, it is now necessary to admit that most of the quantitative data that exist deal with electrical events along the classical afferent pathway. This admission should give one a more realistic appreciation of what the phenomena are for which there exist functional relations of the stimulus-response type. What follows should, therefore, be merely considered as an introduction to some problems of recording, data-analysis, and model-making in relation to the electrical activity found at various levels of the nervous system.

The left side of Fig. 2 depicts samples of responses to clicks from populations of neural units at the level of the auditory nerve and at the level of the auditory cortex. As indicated, it is possible to make quantitative measurements along both the voltage and the time axes of these displays. Thus, one can measure amplitudes of deflections (either peak-to-peak or baseline-to-peak) and "latencies" (i.e., time intervals that have elapsed since the delivery of the stimulus) of extreme values or zero crossings. Naturally, the characteristics of the recording equipment must be chosen appropriately. It would be futile if one were to attempt to measure accurately either the latency or the amplitude of rather sharp deflections on the ink tracings taken by the customary EEG recording device.

When such amplitudes or latencies are measured, one must ask whether one shall be satisfied with average values or whether one shall need to know entire distributions in order to be able to give a rational account for the neuronal events. As has been shown by McGill,[15] Macy,[16] Frishkopf[17] and others, evoked responses are afflicted with variability, especially in regard to amplitude and particularly at the higher neural centers unless the animal is rather heavily anesthetized. It is important to realize that this variability of evoked responses to identical stimuli is present in spite of the fact that the gross electrodes that record the activity of reasonably large neural populations are already performing an averaging process. Some studies of the variability of evoked responses in anesthetized preparations have been undertaken[16–18] and have yielded results that

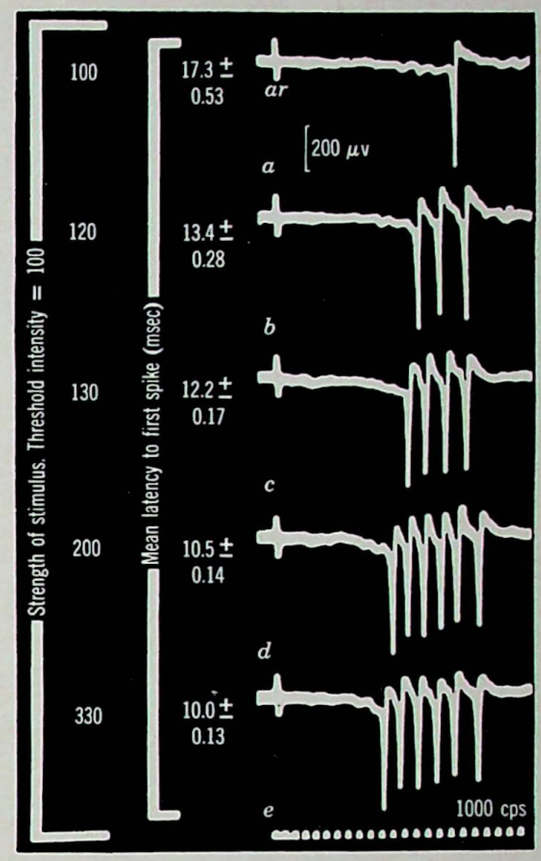

FIG. 3. Responses of single units in tactile thalamic region to transient electrical stimulation of forepaw. Position of stimulation is unchanged for all records. Numbers in column at extreme left give a measure of stimulus strength. Numbers in second column indicate (in msec) mean latency to first spike and standard error of the mean for each stimulus intensity. The records in the right-hand column depict the modal value of the number of spikes that are recorded for each intensity. The short vertical line at the left of each response trace indicates the delivery of the electrical stimulus [from J. E. Rose and V. B. Mountcastle, Bull. Johns Hopkins Hosp. 94, 238 (1954)].

are suggestive from the viewpoint of probabilistic models.

On the basis of amplitude and latency measurements, one can plot intensity functions, i.e., functions that relate the average amplitude of characteristic deflections and their average latency to the intensity of the stimulus. Figures 2(b) and 2(d) illustrate such functions. These and similar graphs permit one to state the following generalization: As the intensity of a transient sensory stimulus is increased, the average amplitude of evoked responses increases (or at least does not decrease), and the average latency of either the onset or the peak of the deflection decreases. [Parallel generalizations can, of course, be formulated for single neural units (see Figs. 3 and 4, from Rose and Mountcastle[19]).] The detailed shape of these intensity functions varies for different locations in the nervous system and for different stimuli, and it is, therefore, hardly appropriate to search for a unique representation of stimulus intensity in the nervous system.

It must be noted that the quantification process just described runs into difficulties if stimuli of appreciable

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

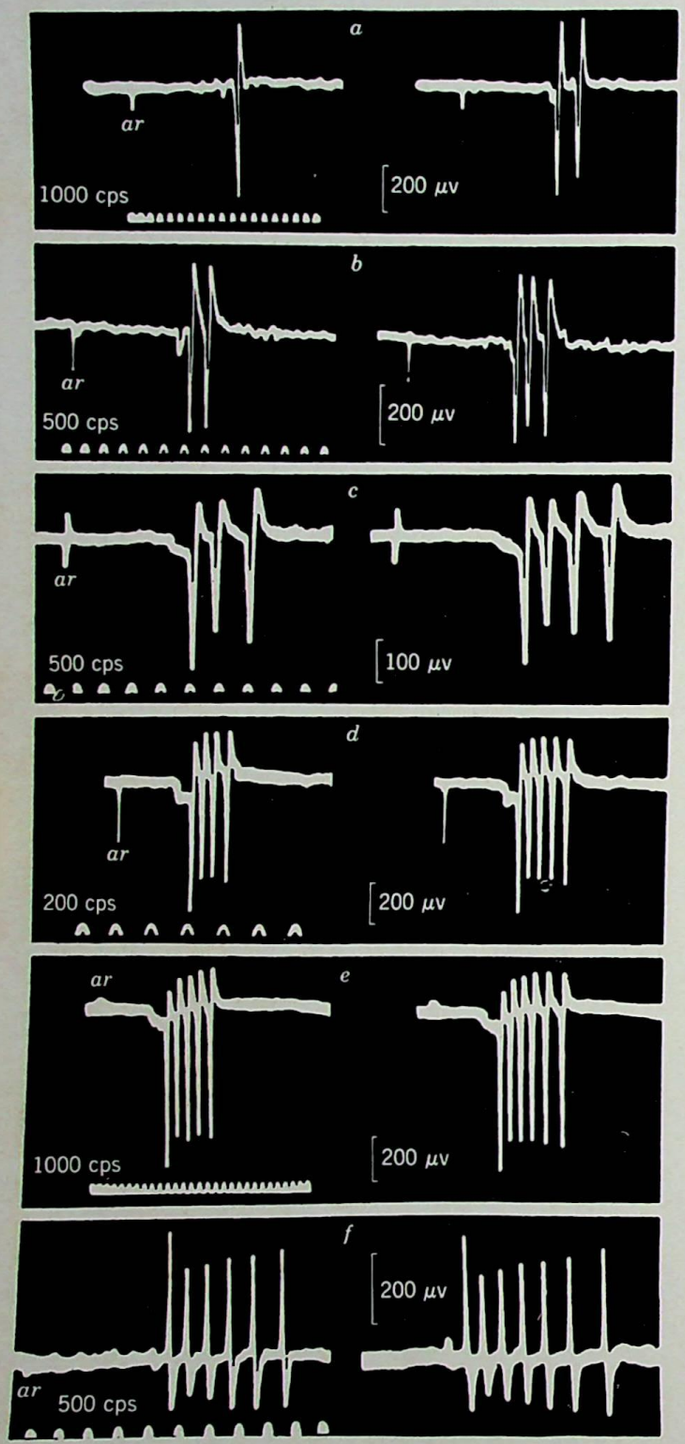

FIG. 4. Each pair of records comes from the same unit. All six units were activated by electrical stimulation of different locations on the skin. The stimulus artefect (*ar*) indicates the instant of stimulus delivery [from J. E. Rose and V. B. Mountcastle, Bull. Johns Hopkins Hosp. 94, 238 (1954)].

duration are used. Thus far, it has not been possible to suggest, especially for the higher neural centers, meaningful measures of the evoked activity on the basis of visual inspection only. It is by no means certain that simple intensity functions will be obtained for all instants during which the stimuli are "on"; the interaction of excitatory and inhibitory phenomena, as well as various adaptation phenomena, can be counted upon to complicate the picture.

Before dealing with microelectrode data on the behavior of single units at various way stations of the nervous system, mention should be made of the series of mathematical models developed by McGill,[15] Frishkopf,[17] Goldstein,[20] and Macy.[16] These models, which are all probabilistic in character, relate certain aspects of gross-electrode responses (i.e., responses to which populations of neural units have contributed) to stimulus parameters. All of these models make certain, physiologically not unreasonable, assumptions regarding the behavior of single units in the auditory nerve or at the auditory cortex. From these postulated properties and from certain assumptions regarding the interaction between various members of a population of neural units, the behavior of population responses (i.e., evoked responses recorded by gross electrodes) can be predicted and compared with experimentally available data. The response parameters that have been investigated include average amplitudes, variability in amplitude, wave form of a population response, and temporal recovery characteristics. The stimuli were clicks or bursts of noise: these were presented either singly or in pairs (or even triplets), either in the absence or in the presence of background noise. While it is obviously premature to forecast the ultimate success of such model-making, it is safe to assert that the models have demonstrated their usefulness in summarizing sizable quantities of experimental data and in suggesting systematic experimentation in an area wherein workers seem only too often satisfied by demonstrating the existence of phenomena. These models force one, furthermore, to face an issue that may well be critical for the understanding of the organization of the nervous system: What is the relationship between the behavior of the components that can be studied (single cells), the behavior of subsystems (made up of more or less homogeneous populations of single units), and the behavior of an entire sensory system? For it is hardly reasonable to expect that the knowledge of the functioning of the brain will be revealed *in toto* in the absence of a working knowledge of principles of organization of functional units of the brain.

PATTERNS OF ELECTRICAL ACTIVITY IN SINGLE UNITS OF SENSORY SYSTEMS

Over twenty years ago, first Blair and Erlanger[21] and then Pecher[22] showed that, under carefully controlled conditions, a single nerve fiber will sometimes respond and sometimes not respond when the same stimulus is presented repeatedly. They furthermore showed that, at least to a first approximation, spike responses in fibers that belonged to the same nerve trunk were statistically independent. In 1950,[23,24] it was shown that the probability of response to a click of a single unit in the cochlear nucleus of the cat increases from "almost never" to "almost always" as the stimulus energy was multiplied by a factor of approximately 100 (or 20 db);

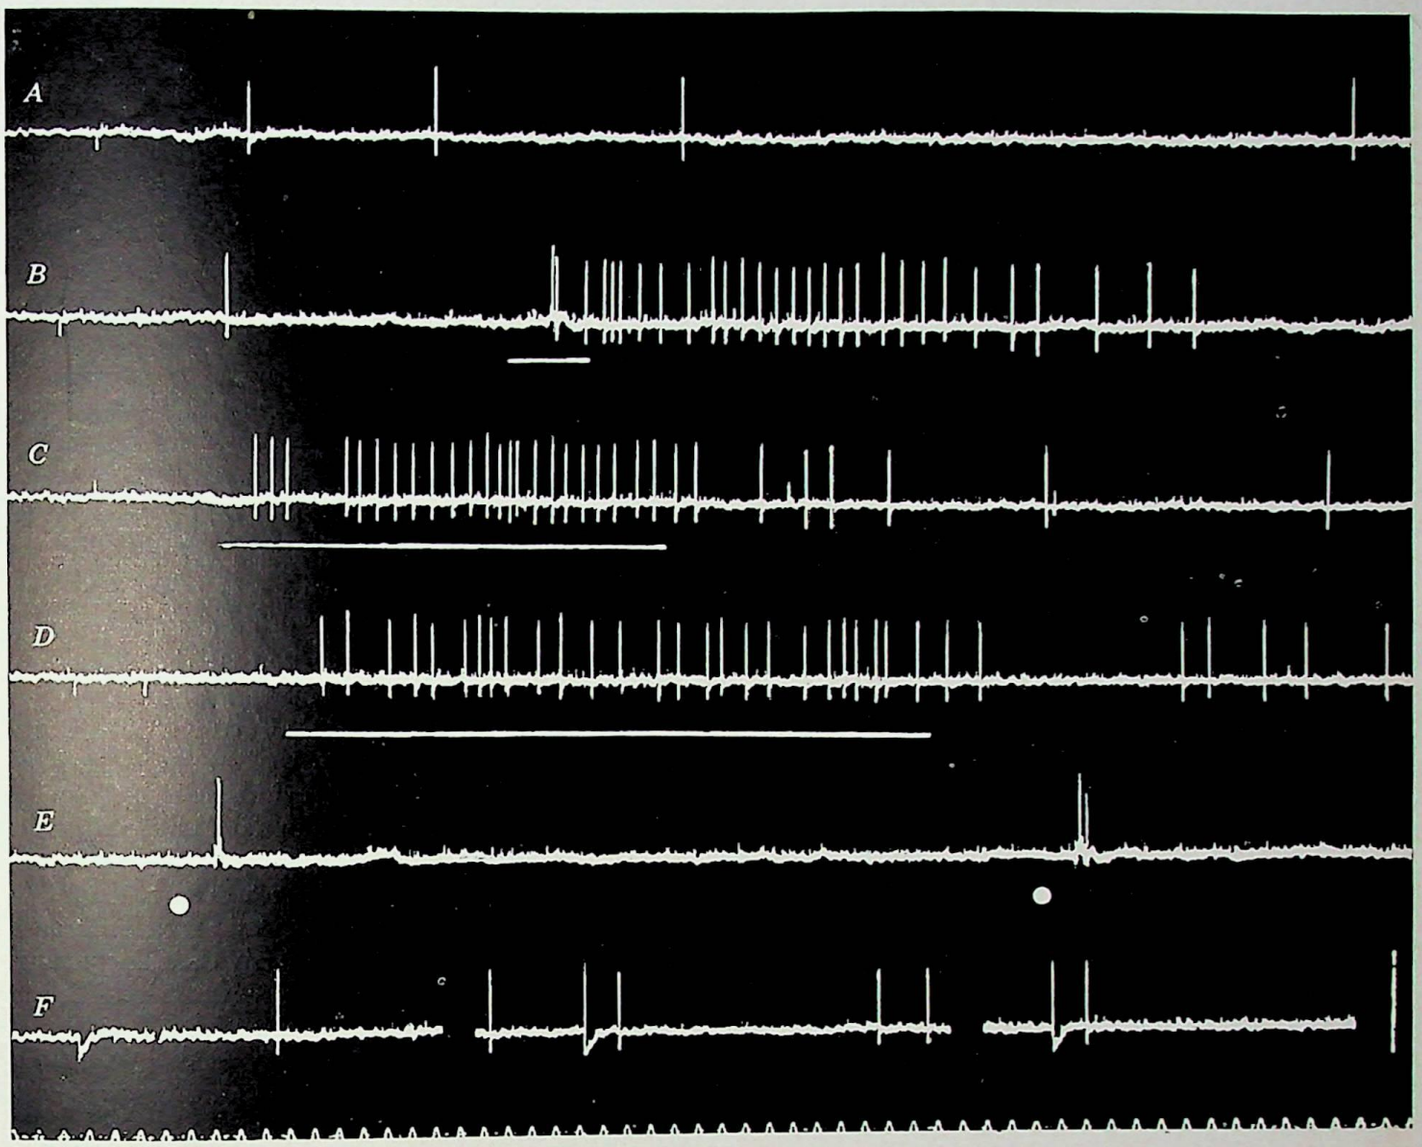

FIG. 5. Microelectrode recording from a unit in the medial part of the pontine reticular formation of a cat: *A*, spontaneous activity; *B*, tapping the ipsilateral forelimb; *C*, rubbing the animal's back; *D*, touching the cat's whiskers; *E*, hand claps; *F*, single shocks delivered to the animal's sensorimotor cortex. Delivery of stimuli is indicated by white horizontal lines (*B*,*C*,*D*), dots (*E*), and artifacts that displace the record's baseline (*F*). Time calibration at the bottom of figure indicates 10-msec intervals [from M. Palestini, G. F. Rossi, and A. Zanchetti, Arch. Ital. Biol. **95**, 97 (1957)].

at the same time, the latency of the spike response that is elicited decreases substantially. Since then, a considerable amount of such data has become available for different structures in the nervous system.[25,26]

Rose and Mountcastle[19] have given some of the most beautiful records that are available today. These records illustrate the finesse and the subtlety with which the nervous systems can "code" stimulus intensity into response patterns of single cells. These workers stimulated the skin of cats electrically and recorded the activity of single neurons in the thalamic relay nucleus of the cat's tactile system. Figure 3 shows how the number of spike responses increases and the latency of the first spike decreases as the strength of the transient peripheral stimulus is increased. Measurements of intervals between spikes yield such interesting results as: (a) Units start to fire at a rate which is higher, the larger the number of spikes in a train of repetitive discharges. (b) The interspike interval increases throughout a train and firing ceases when the interval exceeds a value such as 2 msec.

Figure 4 shows, in each horizontal subdivision, pairs of responses from the same unit to identical stimuli. These discharges are again all-or-none in character and, in spite of the fact that their height (amplitude) varies within a given train, there is overwhelming evidence that all spikes in a single train come from the same unit. This figure furnishes striking evidence for the view according to which the variability in response patterns of single units to identical stimuli renders their statistical description imperative.

Figures 3 and 4 represent locations in the modality-specific classical afferent pathway. The next record, taken in Moruzzi's laboratory (Fig. 5, from Palestini *et al.*[27]), illustrates, in contrast, the response pattern of a single unit in the brain stem.[28] This unit was responsive

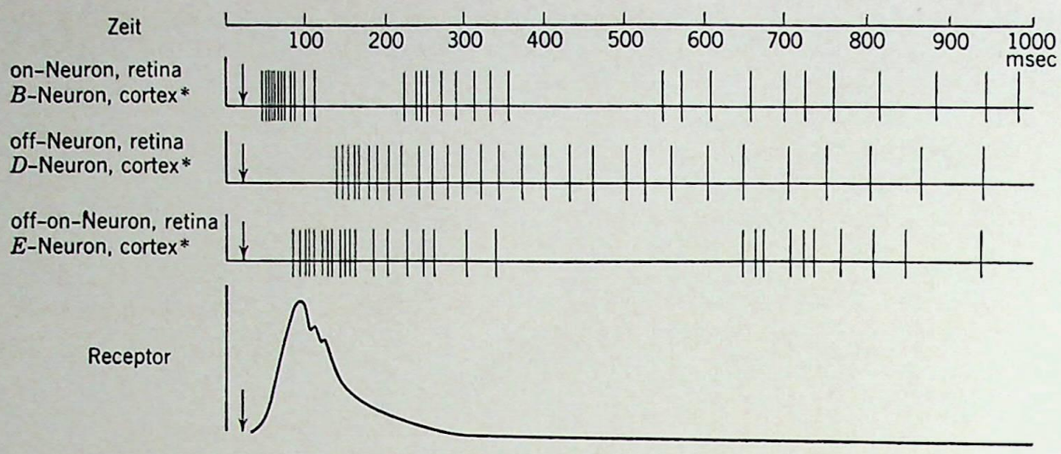

FIG. 6. Typical patterns of unitary discharges in the cat's visual cortex in response to a short flash of 3000 Lux; the bottom trace shows a typical electroretinogram that is observed at the same time. Arrow indicates delivery of flash; the *B*-, *D*-, and *E*-neurons reflect, to a certain degree, patterns of retinal excitation (on, off, and on-off). The pattern of activity of the *B*-neuron—i.e., an initial burst followed by a pause of about 0.1-sec duration—is found in other sensory systems (after O. J. Grüsser and A. Grützner[29]).

to all test stimuli that were tried, although the pattern of spike activity was rather different for the different modalities.

The next microelectrode record (Fig. 6) demonstrates that some of the response patterns that can be observed in sensory systems are discernible over time intervals whose length is comparable to behavioral reaction times. Jung and his group[30] distinguish four different types of neurons in the visual cortex on the basis of their activity patterns. Figure 6 describes schematically three of these typical patterns. The fourth pattern, which corresponds to the so-called *A*-neuron, is not represented. Actually, more than one-third of the units in the visual cortex from which records have been obtained fail to yield visually detectable changes in their spontaneous activity after delivery of an optical stimulus.† There is, however, some evidence that these units may exhibit some kind of responsiveness, provided a form of optical stimulation is used that attracts the animal's attention..

From the highly selected evidence that has been presented in Figs. 3 to 6, a certain number of conclusions impose themselves regarding the strategy of future model-oriented research in this area. New recording devices and new techniques of analysis are needed. One must be able to record simultaneously the firing patterns of not one or two cells but of significant assemblies and subassemblies of cells. Gross electrodes permit the recording of potentials that are very coarse spatio-temporal averages of both spike and continuously graded

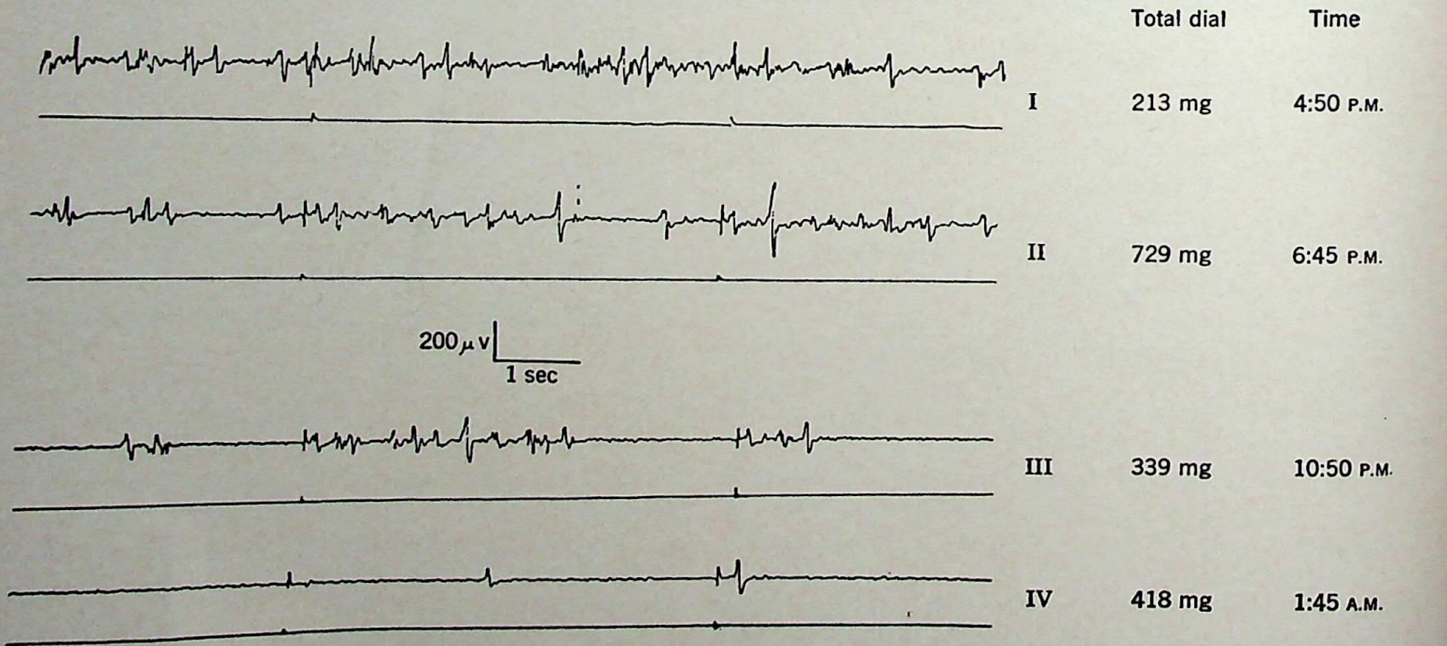

FIG. 7. Four tracings (I, II, III, IV) of electrical activity by a gross electrode from the auditory cortex of a cat. These records were taken during the presentation of clicks. The delivery of the stimuli is indicated on the accompanying lower traces. Depth of anesthesia increases from I to IV, as the amount of dial administered is increased.[32]

† Erulkar, Rose, and Davies[31] found, likewise, that about one-third of the units in the auditory cortex was unresponsive to acoustic stimulation.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

activity. The time has now come for solid-state recording devices that will permit the exploration of what might be called the "domain-structure" of sensory systems. It would, however, be foolish to expect that the data from 10 or 50 inputs could be handled adequately without the help of digital computers of appreciable capacity. One cannot be satisfied with visual inspection of records if one wants to find out whether unit X responds most of the time only if units Y and Z are inhibited or after units A, B, and C have fired in a certain order and separated by certain time intervals.

DETECTION OF EVOKED RESPONSES IMBEDDED IN BACKGROUND ACTIVITY

In recent years, as neurophysiologists attempted to study cortical responses to sensory stimuli in animals that were, physiologically speaking, in a "more normal" state, two problems arose: First, it became more difficult to detect the evoked responses that were now imbedded in a much livelier background activity of the cortex than had been observed in the previously used, deeply anesthetized preparations. Second, it became important

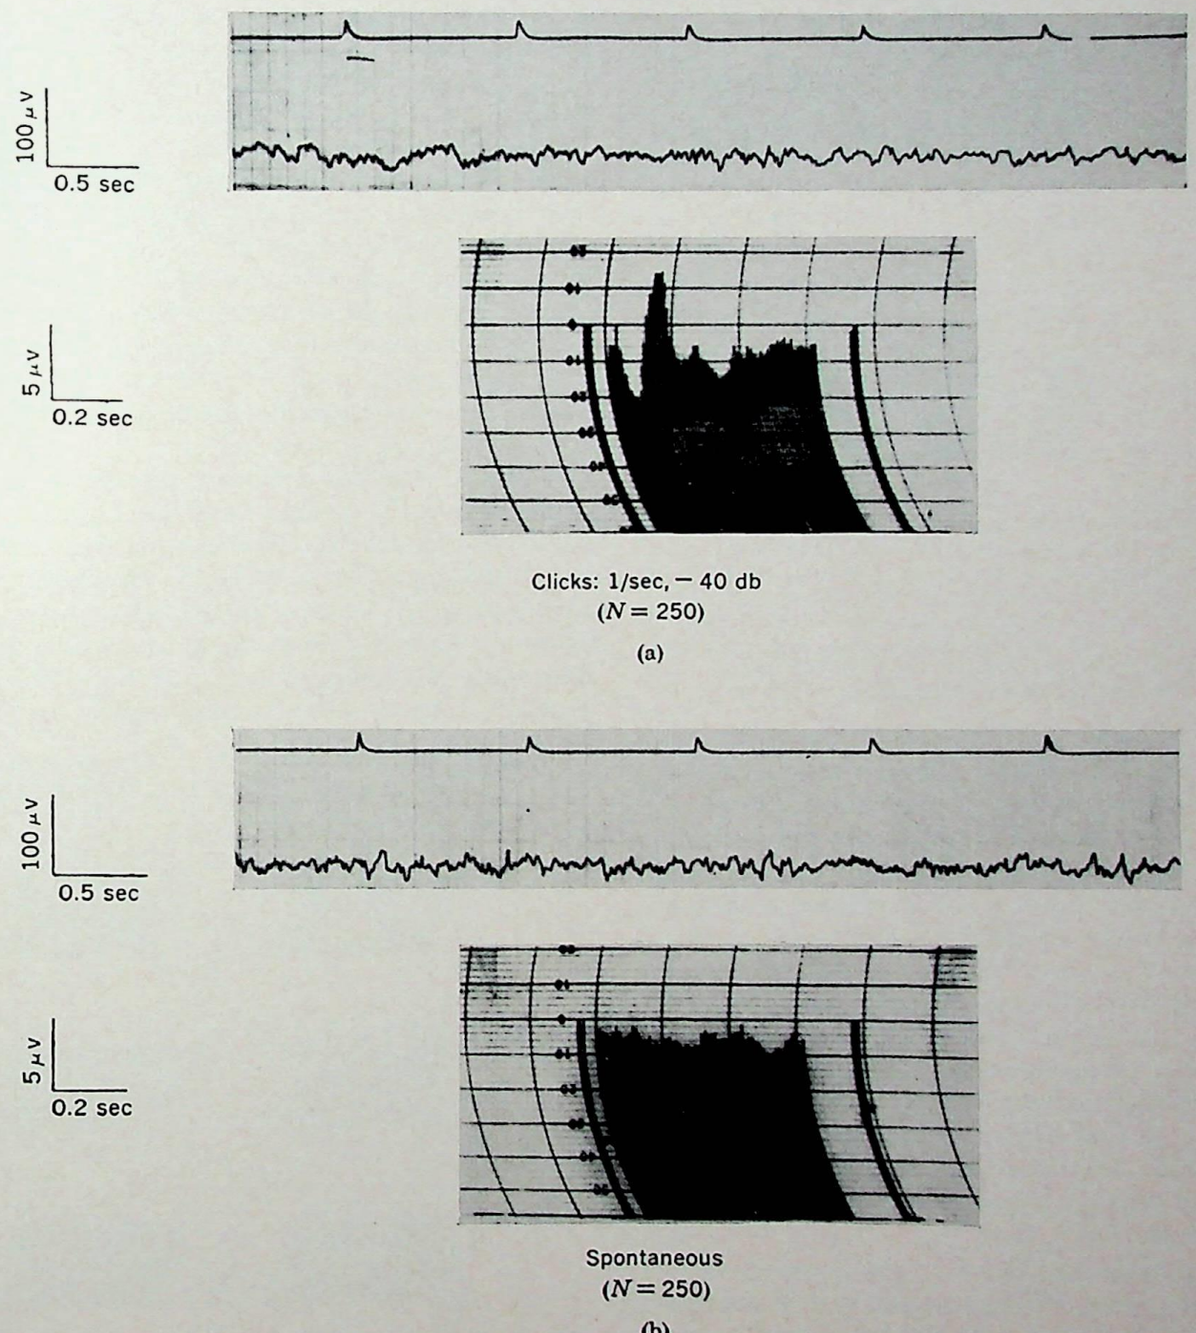

FIG. 8. The upper records of (a) and (b) show ink traces obtained from the skull (vertex) of human subjects (a) in the presence of clicks and (b) in the absence of clicks. The pulse channel, recorded simultaneously, indicates in (a) the instants at which clicks were delivered and in (b) serves as a comparable time reference. The lower records are the average wave forms obtained, by a process of cross correlation of the signal with a series of brief pulses,[14] from a sample of 250 intervals of which 5+ are shown in the ink records directly above. The average wave forms are the envelope of a series of closely spaced lines (10 msec).[33]

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

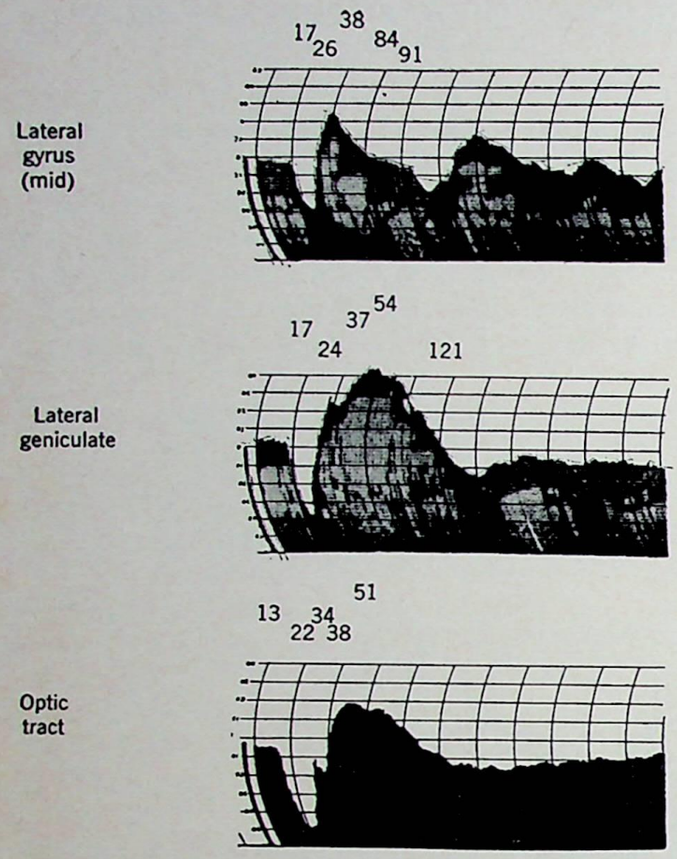

FIG. 9. Averaged responses to flash from three stations in the visual pathway of a cat; simultaneous recordings under moderate pentobarbital anesthesia with reference lead on the back of the neck. The average response is the envelope of a series of pen deflections separated by intervals of 1 msec. The delivery of the flash coincides with the first of the continuous series of pen deflections. The numbers above each average response are the latencies of characteristic points in the particular wave form [from M. A. B. Brazier, Acta Physiol. Pharmacol. Neerlandica 6, 692 (1957)].

to find ways of characterizing this background activity in a more than impressionistic manner.

Figure 7 illustrates the first problem by demonstrating how additional doses of anesthetic make it much easier to detect the "signal" (the evoked response) in the much diminished background activity that can, however, hardly be called "noise." Raab and Kiang[32] were actually looking for correlations between measures of the activity that preceded the delivery of a stimulus and the size of the evoked response. Their precise results are not of particular import here. It is, however, important to note that the interaction between evoked and background activity of the nervous system is not a problem for which a simple or even a single solution can be assumed.

Having a probabilistic bias in the interpretation of the electrical activity of the nervous system, members of our laboratory have attempted for several years to treat the obtained data in a manner that will yield average responses to sensory stimuli. The reasoning was, qualitatively, somewhat as follows: In the handling of sensory information, organisms behave as if they were acting on the basis of estimates of activity averaged over substantial regions of the nervous system; such a weighted averaging process could be carried out by comparing the outputs of a large number of neural elements. Since there are at present no devices capable of performing this task (even if one knew exactly where and how to perform it), one chooses to average over an ensemble of responses to repeated identical stimuli in order to bring out certain typical aspects of the behavior of the nervous system. Once the "correlator system" (referred to below) was available, it became possible to use it with comparatively slight modifications for the detection of evoked responses.[14] Figure 8 illustrates how this averaged display yields average results that would be hard to foretell on the basis of visual inspection either of ink tracings or of tracings of single responses photographed from the screen of an oscilloscope. Electronic computation of the sort used in our laboratory necessitates the recording of data onto FM magnetic tapes. Such tapes not only contain, in general, the specific responses that are set off by delivery of the stimuli but also offer, especially when multichannel recording is used, a much more representative sample of the organism's electrical activity. Appropriate programming permits the carrying out of different analyses of the recorded data as desired by replaying the tapes as often as is necessary.

Figures 9 (from Brazier[34]) and 10 offer just two examples of how the Evoked Response Detector (ERD) modification of the correlator system was used in the study of the visual[34] and auditory[35] systems. Other problems investigated include: cortical off-responses in the auditory system,[36] the effect of anesthesia upon the wave form of evoked cortical responses,[37] as well as responses to photic stimulation in man.[38]

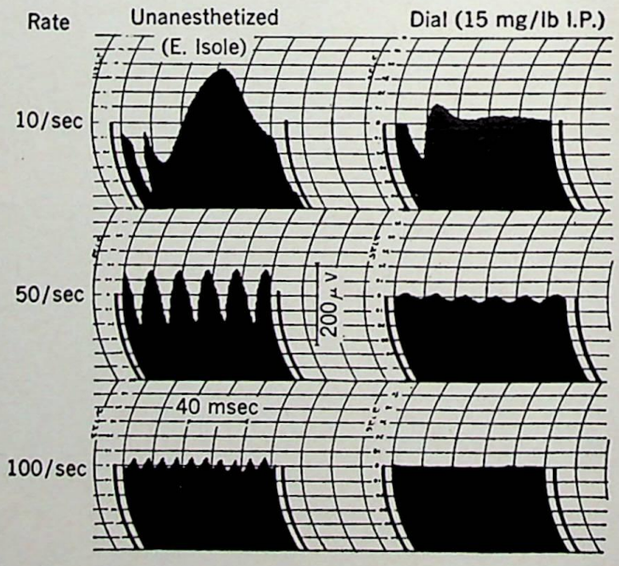

FIG. 10. Averaged cortical responses to repeated clicks (25-db threshold) indicate that the auditory cortex in nonanesthetized preparations is capable of "following" at higher rates. Note, also, the difference in wave form of response in anesthetized and nonanesthetized preparations for 10 clicks/sec. The evoked-response detector averaged the following number of responses at the different rates: 600 responses at 10/sec, 3000 at 50/sec, and 6000 at 100/sec.[35]

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

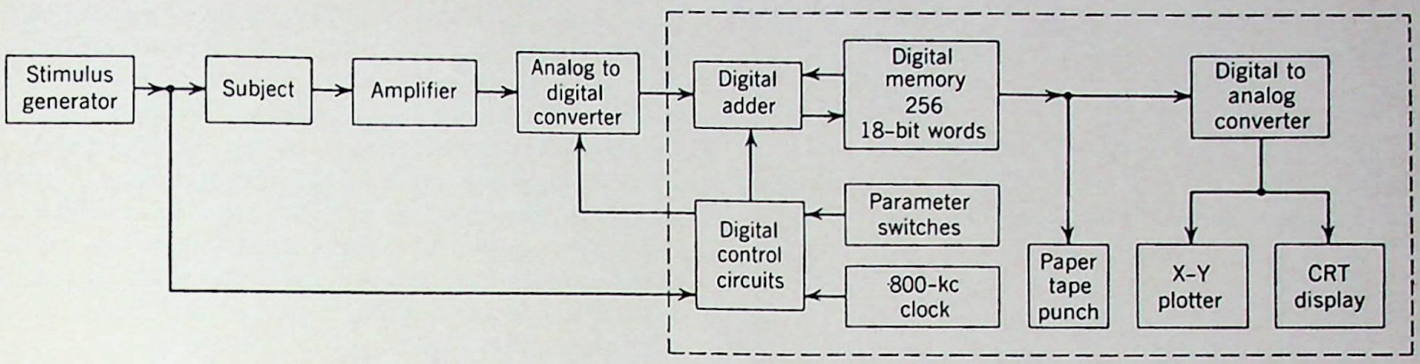

FIG. 11(a) Block diagram of average response computer (ARC-1).

More recently, we have been able to use (thanks to the cooperation of some colleagues at the Lincoln Laboratory) a considerably more powerful special-purpose digital computer, the ARC-1 (Average Response Computer[39]) in these investigations. Perhaps the most significant feature of this transistorized computer is that it computes "in real time" (Fig. 11). Thus, a display can be obtained instantaneously of the average of all response traces including the one just recorded from the animal's or subject's head. This immediate access to knowledge of results offers advantages, especially when as complex a system as the nervous system is being investigated. Without entering into the realm of science fiction, one can foresee experiments in the near future in which an organism and a computer operate in a "closed loop," i.e., in which the organism's response behavior alters the programming of sensory stimuli that the organism is instructed to deal with. With the help of ARC-1, our laboratory has continued (see Fig. 8) a rather exciting study of evoked potentials in man. It has thus been possible not only to record extracranially what appear to be cortical responses to acoustic clicks in many experimental subjects,[40] but also to demonstrate that these electrical responses appear at stimulus intensities that are quite comparable to the subject's absolute psychophysical threshold for clicks (see Fig. 12). Furthermore, it has been noted that the responses disappear near the subject's masked threshold. These findings suggest numerous sensory experiments in which convergent neurophysiological and psychophysical data can be obtained from human beings and are thus in tune with an era of experimentation in which the electrical activity of behaving animals will be recorded by implanted electrodes and broadcast by transistorized transmitters.[41]

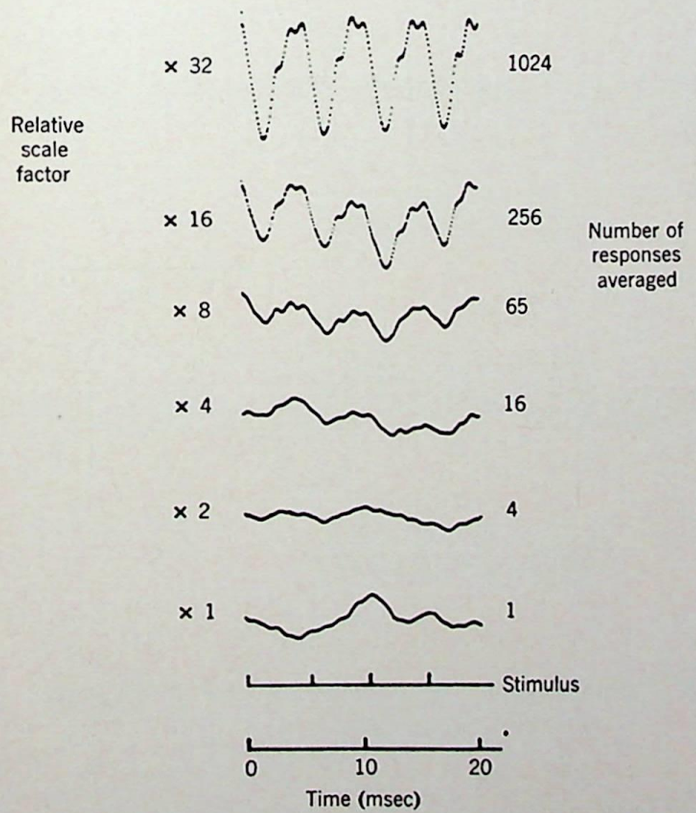

FIG. 11(b). Emergence of an average response from background activity as the number of averaged responses is increased.[39]

ATTEMPTS AT QUANTIFICATION OF ONGOING ACTIVITY

Up to this point, this paper has emphasized specific electrical responses to specific sensory stimuli, although it has been pointed out that these responses are, at all levels of the nervous system, in a nontrivial sense functionally related to the existing background activity.§

Trained electroencephalographers are clearly capable of arriving at diagnostic judgments on the basis of ink tracings of the EEG. Attempts have been made to "quantify" (here the term is used in its broadest meaning) various aspects of brain-wave activity in experimental situations. These attempts at quantification have ranged from a classification of the recorded complex visual patterns into broad classes (corresponding either to characteristics of the EEG wave form or to such states as *arousal* or *drowsiness*, or to some pathological condition) to a running Fourier analysis of short-time (several seconds) samples of the EEG activity. Given our lack of theoretical understanding of the physiological mechanisms that underlie the EEG[42] and the multiplicity of purposes for which EEG data have been used, it is not surprising that no ideal method

§ This background activity has been designated as *spontaneous* or *ongoing* activity. The precise conditions under which it is observed in pure form are extremely hard to define.

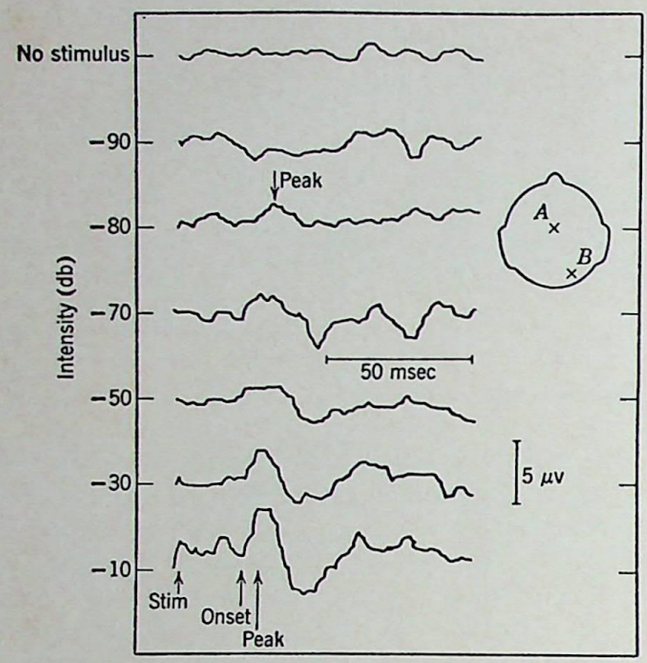

FIG. 12. Computed average responses to monaural periodic clicks obtained from scalp electrodes for different stimulus intensities. Each trace represents the wave form of the average response to 400 individual presentations of identical click stimuli delivered at a rate of 1.5/sec. The subject's (W. P., 10 September 1957; awake, eyes open) psychophysical threshold for these clicks, as determined during the same experiment, lay at approximately −85 db. Upward deflection indicates that electrode *A* is positive with respect to electrode *B* [from C. D. Geisler, L. S. Frishkopf, and W. A. Rosenblith, Science 128, 1210 (1958)].

of analysis has been found. Several years ago Wiener—intent on testing certain of his ideas regarding the presence of a "clock" in the brain[43]—interested Brazier's group at the Massachusetts General Hospital and the Communications Biophysics group in the Research Laboratory of Electronics, MIT, in applying correlation analysis to the EEG. A "correlator system"[44] was built, and a great quantity of experimental data has by now been processed.[45] There developed a considerable amount of discussion regarding the mathematical nature of the EEG time series, regarding the usefulness of correlation analysis of the EEG (since it discards so much of the information contained in the raw data), and even regarding the ease with which a correlation function of the EEG can be interpreted in a really quantitative manner. Whatever the merits of these issues, any data-reducing scheme should prove of some usefulness if the final display of the dependent variable satisfies several requirements: (a) it should be stable for a given organism when data are taken under comparable conditions; (b) it should be sensitive to important changes in the organism's environment; (c) it should perhaps be possible to classify a whole population on the basis of a limited number of displays.

Figures 13 to 15 illustrate some of the properties of the autocorrelation function as such a display. Figure 13 demonstrates that the display is capable of reflecting a threefold classification of the EEG ink tracings into

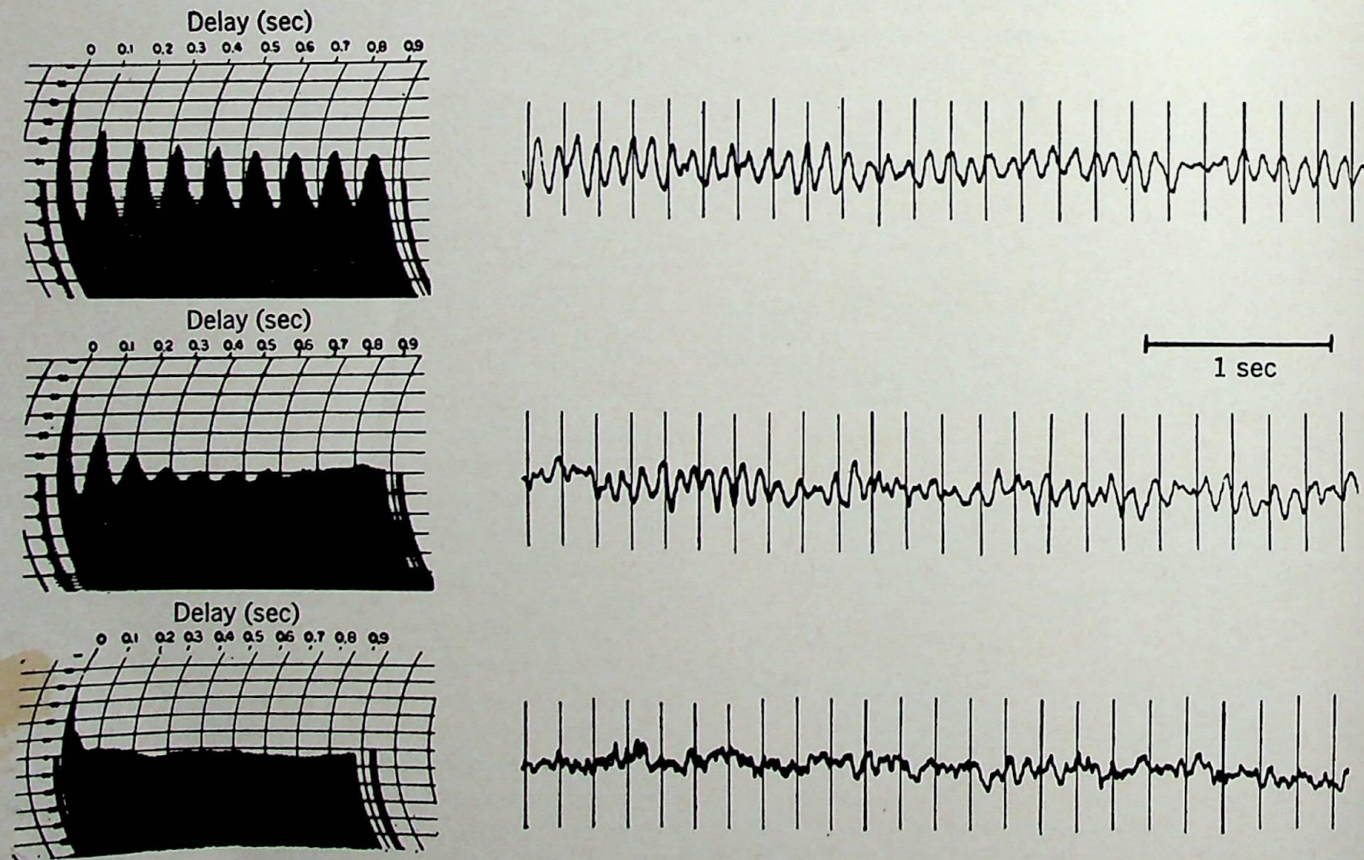

FIG. 13. Left: Autocorrelograms of 1-min samples of the EEG of three normal human subjects recorded from bipolar electrodes (right parietal to right occipital) on the scalp. Right: Sample of ink records from these same subjects [from J. S. Barlow, M. A. B. Brazier, and W. A. Rosenblith, "The application of autocorrelation analysis to electroencephalography," in *Proceedings of the National Biophysics Conference* (Yale University Press, New Haven, to be published)].

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

"high alpha," "medium alpha," and "no alpha." It remains to be seen to what extent a much larger population could be accurately classified on the basis of a certain number of such displays for various locations on the skull.

Figure 14 asks the question: How stable is such a display for a given person over a prolonged period of time? Although it is not possible at present to evaluate the similarity of these two displays in precise numerical terms, they appear to be quite comparable if the conditions of recording the EEG are reasonably well con-

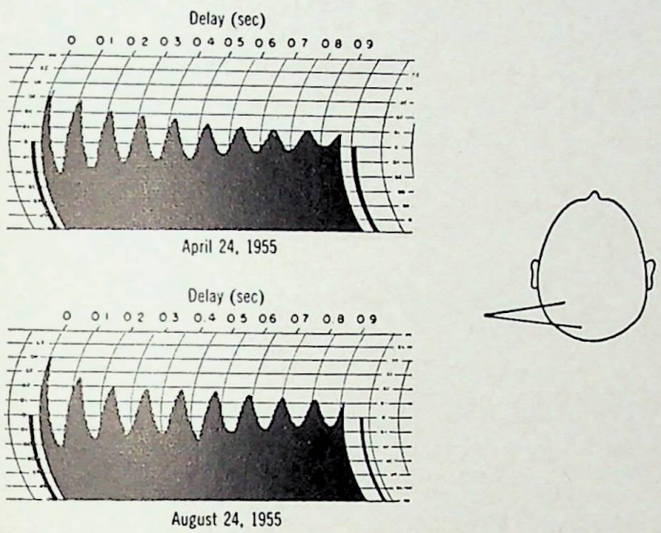

FIG. 14. Autocorrelograms of the EEG (1-min sample) of a normal human subject recorded four months apart [from J. S. Barlow, M. A. B. Brazier, and W. A. Rosenblith, "The application of autocorrelation analysis to electroencephalography," in *Proceedings in the National Biophysics Conference, 1957* (Yale University Press, New Haven, to be published)].

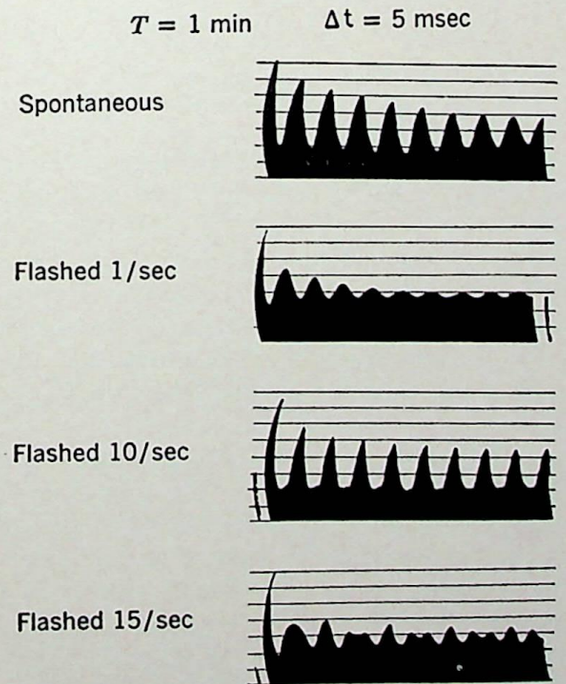

FIG. 15. Autocorrelograms computed for same subject in absence of controlled sensory stimulation ("spontaneous") and in presence of different rates of periodic photic stimulation [from J. S. Barlow, M. A. B. Brazier, and W. A. Rosenblith, "The application of autocorrelation analysis to electroencephalography," in *Proceedings of the National Biophysics Conference, 1957* (Yale University Press, New Haven, to be published)].

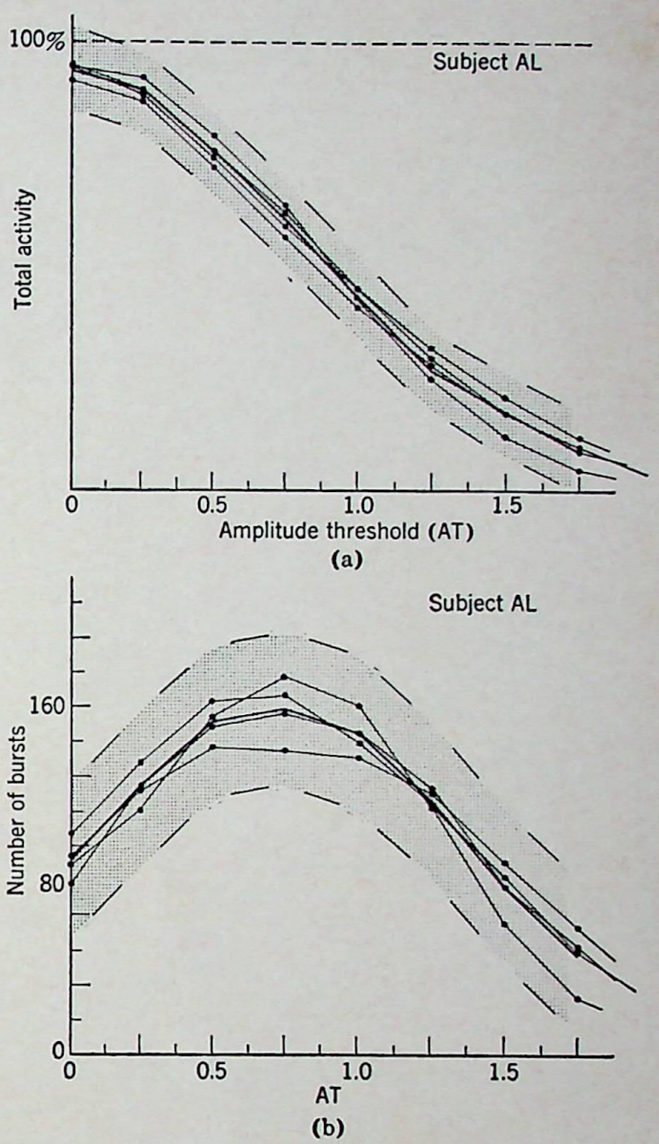

FIG. 16. Brain waves were recorded on four consecutive days (at same time of the day) from an awake subject sitting with closed eyes in an anechoic chamber. The displays show the four sets of results in fine lines, with the mean of the four runs as a heavy solid line. Each analyzed run lasted 3 min. For details of computer program and definitions of such terms as *amplitude threshold*, *total activity*, and *number of bursts*, see Farley *et al.*[46] The shaded region is bounded by the estimated confidence limits for the variation of the displays.[46]

trolled and the time sample from which the correlation function is computed is sufficiently long. Figure 15 demonstrates that the autocorrelational display is sensitive to photic stimulation.

It is not possible to examine here the extent to which the findings obtained with the aid of correlation (both autocorrelation and crosscorrelation) analysis support a particular model of brain function. One must, of course, admit that any method of data analysis implies a model of the process that is being investigated. The research worker has a burden of proof in the sense that he must show that the implied model fits the process well enough for his purpose. The fact remains that, in the absence of systematic computational analysis, most questions regarding the mathematical nature of the signal cannot even be raised in a meaningful manner. In addition, one should not underestimate the heuristic

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by eGangotri. In public Domain, Google-digitized. USA

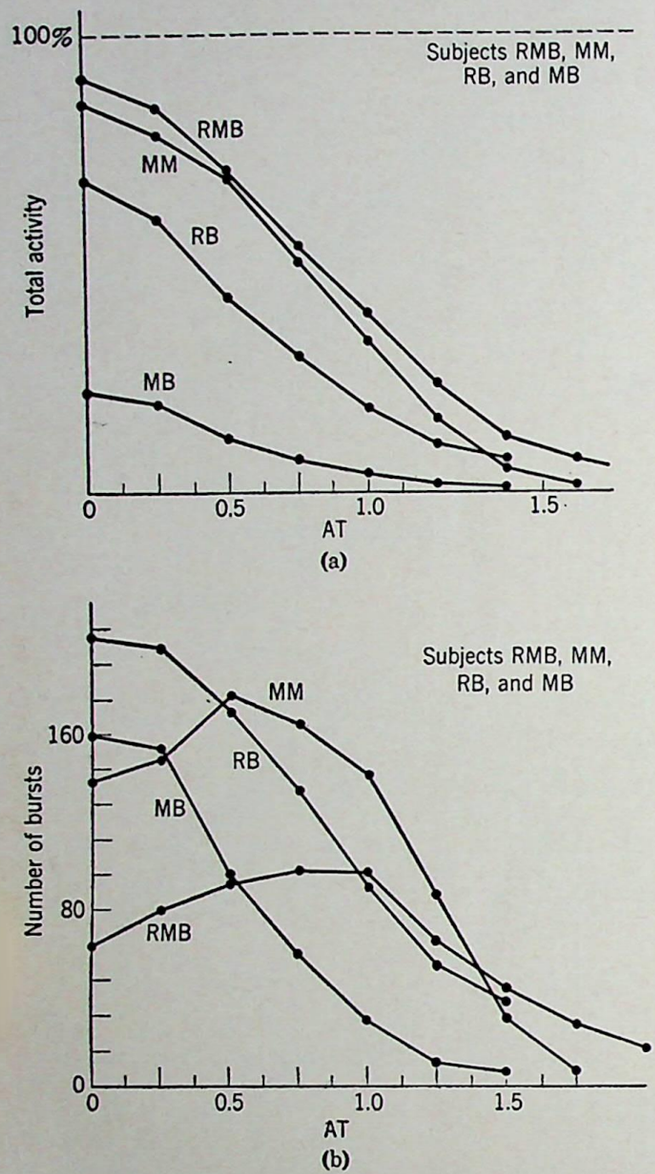

FIG. 17. Functions obtained for four different subjects on the basis of single 3-min runs. Note that subjects RMB and MM do not differ much in their total activity profile, but they are clearly distinguished in the display depicting the number of bursts.[46]

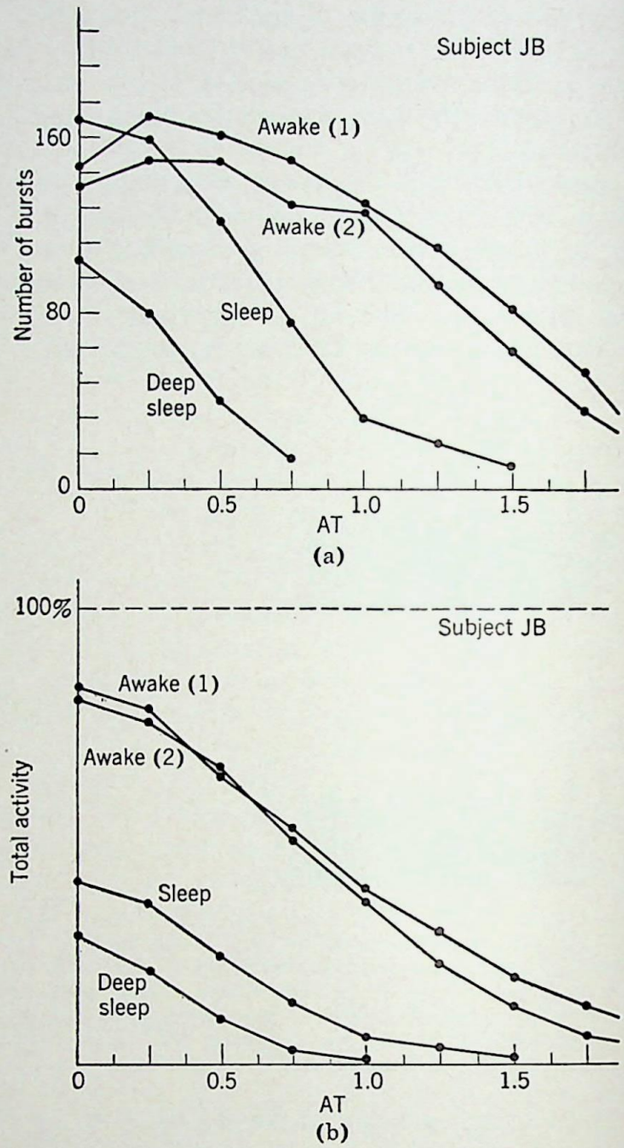

FIG. 18. Four runs for a subject, two while he was awake and two in two different states of sleep.[46]

benefits that derive from the use of a display that is in itself "anschaulich."

Displays of correlation functions of ongoing electrical activity are just one way of trying to describe an organism's "state" in terms of pseudo-state-variables. A report entitled "Computer Techniques for the Study of Patterns in the Electroencephalogram"[46] represents perhaps the most far-reaching effort in this direction. With the help of a rather flexible general-purpose digital computer equipped with a large memory, the attempt was made to "recognize the pattern of rhythmic bursts" in a given individual's EEG. Once a program for this purpose had been written, the attempt was made to distinguish different subjects from each other, as well as different "states" in the same subject.

Figures 16 to 18 show some of the results that have been obtained. Figure 16 illustrates that it is possible to obtain quite reproducible displays for the same subject if precautions are taken to obtain the data under fairly constant conditions. It was even possible to estimate confidence limits for the variability of the display for this subject and to compare displays from other subjects with these limits in order to assess significant differences. The initial results by Farley *et al.*[46] indicate that even a limited number of displays is capable of separating subjects into statistically distinguishable classes. Increasing the number of displays by increasing the number of pseudo-state-variables should make it possible to remove existing "degeneracies."

Figure 18 shows how these displays in a given subject are affected by his going to sleep. The influence of drugs or of sensory stimulation could be studied in this manner. Some evidence has already been obtained that these displays are sensitive to even short periods of sensory deprivation.

It is, however, appropriate to utter here a caveat regarding this and other methods that aim at quantifying data on the electrical activity of the nervous system. The multivariate nature of the nervous system prevents one from taking too much stock in any given number or even in a computed curve. Somehow one must learn to derive quantities that characterize the essentials of

CC-0. Library of Congress Collection. Digitized by Sarayu Foundation USA

neural activity in a fashion that is perhaps somewhat analogous to the dimensionless parameters of engineering systems. To make this point more concrete: Farley *et al.*[46] have shown that there are individuals whose total activity profile when they are awake bears some resemblance to the profile of another individual while the latter is asleep. However, whenever a person falls asleep there are changes in his activity profile. In other words, one must learn to assess the significance of change in relation to certain base lines and must refrain from attaching too much value to isolated pieces of numerical information. Unfortunately, economical mathematical descriptions of patterns and sequences are not yet available. These considerations can perhaps be carried somewhat further by noting that Fig. 13 illustrated how widely the autocorrelogram from apparently normal individuals may vary. It would thus seem unwise to draw too far-reaching conclusions regarding, for instance, a person's psychological make-up on the basis of a single display or even a set of summary displays computed from the electroencephalogram.

ACKNOWLEDGMENTS

The author owes a debt of gratitude to his colleagues and associates in MIT's Research Laboratory of Electronics. In connection with the data presented in this paper, he is particularly indebted to J. S. Barlow, M. A. B. Brazier, R. M. Brown, B. G. Farley, M. Z. Freeman, L. S. Frishkopf, C. D. Geisler, M. H. Goldstein, Jr., N. Y.-S. Kiang, J. Macy, Jr., C. E. Molnar, W. T. Peake, D. H. Raab, T. T. Sandel, and T. F. Weiss. To some extent, their views are reflected in the discussion, although the author must bear sole responsibility for the conclusions that he has drawn.

Imitation of Pattern Recognition and Trial-and-Error Learning in a Conditional Probability Computer*

ALBERT M. UTTLEY

National Physical Laboratory, Teddington, Middlesex, England

A CONDITIONAL probability computer, appropriately connected with input and output devices, can "recognize" patterns and "learn" by trial and error. The principle of such a system developed at the National Physical Laboratory is described briefly in this paper, together with some comments on the role of engineering in the study of biological problems.

An engineer generally starts with a specification, a set of rules of behavior for a machine, and then tries to design a machine that possesses that behavior. He designs an airplane, for example, to fly at certain speeds, to go certain distances, and to carry certain loads; from these requirements he deduces the required structure.

Nature is the engineer that constructs the difficult bridge between structure and behavior of living systems. In psychology, one discusses the behavior of an organism and wonders what kind of structure could cause it. In physiology and anatomy, on the other hand, one usually studies the structure and wonders what it is doing, what function it is supposed to serve.

We believe, in all humility, that the engineer can perhaps help to bridge the gap between structure and behavioral function in biological systems. Using his known methods, the engineer can most fruitfully start with observed behavior and work toward a possible elucidation of structure. Some engineers have tried to work in the opposite direction: to think up some properties of units, give them random connections, and find out what they will do. We do not think that that approach has been fruitful. We have considered, specifically, the problems of pattern recognition and learning, and have tried to design computers to do these things in the hope that the structure of the computers might be suggestive of the organization of the nervous system.[1]

This approach differs in one respect from that of Shannon and many others, who have also studied the design of machines to do certain things which animals and men can do. Their approach has been to program a universal computer. Such an approach should lead to a deep mathematical understanding of behavior, but it is not likely to lead to a specific structure which will give clues to the physiologist, because a universal machine can do anything.

The first step toward synthesizing pattern recognition is to devise a method for distinguishing one *set* of signals from another, corresponding to sets of signals in nerve fibers. The signals might be continuously variable, or they might be discrete and binary; the latter type is much easier to handle, and is used in this study. The machine must have a component unit for each signal-input channel to indicate if that channel is active; and a unit for each possible pair of channels to indicate, by means of a coincidence circuit, whether or not that pair of channels is active. In general, one needs a unit for each possible set of channels. Such an arrangement is called a classification system; an example is shown in Fig. 1.[2]

Next, the system must be made to recognize patterns in *time*; this requires the introduction of delay circuits. Suppose that there are only two input channels, and that each is put through a fixed delay. If these two inputs and their delayed versions are used as four inputs of a classification system, the system will recognize all 12 "tunes" which can be played on a two-note piano if one allows only two temporal ideas: "before" and "after." The connections and recognition possibilities of such a system are shown in Fig. 2.

A classification system can be built with quite *random* connections. The reason is that all possible arrangements of connections between units and channels are required. If there are sufficient units to accommodate the desired inputs, and if they are connected entirely at random to the inputs, a classification system will arise automatically.

Next, the system must be given *plastic* behavior, in which past events can influence future responses. This property is introduced through the computation of *conditional probability*. Suppose that there are two

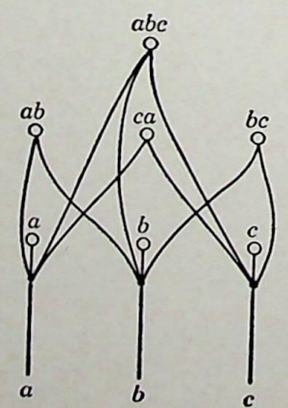

FIG. 1. A classification system for three inputs has seven units.

* This paper is published by permission of the Director of the National Physical Laboratory.

events, A and B, which occurred as follows on nine occasions:

A: $I\ I\ I\ I\ I\ O\ O\ O\ O$ (I = occurrence,
B: $O\ O\ I\ I\ I\ I\ I\ I\ I$ O = nonoccurrence)

One now asks: "If the future is like the past—if one accepts the inductive principle—and if A occurs, what is the chance of B?" In the past, A occurred on five occasions, and on three of these B also occurred. The corresponding probability of B, given A, is three out of five. Conversely, the probability of A, given B, is three out of seven. A machine to make these calculations must be able to count the five, in an A unit; the seven, in a B unit; and the three, in a coincidence-counting AB unit. Thus, to possess plastic behavior, the machine needs an additional feature: each unit must be able to *count*, even if in a very nonlinear way. The system will then be capable of inductive inference.[3]

Another important matter which comes easily out of this approach is the "context" in which events occur. Suppose that, in the foregoing example, an event C occurred on the last five occasions:

A: $I\ I\ I\ I\ I\ O\ O\ O\ O$
B: $O\ O\ I\ I\ I\ I\ I\ I\ I$
C: $O\ O\ O\ O\ I\ I\ I\ I\ I$

This history now has two different contexts (C occurs and C does not occur), and one can ask: "In the context C, what would be the probability of A, given B?" In this context, B occurred five times and A once, so the three-out-of-seven chance has changed to one-out-of-five. Similarly, the probability of B, given A, in the context C, is unity. The system can be extended indefinitely to infer one thing from another in all sorts of different contexts.[4]

There is a practical difficulty in the design of counters: after a time they get full. The engineer has to put a leak into the counter to avoid this dilemma—and a very interesting property is thereby produced. The leaky counter gives a time weighting in which past events matter less than recent ones. The computer can then *adapt* fairly quickly to new conditions.

Finally, the system must be able to *calculate ratios* of

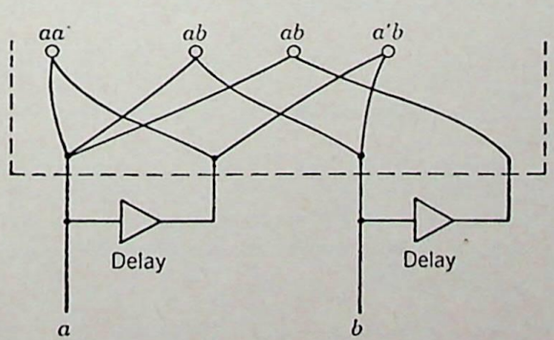

FIG. (2a). A classification system for 2 inputs which distinguishes "before" and "after." Four of the 15 units are shown.

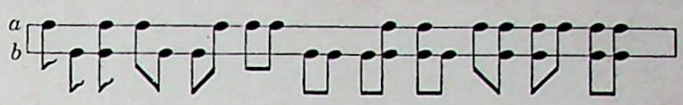

FIG. 2(b). The 12 tunes which can be distinguished by the system of Fig. 2(a). For the first 3 tunes—a, b, and ab—there are duplicate units.

numbers. Division is done most easily by using logarithms. It turns out that a leaky counter produces something very close to a logarithmic count, so the required ratios can be obtained simply by taking the differences between the states of two units. (The "state" is just the stored voltage in the counter.) Clearly, the effect of an active counting unit on one to which it is connected must depend on their relative state.

This relationship suggests a very important feature of a system that is capable of learning. The old idea that "facilitation" of a path depends on the number of times that it is used is not adequate; it is as illogical as the story of the Irishman and his boots—he couldn't get them on until he had worn them a few times. It is well known that a novel stimulus may, initially, produce no reaction from an animal, but eventually produce a response owing to trial-and-error learning. If initially a path is not made at all, how could it possibly be made on the principle that the more often it is used, the better it is?

The difficulty is resolved by a comparison of the states of two units. In neural terms, if a probability is to be computed, the numerator must be stored on one side of a synapse and the denominator on the other, so that a comparison can be made.

In summary, a machine to simulate pattern recognition and learning must be able to:

(a) distinguish sets of signals, through the use of coincidence counting;
(b) recognize time patterns, by use of delay circuits;
(c) count occurrences of signals and sets of signals;
(d) store information regarding past occurrences, at least for a certain length of time; and
(e) calculate ratios to determine relative states of units with stored counts of occurrences.[5]

These properties are incorporated in the machine shown in Fig. 3.

CONCLUDING REMARKS

Mathematical models can be very useful for studying complex systems and functions, including those of living organisms. The utility of a model, and especially the confidence with which one can draw inferences from its behavior, can be greatly enhanced by building a physical analog of the model—a machine. In the process of building the machine and making it work, one may find shortcomings or omissions in the theoretical model. More important, one may find that the machine is capable of doing more than was anticipated. The system reported here, for example, was designed to do pattern

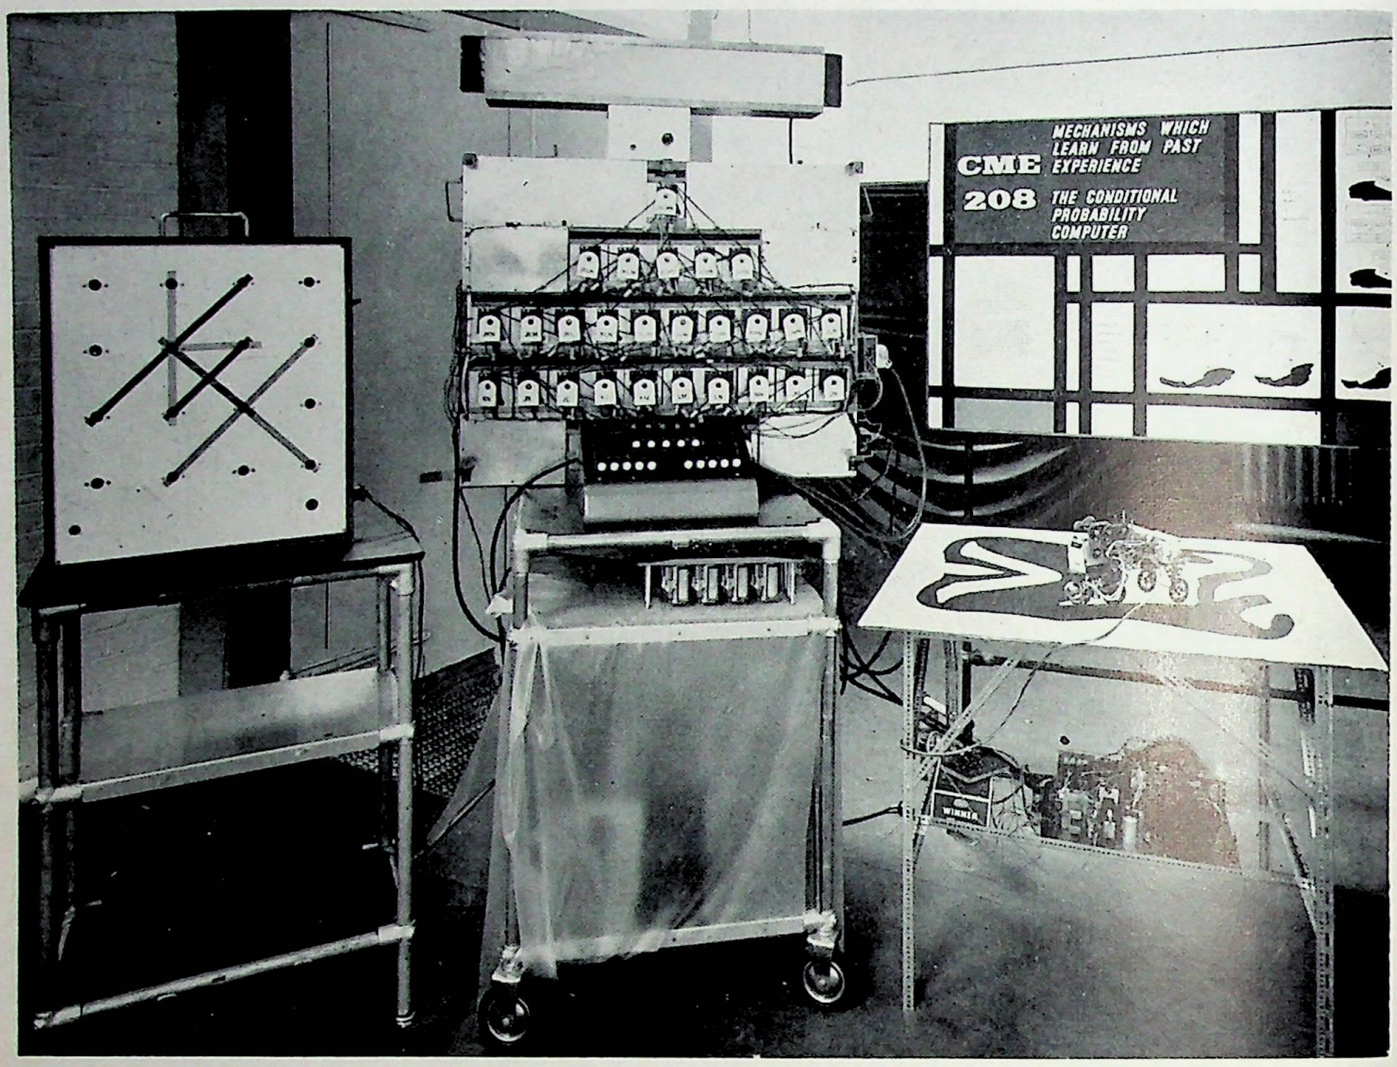

FIG. 3. A conditional probability computer, built at the National Physical Laboratory, capable of pattern recognition and trial-and-error learning. On the left is a model "retina" of photo cells to receive T-shaped shadow patterns. On the right is an electrically driven "vehicle" that learns, with the help of its computer "brain" which is shown in the center of the picture, to move efficiently along the black-white border of its "highway."

discrimination, and it turned out to be capable of trial-and-error learning as well.

Another important reason for making models is that people in different specialties use different languages—as is amply evident in a conference such as this Study Program. People try to talk about the same thing and hardly understand one another. A model is a sort of universal language. No matter what your field is, if you look at a physical model and see it working—see its parts working—you can get something out of it. In particular, the physiologist and anatomist can look at an engineer's model of a psychologist's observation and consider whether the structure of the model bears any resemblance to the structure of the living organism.[6]

One final comment: engineers use a very limited number of types of vacuum tubes to do a very large number of different things. The nervous system appears to be similar. There must be an enormous number of things neurons can do with just a few basic properties. The computation of conditional probabilities is, perhaps, just one of them.

Chemical Specificity in Biological Systems

WALTER KAUZMANN

Department of Chemistry, Princeton University, Princeton, New Jersey

THE importance of specificity in biology has been mentioned or implied in a great many contributions presented in this volume, and many examples have been discussed. It is worthwhile, however, to examine the concept of specificity by itself, and it is advisable to review some of the more important physical and chemical factors that are currently believed to be involved in the phenomenon.

In this paper are considered some typical examples of biological specificity involving more or less well-defined chemical systems as one of the specific interacting agents. The molecular basis of specificity is discussed with special emphasis on the concept of complementarity. Finally, some words are devoted to a review of the important and old-fashioned idea of specificity as a form of organization.

Serological specificity was defined by Landsteiner[1] as "the disproportional action of a number of similar agents on a variety of related substrata," and this definition is readily extended to other fields in which biological specificity manifests itself. Boyd[2] points out that this definition "would also include many chemical reactions, as might be expected if serological specificity were fundamentally chemical in nature, which we now believe," and again there is no need to hesitate in applying the remark to biological specificity in general. Indeed, specificity is an important aspect of chemistry; qualitative and quantitative analysis in organic and inorganic chemistry depends in a large degree upon "disproportionate actions" of similar agents on "related substrates" (e.g., the precipitation of silver halides in water and the separation of silver chloride from the bromide and iodide by treatment with ammonia, H_2O and NH_3 being regarded as similar agents and the silver halides being related substrates).

It is important to emphasize at the outset, too, that biological specificity is very variable in degree. Certain systems show a wide range of specificity whereas other systems show extremely narrow selectivity. What is likely to impress the chemist about biological specificity is the sharpness with which closely similar substances can be distinguished in some instances, but this sharpness is not at all universal.

It is worth mentioning that the concept of specificity is involved in the actions of inhibitors as well as in those of normal substrates, since many closely related biological systems are poisoned to decidedly different degrees by substances having similar chemical compositions. The drug industry thrives on this fact—as does mankind in general.

EXAMPLES OF CHEMICAL SPECIFICITY IN BIOLOGICAL SYSTEMS

1. Antibody-Antigen Interactions

Because of the pioneering work of Landsteiner,[1] the field of immunochemistry provides one with probably the most easily understood examples of biological specificity, and it has made possible a fruitful method of attack on the relationship between specificity and chemical structure. When certain foreign substances (antigens) are introduced into an organism, the organism reacts by producing proteins (antibodies) which are capable of reacting specifically with the antigens that gave rise to them. Antigens are invariably substances of rather high molecular weight, so that it is difficult to alter their chemical composition in a systematic fashion. Landsteiner was able to show, however, that new antigens may be prepared by combining small chemical groups (such as substituted aromatic rings) with proteins. These new antigens give rise to antibodies whose specificity depends on the nature of the conjugated groups. The small chemical group is called a hapten. Let w, x, y, z represent a series of chemically related haptens, let Aw, Ax, Ay, Az represent antigens produced from protein A by conjugation with these haptens, and let Bw, Bx, By, Bz represent the antibodies arising from injection of Aw, Ax, Ay, Az into a rabbit. It is clear that a great deal might be learned about the chemical factors involved in immunological specificity by comparing the interactions of the different antibodies with the different antigens. Furthermore, it is found that a low molecular-weight compound, aw, containing the hapten group w, is able to inhibit the interaction between Aw and Bw. Evidently, Bw contains sites which are capable of reacting with the hapten groups on Aw, and the haptens in aw can compete for these sites. The study of this competition using a series of related haptens makes possible a more quantitative study of antibody-antigen specificity.

Some typical results of this general approach are reported in a paper by Landsteiner and Lampl.[3] Metaaminobenzoic acid and metasulfanilic acid were coupled by diazotization of the amino group to the proteins of horse serum, and antibodies to these modified proteins were obtained by injection into rabbits. The resulting rabbit antisera then were mixed with samples of chicken sera which had been diazotized to aniline or to various aniline derivatives. Evidence for interaction consisted in the formation of a precipitate. (The use of horse serum in the production of antibodies and of chicken serum in the antibody-antigen test

TABLE I. Effects of structural changes in the hapten on antibody-antigen interaction.[a]

Hapten present on horse-serum antigen used in preparing antisera.	Hapten present on chicken-serum antigens used to test interaction with antisera.					
							0	+++	++++	+++	0	+
	0	0		0	0	++++

[a] 0 = no precipitate; +, +++, ++++ = increasing amount precipitate.

eliminates any contribution of the nonhapten portion of the antigen to the antibody-antigen interaction.) The results are shown in Table I. It is seen that:

1. No interaction will occur if an acidic group is not present on the hapten of the chicken-serum antigen.
2. No interaction will occur unless the acidic group is meta to the amino group (i.e., CO_2^- and SO_3^- must be meta to the point of coupling of the hapten to the protein).
3. Replacement of a hydrogen atom on the benzene ring by a chlorine atom or a methyl group has little effect on the interaction.
4. The antibodies are readily able to distinguish between a carboxyl group and a sulfonic-acid group on the antigen.

On the basis of many experiments of this type, it could be concluded that the nature of the charged groups of the hapten is of decisive importance in determining the specificity. Haptens containing sulfonic-acid groups do not tend to compete effectively for sites on antibodies which are generated by carboxyl-containing haptens, and vice versa. The introduction of an arsenic-acid group into an antigen makes for a particularly strong interaction between the modified antigen and the antibodies which it induces. Introduction of an uncharged methyl, halogen, methoxyl, or nitro group into a hapten has a much smaller effect on the specificity; strong cross reactions are observed between antigens containing a given hapten and antibodies induced from antigens containing haptens that differ from the given hapten merely through the presence of one of these uncharged groups. On the other hand, antibodies are found to be able to distinguish very well between two haptens which are optical isomers or which are (*cis*-)(*trans*-) isomers.

The important inference to be drawn from these studies is that the specificity of the antibody-antigen reaction must depend upon a complementarity between the surfaces of the antibody and antigen molecules. This complementarity presumably involves an apposition of positive and negative electric charges, if a charge is present in the antigen. It also involves a rather close matching of the contours of portions of the surfaces of the antibody and antigen molecules—a lock and key relationship that had been visualized already by Ehrlich early in the development of immunology. Small deviations in the perfection of this complementarity are tolerated (e.g., replacement of a methyl group by a chlorine atom, or even of a hydrogen atom by a methyl group). Forces of all types are presumably in action across the surface of contact of the antibody and antigen, but electrostatic forces seem to be particularly important. One can visualize these relationships by means of semischematic drawings such as Fig. 1, where a portion of the antibody molecule

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

is supposed to envelop the hapten, with electric charges suitably located on the antibody surface so as to interact favorably with the opposite charge on the hapten.

A paper by Pressman, Siegel, and Hall[4] illustrates the possibility of obtaining quantitative information about complementarity by making use of the hapten-inhibition phenomenon. Samples of ovalbumin were diazotized to ortho-, meta-, and para-aminobenzoic acid. Three antigens were produced in this way, consisting of ovalbumin molecules bristling with azobenzoate groups having the three isomeric configurations shown in Fig. 2. The three antigens are referred to as "X_o-ovalbumin," "X_m-ovalbumin," and "X_p-ovalbumin." The three corresponding antibodies were prepared by injecting these antigens into rabbits, bleeding the rabbits, and separating the globulin fraction (which contains the antibodies) by ammonium-sulfate precipitation. The addition of suitable proportions of X_o-ovalbumin to anti-X_o-globulin gave a visible precipitate, the amount of which could be measured. When low molecular-weight haptens [such as benzoate, *o*-chlorobenzoate, *m*-chlorobenzoate, *p*-chlorobenzoate, *o*- (*p*′-hydroxyphenylazo) benzoate, and various chlorinated derivatives of *o*- (*p*′-hydroxyphenylazo) benzoate] were added, the amount of the precipitate was decreased because of the competition of the small haptens for the complementary site on the antibodies. By varying the concentration of low molecular-weight hapten and observing the change in the amount of precipitate produced, it was possible to compare the affinities of the different hapten groups for the sites on the anti-X_o-globulin.* These relative affinities could be expressed in terms of the differences between the mean free energies of combination of the haptens for the sites on the anti-X_o-globulin.

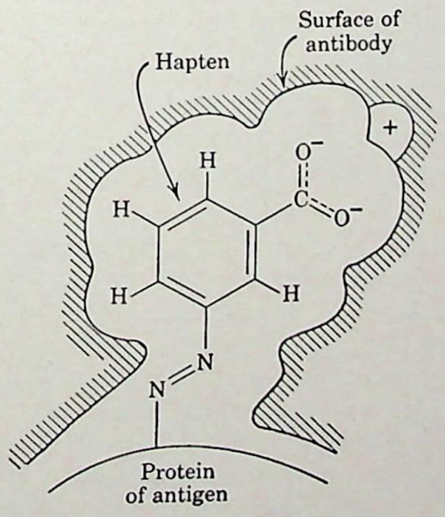

FIG. 1. Diagrammatic representation of complimentarity of the hapten-antibody relationship.

TABLE II. Relative affinities of various haptens for anti-$X_{o,m,p}$-globulins.

Hapten	Δ F_{rel}. cal/mole of hapten
For anti-X_o-globulin:	
Benzoate	(0)
o-chlorobenzoate	−580
m-chlorobenzoate	0
p-chlorobenzoate	430
o-(*p*′-hydroxyphenylazo) benzoate	−1700
3-Cl, 2-(*p*′-hydroxyphenylazo) benzoate	−1100
4-Cl, 2-(*p*′-hydroxyphenylazo) benzoate	−1100
5-Cl, 2-(*p*′-hydroxyphenylazo) benzoate	−1300
6-Cl, 2-(*p*′-hydroxyphenylazo) benzoate	−1500
For anti-X_m-globulin:	
Benzoate	(0)
o-chlorobenzoate	680
m-chlorobenzoate	−300
p-chlorobenzoate	480
m-(*p*′-hydroxyphenylazo) benzoate	−1600
2-Cl, 3-(*p*′-hydroxyphenylazo) benzoate	−560
4-Cl, 3-(*p*′-hydroxyphenylazo) benzoate	−350
5-Cl, 3-(*p*′-hydroxyphenylazo) benzoate	−980
6-Cl, 3-(*p*′-hydroxyphenylazo) benzoate	−500
For anti-X_p-globulin:	
Benzoate	(0)
o-chlorobenzoate	960
m-chlorobenzoate	−300
p-chlorobenzoate	−560
p-(*p*′-hydroxyphenylazo) benzoate	−1700
2-Cl, 4-(*p*′-hydroxyphenylazo) benzoate	−940

Similar experiments were performed on the X_m-ovalbumin-anti-X_m-globulin system and on the X_p-ovalbumin-anti-X_p-globulin system. As a result, it was possible to observe the effects that different groups in different positions in the hapten have on the ability of the hapten to combine with a given antibody. Some results for a series of chlorobenzoates and chloro-*p*-hydroxyphenylazobenzoate haptens are shown in Table II. The numerical values of ΔF_{rel} listed in this table are the differences between the average free energy for the combination of the hapten in question with the antibody sites and the average free energy of combination of the unsubstituted benzoate ion with the same sites. It is seen that, with each of the three globulins, the *p*-hydroxyphenylazo group greatly increases the affinity as compared with the benzoate ion (makes ΔF_{rel} more negative), presumably because it is able to take advantage of some of the binding forces associated with the portion of the antibody site that the organism intended to be occupied by the azo group and by the side chain of the protein to which the azo group is attached (see Fig. 3). This simple picture also shows

* The detailed mathematical analysis by Pauling, Pressman, and Grossberg[5] of the dependence of the amount of precipitate on the concentration of the low molecular-weight hapten showed that there must be a considerable variability in the affinities of the hapten for different sites on the antibody molecules. That is, the antibody sites at which the haptens are bound are not all alike. This heterogeneity can be described adequately by means of a Gaussian distribution of the free energies of binding about a mean value which is characteristic of each hapten, the spread in the free energies on either side of the mean value amounting to 1000 to 2000 cal/mole of hapten. The complication introduced by heterogeneity can be avoided by talking in terms of the mean free energy of binding for a given hapten at the sites on the anti-X_o-globulin.

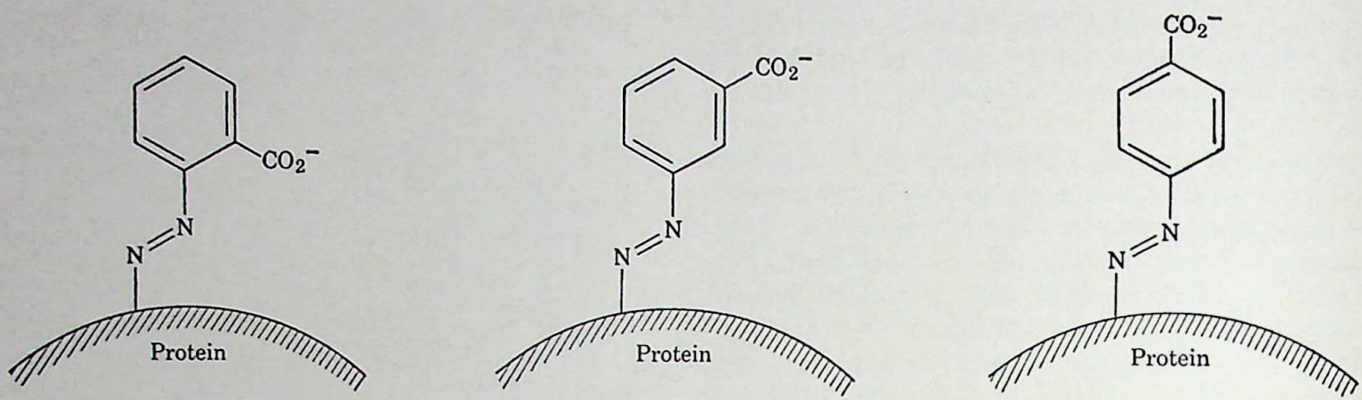

FIG. 2. Configuration of haptens used in studying antibody-antigen complementarity.

why the introduction of a chlorine atom in place of a hydrogen atom at various positions in the benzene ring in the simple benzoate ion tends to be unfavorable (makes ΔF_{rel} more positive by several hundred calories), if the slightly bulky chlorine atom is not able to go into the position intended for the azo group of the original antigen. When the much larger *p*-hydroxyphenylazo group is present in the hapten, it occupies the position intended for the protein of the original antigen; the introduction of a chlorine atom into such a hapten then invariably decreases its affinity for the antibody site. The amount of the decrease in affinity is different, depending upon the location of the chlorine atom on the benzene ring. This reveals something about the nature of different portions of the surface of the hapten-binding site on the antibody. It is clear that experiments of this kind allow one to probe the various regions of the antibody-combining sites and to obtain quite detailed information on the factors that determine antibody-antigen specificity.

2. Enzyme-Substrate Interactions

Enzymes are well known to be rather particular about the substrates whose reactions they choose to catalyze. The degree of this specificity varies widely, however. The enzyme urease evidently catalyzes only the hydrolysis of urea and appears to have no noticeable effect on any urea derivative or other substance that has yet been tested. Fumarase adds water to the double bond of the fumarate ion to produce L-malate ion and no other double-bonded organic molecule has been found which is attacked by this enzyme. On the other hand, certain lipases will hydrolyze ester bonds containing widely different organic groups attached to either side of the bond.

It is generally agreed that enzymes act by adsorbing the substrate molecule or molecules at some "active site" on the enzyme molecule in such a way that the appropriate bonds in the substrate show an increased reactivity. It is difficult to avoid thinking in terms of the hypothesis that the enzyme-substrate interaction, like the antibody-antigen interaction, depends upon a complementarity in structure between the two substances, the substrate molecule fitting into a characteristically shaped impression in the surface of the enzyme molecule. The increased reactivity may arise because in the adsorbed state the bonds involved in the

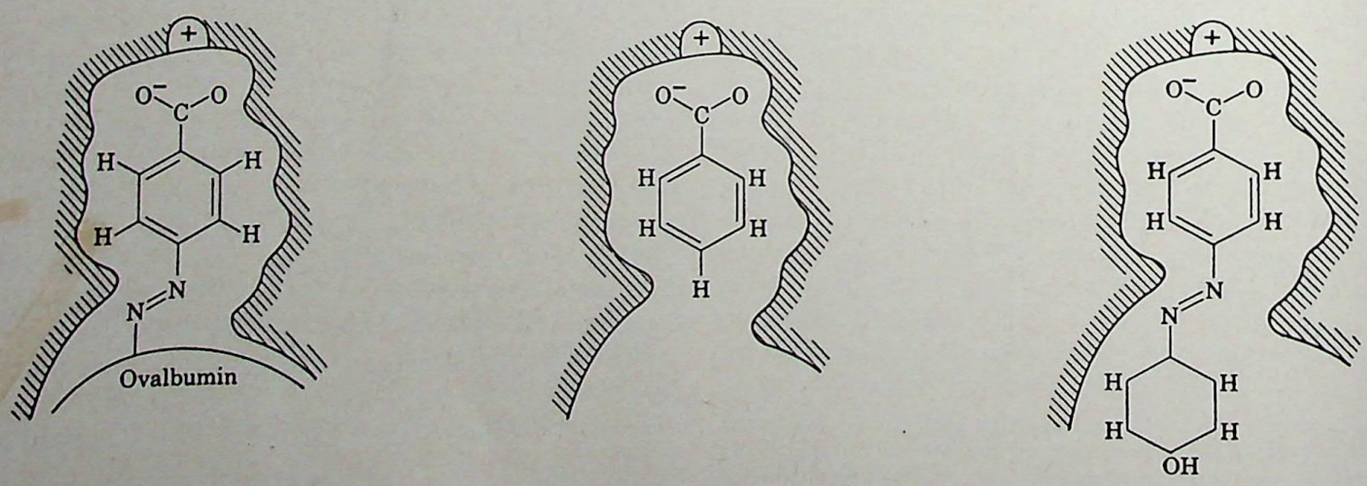

FIG. 3. Hapten inhibition of anti-X_p-globulin.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

reaction are placed under strain or because they are brought into a favorable position for reaction. This simple picture seems to be consistent in a general way with the wide range of specificity found among enzymes. Highly specific enzymes presumably contain a highly characteristic impression of the substrate molecule into which it is not possible to fit even closely related molecules capable of undergoing the same reaction as the substrate. Enzymes showing a wide range of specificity, on the other hand, must interact with only the region of the substrates in the immediate vicinity of the bonds that are involved in the reaction. This picture also explains why substances closely related to a given substrate, but incapable of undergoing the reaction that is catalyzed by the enzyme, often act as powerful inhibitors (e.g., malonic acid and malic acid strongly inhibit the conversion of succinic acid to fumaric acid by succinic dehydrogenase). These inhibitors must fit into the site intended for the substrate but, like the dog in the manger, they neither take advantage of the catalytic capabilities of the site nor permit access to the true substrate.

The hypothesis of structural complementarity also explains the high degree of stereospecificity shown by practically all enzyme reactions in which the potential substrates are capable of existing as stereoisomers. (E.g., the dehydration of malic acid in the presence of fumarase to form fumaric acid is absolutely specific for L-malic acid, D-malic acid being unaffected by fumarase to any detectable degree; similarly, maleic acid, the *cis* isomer of fumaric acid, is not hydrated by fumarase to any detectable degree. Most peptidases will not hydrolyze peptide bonds involving D-amino acids.) Suppose that the active center of an enzyme is surrounded by a mold into which all of the chemical groups in the vicinity of a double bond of the *trans* isomer of a compound will fit. It is easy to understand why this mold will not be able to accommodate the *cis* isomer of the compound, which has an entirely different external shape. The specificity to optical isomers is no less easy to understand in terms reflecting the common experience that a left hand will not fit into a glove made to cover its mirror image, the right hand.

It is interesting to examine some typical enzyme systems in order to observe the types of behavior that can be accommodated to the complementarity concept. One finds that many systems can be interpreted very easily in these terms, but one finds also that there are certain instances in which the concept does not present a very convincing picture of what must be going on.

(*a*) *Peptidases*

Bergmann studied the action of various peptidases on simple peptides and was able to show that there is a high degree of specificity among these enzymes which depends on the nature of the groups located on either side of the peptide bond that is split. He was able to formulate certain general specificity requirements for the action of pepsin, trypsin, and chymotrypsin, which are summarized in Table III. Further work has shown, however, that many of these requirements are not met by all substrates of these enzymes, and the specificity picture has become somewhat more complex (see, for example, the discussion in Dixon and Webb[6] and Neurath and Schwert[7]). To illustrate these complexities, the chief points of attack on ribonuclease by various peptidases are shown in Fig. 4. Inspection of this figure and Table III will show that the specificity discovered by Bergmann for trypsin is invariably maintained: the points of attack by trypsin are always at the peptide bond next to either arginine or lysine, with the carbonyl end of the bond that is hydrolyzed belonging to the cationic amino acid. It does appear, however, that the bond adjacent to one of the cationic amino-acid residues of ribonuclease (the lysine at position 44 from the lysine end of the chain) may not be attacked by trypsin. The points of attack on ribonuclease by chymotrypsin are frequently adjacent to aromatic side chains (usually at the carbonyl side), as demanded by the Bergmann rules. Unexpected exceptions are found, however, in the ready opening of the leucine-threonine linkage between positions 35 and 36, and of the alanine-lysine linkage between positions 103 and 104. A weak ability of chymotrypsin to split peptide bonds involving methionine had been noted in simple peptides (chymotrypsin also hydrolyzes a cystine-serine bond in insulin). These exceptions are somewhat puzzling from the point of view of the complementarity concept, because the groups that are involved can hardly be said to resemble in general shape the aromatic groups that the Bergmann rule demands for chymotrypsin. More complex factors seem to operate than the mere binding by the enzyme of the amino-acid residue next to the peptide bond that is being hydrolyzed. The slight ability of methionine and cystine to replace an aromatic ring in some substrates for chymotrypsin is especially puzzling and might suggest that an electronic mode of interaction may be involved rather than one involving steric complementarity.

TABLE III. Bergmann's specificity rules for the hydrolysis of the peptide bond in $R_2—NH—CHR_1—CO—NH—R_3$.

Enzyme	R_1	R_2	R_3
Pepsin	glutamic or aspartic	not H	aromatic (tyrosine or phenylalanine)
Trypsin	cationic (lysine or arginine)	not H	nonspecific; may be H
Chymotrypsin	aromatic (tyrosine or phenylalanine)	nonspecific	nonspecific

The specificity rule for pepsin proposed by Bergmann on the basis of its action on simple peptides turns out to be violated frequently when pepsin acts on long

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

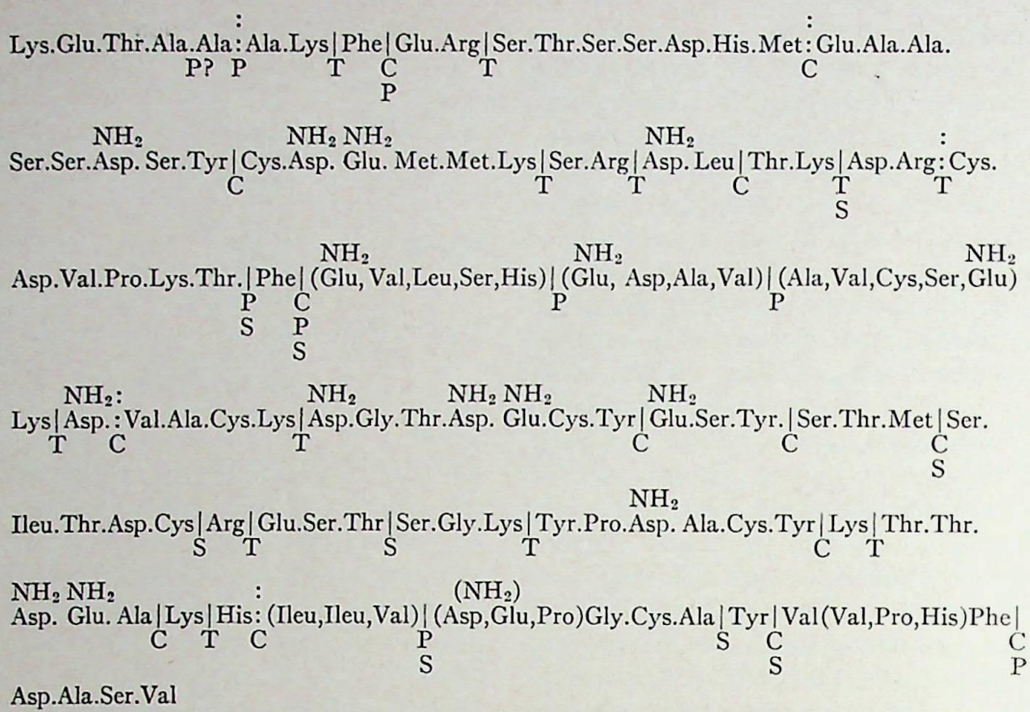

FIG. 4. Points of hydrolysis of ribonuclease by chymotrypsin (C), pepsin (P), trypsin (T), and subtilisin (S). Dotted lines represent points of slower hydrolysis.

polypeptide chains. This is evident from Fig. 4, where the attack on an alanine-alanine bond may be noted. Pepsin also attacks an alanine-serine bond in ACTH and a leucine-valine linkage in insulin. In general, however, pepsin does show a tendency to attack either bonds involving glutamic or aspartic acids by themselves, or bonds involving aromatic amino acids by themselves—in partial agreement with Bergmann's rules. It appears that the true range of specificity of pepsin does not reveal itself until one allows it to act on relatively long polypeptides.

It is interesting that trypsin and chymotrypsin are able to hydrolyze esters and suitably activated carbon-carbon bonds as well as peptides. The specificity requirements on the amino acids adjacent to the ester or carbon-carbon bond are similar to those observed for peptides with the same two enzymes. Here one has a particularly striking example of the importance of the environment of a reacting bond, rather than the bond itself, in manifesting the specificity of the enzyme.

(b) *Cholinesterase and Acetylcholinesterase*

The reaction

$$(CH_3)_3N^+-CH_2-CH_2-O-CO-CH_3 \quad \text{(acetylcholine)}$$
$$+H_2O \rightarrow (CH_3)_3N^+-CH_2-CH_2-OH \quad \text{(choline)}$$
$$+CH_3-CO-OH$$

is catalyzed by two distinct groups of enzymes which have interestingly different specificity requirements. One of these groups of enzymes, the acetylcholinesterases is inhibited by the substrate acetylcholine at higher substrate concentrations, so that its activity *vs* substrate-concentration curves pass through a maximum. The other group of enzymes, known as cholinesterases, is not so inhibited, and the activity *vs* substrate-concentration curves follow the normal Michaelis-Menton behavior. Both kinds of enzymes can act on many substrates related (in some instances rather distantly) to acetylcholine, but mention is made only of the interesting and opposite effects of replacing the acetyl group with other acyl groups containing longer hydrocarbon chains. In mammalian brain acetylcholinesterase, the replacement of acetyl with butyryl greatly lowers the activity and does not remove the inhibition at high substrate concentrations. In cholinesterase, on the other hand, the same substitution greatly increases the activity of the enzyme. Here one has an example of two enzymes which catalyze the same reaction but whose specificity patterns are markedly different, showing that considerably different types of complementarities must be possible for a given substrate.

(c) *Glycosidases*

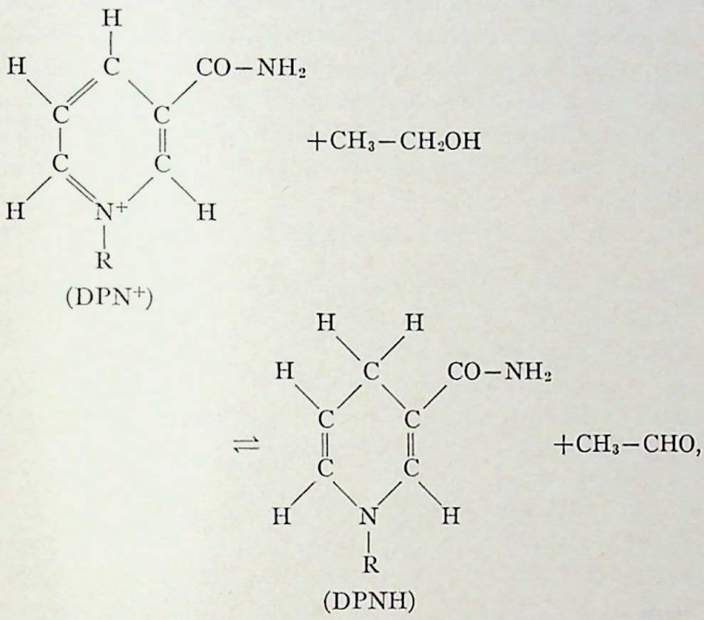
The hydrolysis of α- or β-alkyl- or aryl-glycosides to form free sugars plus alcohols or phenols is catalyzed by a group of enzymes that show interesting specificities. In general, a given glycosidase is highly specific to the sugar moeity, and to whether the glycoside has the α- or β-configuration, but it is relatively unconcerned about the nature of the aglucone residue. For instance, α-glucosidase will hydrolyze α-methylglucoside, α-phenylglucoside, and many other α-glucosides, but it will not cause the hydrolysis of any β-glucoside or any α-glycoside of a sugar other than glucose. Here one has

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

examples of very high specificity toward a group that lies on one side of the chemical bond that is attacked, and a very low specificity to the other side.

(*d*) *Stereospecificity in the Transfer of Hydrogen to DPN in Dehydrogenase Reactions.*

Vennesland[8] and Westheimer have shown by means of ingenious experiments with deuterium that, in the reaction



both the addition of the hydrogen atom to the pyridine ring of DPN^+ in the forward direction and the addition of hydrogen to acetaldehyde in the reverse reaction are stereospecific. Thus, if the equilibrium

$$CH_3-CH_2-OD+DPN^+ \rightleftharpoons CH_3-CHO+DPNH+D^+$$

is carried out in D_2O, it is found that no additional deuterium atoms are introduced into either DPN^+, DPNH, alcohol, or aldehyde. Similarly, no normal hydrogen is introduced when the reaction

$$CH_3-CD_2-OH+DPN^+ \rightleftharpoons CH_3-CDO+DPND+H^+$$

is equilibrated in H_2O. This proves that the hydrogen atom is transferred directly from the carbon atom of the alcohol to the DPN^+ (and vice versa) and does not go through the solvent. Furthermore, the hydrogen atom introduced into the DPNH must lie on one definite side of the pyridine ring. The ring must lie, therefore, in a definite orientation on the enzyme surface, and relative to the alcohol molecule, in the complex of the enzyme with its two substrates. That the orientations of the ethanol and aldehyde molecules also must be fixed rigidly relative to the pyridine ring is shown by the fact that the reaction

$$H^+ + DPND + CH_3-CHO \rightarrow DPN^+ + CH_3-CHD-OH$$

produces a single optical isomer of ethanol-1*d*. Here is an especially clear example of the detailed stereochemical specification of the structure of an enzyme-substrate complex. It must take advantage of a large fraction of the possible complementarity that can exist between the substances concerned in the reaction.

(*e*) *The Koshland-Stein Rule*

Koshland and Stein[9] have proposed the general principle that "if the enzyme requirements for a substrate having an oxygen bridge, i.e., R—O—Q, show high specificity for R and low specificity for Q, than R—O cleavage occurs in the enzyme reaction." This rule has been found to be valid for invertase, alkaline phosphatase, acid phosphatase, trypsin, and chymotrypsin. The simplest interpretation of the rule in terms of complementarity would be that the group with the highest specificity would be presumed to have the closest contact with the enzyme; the enzyme then would be expected to have the greatest activating effect on the bond adjacent to this group.

(*f*) *Existence of Identical Amino-Acid Sequences in the Active Centers of Enzymes Having Diverse Specificities*

It has been found recently that the active centers of thrombin, chymotrypsin, trypsin, and phosphoglucomutase all contain the sequence aspartic acid-serine-glycine. These enzymes have markedly different specificities, the first three catalyzing the hydrolysis of peptide bonds, whereas phosphoglucomutase catalyzes the transfer of a phosphate group from one glucose ring to another. The specificity of these enzymes must clearly reside in regions quite distinct from the center that activates the chemical bonds which are disrupted.

3. Binding of Small Molecules to Proteins (Other Than Hapten-Antibody Interactions)

Serum albumin is remarkable for its ability to adsorb a wide variety of small molecules, particularly (though not at all exclusively) those bearing negative charges (acetate ion, halide ions, methyl orange, and many other anionic dyes, detergents, etc.). The most striking feature of this adsorption, however, is the lack of any reasonably marked specificity. Changes in the structures of the adsorbed molecules do have some effects on the strength of the binding. These changes in affinity are not, however, as large as one would expect to find if the surface of the serum albumin molecule were covered with a mosaic of rigid binding sites having a reasonably high degree of complementarity to the necessarily limited number of types of substances which such a mosaic might potentially bind. (For example, enantiomorphic isomers of a dye are adsorbed to almost the same extent.) In order to account for this, Karush[10] has proposed the concept of "configurational adaptability," according to which the serum-albumin molecule is considered to possess a degree of internal flexibility.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

As a result, the surface conformation can be changed so as to establish a measure of complementarity with the surface of almost any molecule that approaches it, and there is no need to deal with a limited number of fixed types of potential binding sites. A strong point in support of this concept is the fact that serum albumin does possess a high degree of internal flexibility as compared with other proteins, which also show a far smaller affinity for small molecules.[11] In a sense, the serum-albumin molecule behaves like a lump of putty onto which one can stick an unlimited number of different shapes.

The concept of configurational adaptability is important because it shows that complementarity need not imply specificity. Furthermore, it raises the possibility that, in some instances, the specific complimentarity structure may be developed only when the substrate is present.

SPECIFICITY AND ORGANIZATION

Green has set forth[12] reasons for believing that, in certain biochemical processes involving a sequence of steps, each catalyzed by a different enzyme, the enzyme molecules must occupy fixed positions in space which are located so as to facilitate the successive reactions. He speaks of "an organized mosaic of enzymes in which each of the large number of component enzymes was uniquely located to permit efficient implementation of consecutive reaction sequences." A primary example of this mosaic is the cyclophorase system, which includes all of the enzymes for the citric-acid cycle, fatty-acid oxidation, oxidative phosphorylation, and terminal electron transport. This system of enzymes has been shown to be located exclusively in the mitochondria. In view of the striking mitochondrial structures which have been revealed by electron microscopy [see the papers by Sjöstrand (p. 301) and Fernández-Morán (p. 319) in this volume], there is a certain temptation to accept this theory.

Dixon and Webb[13] have disputed the necessity for assuming organization in this spatial sense. As an alternative, they go back to the point of view presented twenty-five years ago by Hopkins[14] in these words: "The organizing potentialities inherent in highly specific catalysts have not, I believe, been adequately appraised in chemical thought. Highly specific catalysts determine just what particular materials, rather than any others, shall undergo reaction. They select from their environment. The specific catalyst determines which among possible paths the course of change shall follow. It has directive powers . . . ." Dixon[15] speaks of "organization by specificity" as an alternative to Green's spatial organization of enzyme systems. The concentration of the cyclophorase enzymes into the mitochondria is ascribed to the need to reduce the distance between the enzymes involved in consecutive reactions. The cell is able in this way to reduce the "transit times" required for the products of one enzymatic step to diffuse to the enzyme molecules involved in the next step. According to this view, there is no need to assume any regular arrangement of the different enzymes. It is necessary only to have an arrangement (a random one would do) with a sufficiently small mean distance of separation between the enzymes involved in the different enzymatic steps.

It is interesting in this connection to estimate the order of magnitude of the transit time for a typical metabolite to move a given distance from one enzyme to another by a diffusion mechanism. It is well known that if x^2 is the mean square distance moved in time t by a particle whose macroscopic diffusion constant is D, then

$$x^2 = 2Dt.$$

Typical metabolites have diffusion constants of the order of 1 cm^2/day, or 10^{-5} cm^2/sec. Thus, it is found that, if the enzymes required for two successive steps of a reaction sequence are 1000 A apart, the transit time is 10 μsec. If the separation is 100 A, the transit time is 0.1 μsec. It would appear, therefore, that the arrangement of enzymes of a reaction sequence in layers whose repeat distance is a few hundred Ångström units, without any regard to the serial positions in space of the enzymes involved in successive reaction steps, would give a more than adequately short transit time for most biochemical requirements. Specificity alone should be adequate to cope with problems of organization at this level. This is not to say, of course, that the living cell actually is organized in this manner. For reasons unknown, it may have chosen to solve its transit time problems in a less straightforward manner.

Blood Coagulation—A Study in Homeostasis

DAVID F. WAUGH

Department of Biology, Massachusetts Institute of Technology, Cambridge 39, Massachusetts

IN this discussion, a brief account is to be made of one of the mechanisms involved in homeostasis, a word which means that the chemical and physical processes occurring within the fluid matrix or internal environment of an organism are integrated so that a stable physiological level of each is maintained. Thus, if one process deviates from its stable level, other mechanisms are shifted slightly or considerably, as the occasion demands, in an attempt to bring this process and the entire system back to its normal state. Of course, everyone appreciates the fact that the closely related set of activities occurring in one physiological system are influenced by the sets of activities occurring in other systems. For example, the system discussed herein, the blood coagulation system, is influenced markedly by stress (as, of course, are the other physiological systems.) The mechanisms in one physiological system, then, are not at liberty to establish levels of activity which are optimal for that system as an isolated system: the levels are a compromise derived from the activities of the organism as a whole.

It should be made clear at the start that the information presented here is also the result of a compromise: it represents the activities in a chosen individual only in a general way and is a simplification most parts of which can be challenged. This situation stems from the fact that, while there is general agreement about many of the coagulation mechanisms, others have been recognized as possibilities only recently and an understanding of details is incomplete. Extensive use has been made of certain references in preparing this discussion: the books by Wintrobe[1] and Biggs and MacFarlane,[2] the review articles by Brinkhous, Langdell, and Wagner,[3] and Seegers,[4] and the symposium edited by Brinkhous.[5]

Applied to the blood vascular system the word homeostasis would include first, the hemostatic mechanisms—that is, the mechanisms which are involved in sealing a wound which has opened the usually closed circulatory system—and second, the more mysterious set of mechanisms which are involved in maintaining the thin fragile walls of the capillaries in such a state that the proteins and formed elements (red and white cells) of the blood do not escape from the circulation and pass into the tissue spaces. The first set of mechanisms, the hemostatic, involve the closing of small vessels through vascular constriction, plugs of platelets, and coagulation in which the fluid plasma is transformed into a gel. We can be concerned only with coagulation, where it is found that an extensive set of interlocking processes exist in what is quite evidently a poised equilibrium such that a displacement of the equilibrium in the proper direction leads to a rapid autocatalytic development of the clotting enzyme thrombin from its inactive precursor prothrombin. A general scheme of the features of the coagulation system to be discussed here is shown in Fig. 1. The explosive development of thrombin swamps out, locally, all of the anticlotting mechanisms and a clot develops, the latter being the result of a change in the structure and in the state of aggregation of the protein fibrinogen. The clot is confined locally by a set of slower reactions, some of which are autocatalytic and controlled by thrombin development and most of which are backed up by large capacities. These reactions nullify the clot-developing system at several points.

The trigger for the mechanisms which displace the poised equilibrium is apparently disruption of a boundary which isolates key substances, either within small blood elements, the platelets, or within the tissue cells. On wounding, the intermixing of blood and tissue juices and the presence of rough surfaces at the site of injury, which cause platelet decomposition, are sufficient to give the rapid development of thrombin described in the following.

One might venture that if hemostasis were the only objective of the coagulation system it could be much simpler than it is. Many of the extraordinary complications are probably associated with the fact that coagulation must occur continuously at low levels in order to preserve the normal structural and permeability characteristics of the capillaries. The physiological necessity for slow continuous clotting is referred to later in an attempt to justify this statement. It is just mentioned now, however, to focus attention at the start on the possibility that one is dealing with a system which, on the one hand, must operate at a low but precisely controlled level of activity but which, on the

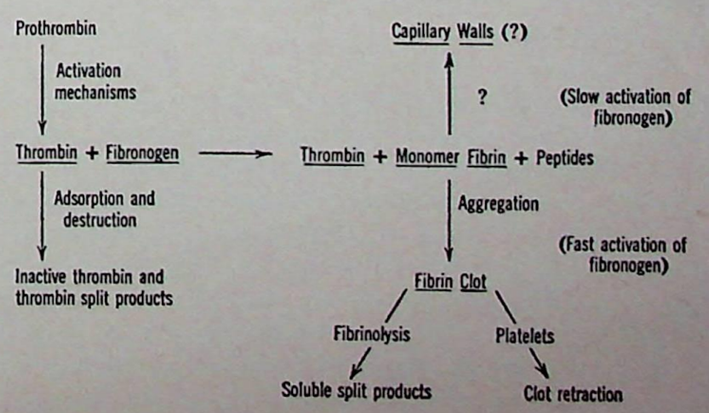

FIG. 1. General scheme.

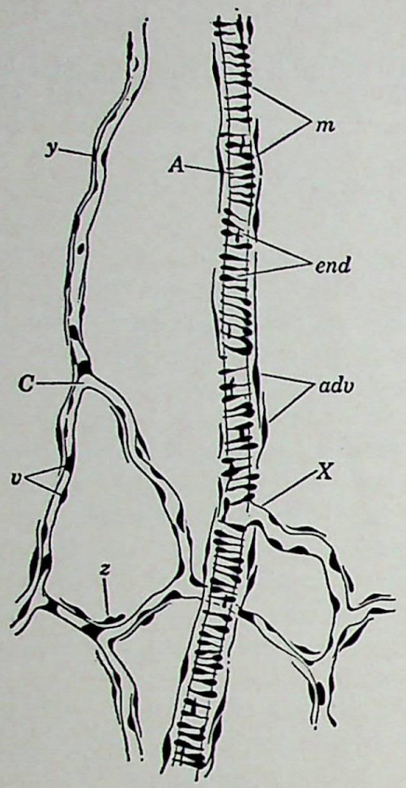

FIG. 2. Small artery, *A*, and capillaries, *C*, from the mesentary of a rabbit; *M*, muscle cells in the media; *adv*, adventitia; *X*, origin of a capillary from the artery; *y*, pericyte; *z*, perivascular histiocyte; *end*, *v*, endothelial nuclei [from A. Maximow and W. Bloom, *A Textbook of Histology* (Saunders Company, Philadelphia, 1942), fourth edition].

other hand, can be triggered into explosive activity which is not controlled but must be confined.

Blood flows within a set of tubes of varying size, the larger tubes (arteries, arterioles, veins, venules) being covered by substantial layers of muscle and connective tissue. The smallest vessels, the capillaries, are our chief concern. These fragile vessels (Fig. 2) have a wall which is constructed of a single layer of flat endothelial cells cemented at their boundaries and invested by a thin network of connective-tissue fibers. The caliber of the capillaries is close to the diameter of a single red cell, and is thus about 8 μ in man. It is believed that water and solutes generally pass through the cytoplasm of the endothelial cells. White cells may migrate through the substance of the endothelial cells or through the boundaries between cells.

Blood[1] itself is a fluid 40% of whose volume is made up of formed elements (red cells, white cells, etc.) and 60% of a straw-colored fluid plasma containing seemingly an endless variety of compounds, many in the process of being transported from one organ to another. The most important of the formed elements in this discussion is the platelet, a disk-shaped body about 2 μ in diameter. The platelets can become sticky and adhere to each other forming a mass which itself is of importance in stopping the flow of blood from capillaries. In addition the platelets, as mentioned, normally act as unavailable depots for important coagulation components. The platelet is fragile. If it comes in contact with a surface foreign to the circulation (i.e., glass) it adheres, spreads out, and bursts liberating its contents.

Within the plasma are found a series of proteins and lipoproteins all involved directly or indirectly in clotting. These proteins are described as they come up for discussion, the current series includes prothrombin, thrombin, and fibrinogen. Prothrombin, in the purified preparation of Seegers *et al.*,[6] appears as a molecule of $M \sim 66\,000$ and as a prolate ellipsoid may be described as having a length of 119 A and a diameter of 34 A.[7] This molecule can dissociate on dilution into halves. It is quite stable in the pure state and stable in plasma when prothrombin activators are absent. Prothrombin, as its name implies, has no action whatsoever on fibrinogen.

Thrombin is one of the derivatives of prothrombin. It can be obtained from prothrombin by a variety of techniques, the important one in this instance being the normal biological-activation process involving a variety of substances. In this activation process, the molecular weight of prothrombin does not appear to change radically. In the concentrated solutions required for physical studies, however, thrombin may be associated. Our current studies suggest that the minimum molecular weight of thrombin is about 22 000. One unit of thrombin is defined as that amount which clots plasma or a solution of purified fibrinogen corresponding to plasma in 16 sec. Since preparations of thrombin containing 2000 units/mg have been made, it is clear that a single unit is represented by about 5×10^{-4} mg. There is sufficient prothrombin in one milliliter of plasma to give 300 units of thrombin, corresponding to the small amount of about 0.15 mg of prothrombin per milliliter of plasma. The total possible number of thrombin units is, however, staggering. Immediate activation of a few percent of the prothrombin would coagulate blood in seconds. In the coagulation process, thrombin acts as an enzyme which splits an acidic peptide from fibrinogen (Fig. 1).

Fibrinogen has a molecular weight of 340 000 and is an asymmetric protein of axial ratio about 10.[8] It has an interesting substructure[9] which cannot be discussed here for lack of space. In pure form, it is a fairly stable protein which survives rough handling. After thrombin has split off an acidic peptide, the reactivity of the original protein is altered, the fibrin monomer produced by this enzymatic alteration having now a marked capacity to interact in a relatively specific fashion with other fibrin monomers. At the same time, a small amount of stabilizing plasma globulin is incorporated.[10] The interaction leads predominantly to end-wise association which produces fibrin fibrils or fibers having asymmetries orders of magnitude greater than that of the original fibrinogen molecule. During growth of the set of fibrin fibrils there occurs a brief interval of time during which the total volume changes from being greater to being less than the sum of the volumes dominated by each fibril. The

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

fibrils start to overlap and to crosslink where they come into contact. In this way a space filling network of strands develops.[11] At first, the strand network is tenuous and easily ruptured, but as old strands become thicker and as new strands are incorporated into the network, the clot progressively develops rigidity. As is seen later, this is not the end of the story, for, in the presence of platelets, a spontaneous squeezing out of fluid may occur (clot retraction). This is an important activity of the clot in forming a compact closure over a wound. If retraction and drying of the clot do not occur, an enzyme plasmin may be activated from its precursor.[12] Apparently, the enzyme plasmin has been devised specifically to dissolve fibrin.

The first portion of this general scheme to consider is the transformation of prothrombin into thrombin. This phase of the over-all problem has received a great deal of attention, the natural result of the fact that discoveries in clinics have revealed an ever-increasing series of patients whose plasmas have lacked one or another of the activators necessary for the prothrombin-thrombin conversion, and of the fact that prothrombin has been prepared in relatively pure form, first by Seegers and more recently by others, and its activation has been studied under a variety of conditions.

The scheme which is shown in Fig. 3 is a simplified version of experience in the field.[1–5] The central theme is the conversion of prothrombin into thrombin. The top half of the figure depicts clotting events which can occur when blood is drawn and every effort is made to keep the blood free of contamination with tissue components. Before proceeding, attention is directed to the central role assigned here to thrombin not only as the clotting enzyme but also as an agent which feeds back and promotes the formation of more of itself. As can be seen, this feedback enters at several levels into the set of interactions and, in order to promote the explosive

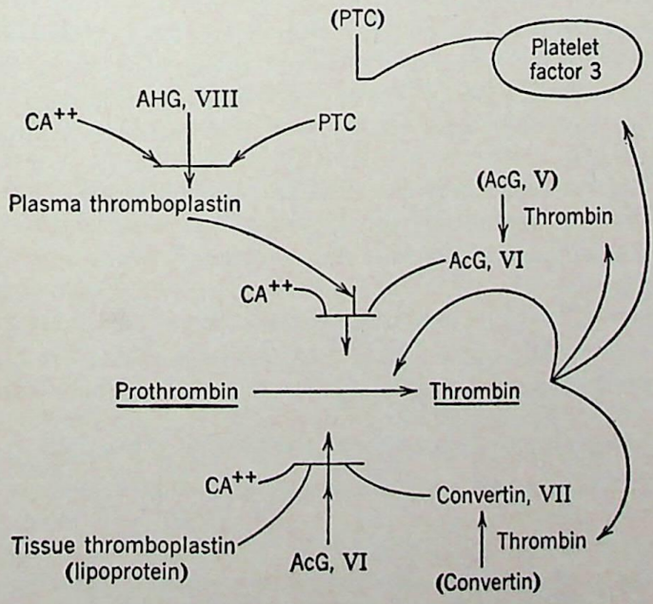

FIG. 3. Illustrative scheme for mechanisms involved in prothrombin activation.

liberation of thrombin, what is necessary, so far as this portion is concerned, is platelet decomposition and a nudge in the direction of thrombin production.

To start with, on being drawn, the blood comes into contact with a foreign surface and certain of the platelets respond by rupturing and liberating a series of compounds, the one singled out being platelet factor 3, a lipoprotein. This factor combines with or activates an inactive form of a substance which is probably a protein called plasma thromboplastin component (PTC). The inactive forms of components have been placed in parentheses, the Roman numerals indicate the accepted number in the "factor" series. Plasma thromboplastin component now interacts with antihemophilic globulin (AHG) and calcium ion to give plasma thromboplastin. This is not sufficient in itself to produce rapid prothrombin conversion, at least one additional step being necessary—namely, an interaction with the active form of accelerator globulin (AcG, VI). A rapid conversion of prothrombin now takes place. Note how thrombin is instrumental in converting inactive accelerator globulin to an active form, that it is involved in platelet alterations and may be involved directly in the conversion of prothrombin. All of the elements in this scheme are present in plasma.

The lower part of the Fig. 3 shows a sequence of events involving tissue components (tissue thromboplastin). Tissue thromboplastin short circuits platelet contributions at the start but requires calcium ion, the active form of accelerator globulin, and a new protein factor, convertin, which is produced from a precursor by the action of thrombin (cf. Goldstein and Alexander in reference 5, p. 93). It is generally held that the tissue thromboplastin-convertin cycle gives an immediate thrombin production which then operates on itself and on the upper mechanisms of Fig. 3 to yield a fast production of thrombin.

During the rapid development of thrombin (upper part of Fig. 3), all of the prothrombin may not be converted to thrombin. In the scheme presented, this is most readily understood by the fact that, during prothrombin activation, plasma thromboplastin, and thus at least some of the components which give rise to plasma thromboplastin, are either inactivated or consumed, as is true also of tissue factors. This is related to the confinement mechanisms which are outlined in the following.

Another aspect of the thrombin-production feedback mechanism which should be mentioned is that the platelets are thought to liberate a substance which is an antiheparin, and since, as is seen, heparin is intimately involved in the destruction of thrombin and thromboplastin, removal of heparin constitutes an additional positive factor in thrombin production.

The scheme of Fig. 3 has presented one possible sequence of events. The situation is probably more complicated than this, as is evident from a consideration of the following. First, at least two possible factors have

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

been omitted from the scheme. These are the Hegeman factor and PTA or plasma thromboplastin antecedent. Second, the number and sequences of reactions leading to the development of plasma thromboplastin are not clear. Not only is it possible that the details of factor interactions as given are incorrect, but also there is known to be opportunity for substitution under the proper conditions. For example, the platelets liberate a material which can substitute for the active form of accelerator globulin.

It is in this series of reactions that one finds the proven genetically controlled clotting defects. An abnormality in antihemophilic globulin is the defect of classical hemophilia, which was described over 150 years ago. It is a sex-linked recessive and manifests itself in varying deficiency. Seegers *et al.*[13] have evidence to show that this abnormality may be owing to inhibitors which block AHG. Lack of accelerator globulin (V), although it may be acquired through liver damage, may also be of hereditary origin; however, the inheritance is uncertain. Lack of PTC (hemophilia B, Christmas disease, etc.) is an hereditary disease which is a sex-linked recessive, similar to AHG deficiency.

There are two important series of reactions which are involved in confining coagulation to a locality and in removing unwanted clots. In approaching the mechanisms which confine clot development, it is necessary to realize that in wounds the hemostatic mechanisms are operating in the relatively stagnant or slowly flowing blood which occurs near the constricted ends of cut vessels. Whatever blood pressure is operating on these cut vessels will tend to work the coagulating system to the exterior. Thus, the problem is one of handling back-diffusion and any back-flow of active clotting agents. Of course, if such agents are carried into the general circulation, there occurs a relatively extensive dilution.

Confinement of clot development and the shutting off of coagulation reactions involve a series of antieffects which operate on the basis of adsorption, stoichiometric combination, and enzyme action. Some mechanisms are not well established, although a high probability can be assigned to their existence.

The first rather interesting reaction which is known to have importance in limiting clot development is the adsorption of thrombin to fibrinogen and fibrin.[3,4,12,13] In a static blood volume, such an effect allows complete local clotting to be accomplished before thrombin can diffuse out of the locality.

There then follows a series of reactions which have been grouped in Table I according to whether or not they are thrombin dependent. The second group is thrombin dependent; the equations mean that thrombin, alone or with other materials, will destroy three key procoagulants: accelerator globulin, prothrombin, and antihemophilic globulin.

What is implied by the three equations listed in the third group is that for every coagulant in the active form there is a factor more or less specifically designed to effect its inactivation. When the mechanisms of the first three groups of Table I are coupled with the many observations that materials such as AHG, PTC, AcG, platelet factor 3, etc., appear to be *consumed* in activating prothrombin, it is apparent that the explosive development of thrombin can be sharply terminated in the region of the clot.

The presence of sizable amounts of free thrombin always, however, constitutes a dangerous situation and two mechanisms, one rapid and the other slow, have apparently been devised to cope with the situation. The first of these is indicated in the first equation under group 4 and is the rapid reaction. The experiments designed to prove the existence of this inactivating factor are assailable, but essentially the suggestion is that, when normal prothrombin is activated to thrombin in plasma, there arises at the same time an ephemeral factor which can inactivate the resulting thrombin.

The greatest capacity for inactivating thrombin is distributed throughout the plasma itself. This activity is indicated in the second reaction under group 4, the responsible substance or substances being referred to as normal antithrombin. There is present in plasma sufficient normal antithrombin to inactivate 1.5 times the thrombin which could appear if all of the prothrombin were activated to thrombin. This places the capacity of antithrombin at about 450 units/ml. Under ordinary conditions, normal antithrombin acts relatively slowly, as is evident from the time disappearance of thrombin added to plasma which has been diluted fifty-fold with saline (Fig. 4, curve 1, see Waugh and Fitzgerald[15]). It is certain that antithrombin is itself inactivated in the process of destroying thrombin; the reaction is thus stoichiometric. A reversal of the thrombin-antithrombin complex has so far *not* been accomplished. It should be emphasized once more that the capacity of plasma antithrombin is about 450 units/ml. This large plasma-antithrombin capacity to a certain extent compensates for the small rate constant of the second-order thrombin-antithrombin reaction, the result being that when one unit of thrombin is present per milliliter plasma, inactivation will take place at the rate of 0.05 units

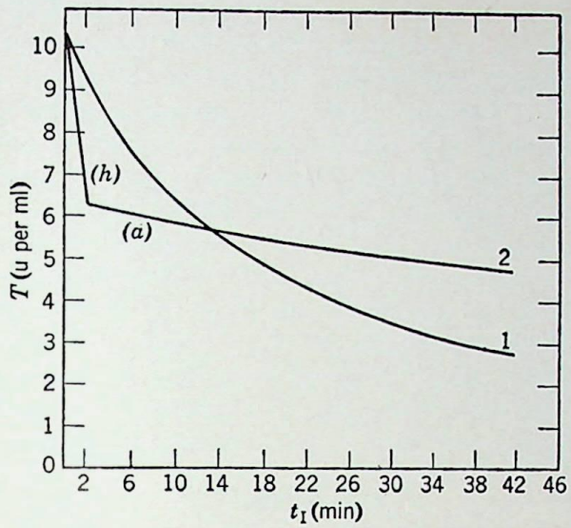

FIG. 4. Inactivation of thrombin by antithrombin. Curve 1 refers to normal antithrombin and curve 2 to the effects which are produced by traces of heparin.

thrombin per second. This rate of inactivation will increase the clotting time under conditions of fast activation but will not act with sufficient rapidity to prevent clotting.

The use of heparin, the highly acidic (sulfated) mucopolysaccharide, as an anticoagulant is well known. At this time, attention is directed only to the fact that heparin, at the small concentrations at which it exerts a strong anticoagulant action, acts through the normal antithrombin mechanism.[15] Figure 4 indicates the important points of this action—namely, that heparin speeds up the rate of normal antithrombin action by a factor of over 50 and at the same time decreases the efficiency of inactivation so that the antithrombin capacity drops by a factor of 1.5 to 2.0. Heparin, a product of the liver, is present in most tissues of the body and can be liberated and appear in the blood stream during anaphylactic shock. The normal concentration of free heparin in the blood, if it is present at all, is so low as to be difficult to measure. From the standpoint of hemostatic feedback mechanisms, the possibility that traces of heparin determine the rate at which normal antithrombin acts is most interesting. Heparin has been mentioned earlier as an important factor in the destruction of plasma thromboplastin.

It is now clear that the shut-off mechanisms attack any active components which leave the clot area. Under more favorable circumstances of time it would be necessary at this juncture to examine some of the concepts concerning the necessity of having threshold levels of procoagulants before the activating mechanisms are effective. There is evidence that such is the case and, if so, threshold levels must be intimately associated with the shut-off mechanism. That is, they would prevent an extensive spread of the explosive development of thrombin under conditions where activators would escape and be carried into the blood stream.

Consider now the clot structure itself. The developing clot has platelets adhering to its fibers, particularly at the fiber junctions. These platelets may be the loci at which such junctions were formed in the first place, it being understood that purified fibrinogens will form firm clots without platelets being present, thus that platelets are not necessary for fibrin development. In any event, the presence of the platelets gives rise in the normal course of events to an expulsion of the fluid portions of the clot, thus to clot retraction. As pointed out at the start, retraction gives rise to a relatively fine-meshed protective wound cover. It is now quite certain that platelets or platelet derivatives (e.g., serotonin) are necessary in the retraction process. The opinion has been expressed that the fibers of the clot are "contracting" in this process of clot retraction. Another alternative, which is the more likely, is that a process of zippering together is initiated at the fiber junctions and that this zippering process extends gradually throughout the clot.

Another important action takes place during clotting. This is the adsorption of an inactive enzyme called profibrinolysin[12] on to the strands of the clot. On activation, profibrinolysin gives rise to the enzyme fibrinolysin whose specificity is directed against fibrin, and to an extent fibrinogen. Fibrin is attacked via the splitting of peptide bonds, the fragments produced being unable to reassociate to form fibrin or a clot structure under the conditions existing in plasma. Not much is known about the normal mechanism for the activation of profibrinolysin, current methods for activation involving such techniques as the shaking of plasma with chloroform or the addition of chemical compounds, for example, streptokinase which is obtained from the corresponding cocci. The focus of attention in this discussion is the fact that fibrinolysin activity is known to be generated within the liquor sanguinis itself: after accidental death, by fear, stress, and severe exercise, after epinephrine injections and at times in "normal" individuals. With an appreciation of the importance of the coagulation mechanisms in everyday physiology, it is not surprising to find an interest in the possibility that a chemical or physical treatment can be found which activates only the fibrinolysin which is adsorbed to the fibrin clot. Another statement, which should come as no surprise, is that there occurs in the blood a potent antifibrinolysin activity which so far has prevented the therapeutic use of fibrinolysin preparations.

At the onset, reference was made to the possibility that a slow, continuous coagulation was necessary in the maintenance of capillary structure. Immediately thereafter, the factors involved in fast clotting and the control of the fast-clotting process were outlined. Return now to the problem of slow clotting, realizing that many of the complications of clotting may occur as a necessity for maintaining and controlling a system acting slowly and continuously, but poised for rapid action.

No absolute proof can be offered in which coagulation factors or the products of coagulation, for example monomer fibrin, can be directly implicated in capillary

TABLE II. Hemorrhage owing to clotting defects.

I. Platelet deficiency: from unknown causes or symptomatic	
II. Defects in activating components	
(a) Antihemophilic globulin	(AHG)
(b) Plasma-thromboplastin component	(PTC)
(c) Plasma-thromboplastin antecedent	(PTA)
(d) Accelerator globulin	(AOG)
III. Prothrombin deficiency: lack of vitamin K, caused by drugs, by disease or is congenital	
IV. Fibrinogen deficiency: congenital or through liver damage	
V. Anticoagulants: heparin, enzymes (shock)	

properties such as fragility and permeability. The evidence is indirect and can be summarized briefly by pointing out that interferences in the normal clotting mechanisms often lead to internal hemorrhage, a situation in which blood cells and plasma leak out through the capillaries into the tissue spaces. A few of the coagulation defects which lead to hemorrhage are shown in Table II (see also Wintrobe,[1] p. 285).

First, it is seen that a deficiency in platelets may lead to hemorrhage. This deficiency can arise either through an inherent platelet deficiency or through an external agent, disease for example, which reduces the numbers of platelets.

Second, deficiencies in procoagulation components have the same effect. Here one finds included antihemophilic globulin, plasma-thromboplastin component (mentioned earlier), possibly plasma-thromboplastin antecedent, and accelerator globulin.

Third, a deficiency of prothrombin, whether it be induced by vitamin-K deficiency, by drugs, by disease, or is congenital.

Fourth, a deficiency in fibrinogen: congenital or as a result of liver damage.

Fifth, drugs which increase antithrombin action such as heparin and circulating anticoagulant enzymes which may appear in shock.

The common denominator for this impressive list is active coagulation. In considering the physiological necessity for slow coagulation, the author has been impressed by the difficulty with which the normal anticoagulation mechanisms remove or inhibit the last traces of thrombin. This is a situation so frequently encountered that one is tempted to think in terms of traces of highly resistant thrombin. Such a conclusion would be premature since the alternative that the coagulation system also has a mechanism which preserves slight traces of thrombin is attractive: such a system would not only provide for slow continuous clotting but would supply the traces of thrombin which might spark the initial stage of autocatalytic activation. I feel that the slow-clotting mechanism will emerge as a mechanism warranting close attention in the future.

Hormone Regulation

DEWITT STETTEN, JR.

National Institute of Arthritis and Metabolic Diseases, National Institutes of Health, Public Health Service, U. S. Department of Health, Education, and Welfare, Bethesda 14, Maryland

IN higher organisms, whether animal or vegetable, there exist channels through which fluids are transmitted from one tissue to another. Into these fluids or humors are delivered many compounds elaborated in one or another tissue. It is to be expected that, in many cases, these compounds will exert recognizable physiological effects in other tissues to which they may be hydraulically transmitted. Among the host of compounds which meet these criteria, a limited number have been set apart under the special category of hormone or "chemical messenger." It is the purpose here to review briefly what these hormones are, whence they arise, whither they go, and how they accomplish their missions. Although hormonal mechanisms are well described in invertebrates and indeed in plants, these remarks are restricted to mammalian endocrinology.

To speak of the mission of a compound is to lapse into teleological jargon. Teleology, however, has been defined as a woman with whom no scientist cares to be seen in public, but with whom all scientists consort in private. It will simplify my task if you will forgive my teleological indiscretions in this paper which permits me to dodge the otherwise necessary cumbersome circumlocutions.

What then is a hormone? It is a compound devoid of intelligence but containing nonetheless in its structure certain information. While there are no Koch's postulates by which one may judge whether a compound is or is not a hormone, there are certain accepted standards to which most respectable hormones conform.

1. In many but not all cases, hormones arise in tissues which appear to be specialized for their production. In the mammal, these organs include the neurohypophysis, the adenohypophysis, the thyroid, the parathyroids, the islets of Langerhans of the pancreas, the adrenal medullae, the adrenal cortices, the testes, the ovarian follicles, and the ovarian corpora lutea. Other organs, such as the pineal body, the hypothalamus, the thymus, the carotid bodies, etc., are not included in the present list of so-called endocrine organs in view of their relatively uncertain status and lack of specific and convincing information.

It should not be supposed, however, that all known hormones arise in tissues anatomically specialized for their production. The word "hormone" was coined actually to describe an as yet unidentified principle termed secretin, discovered by Bayliss and Starling, which appears to arise in the intestinal mucosa, to enter the blood stream, and to stimulate, upon its arrival there, the secretion of juices by the pancreas. A second but distinct material, arising from the same source, cholecystokinin, stimulates the contracture of the gall bladder, and the injection of bile into the duodenal lumen. Similarly, there is partial evidence for the existence of renal hormones affecting vascular tone, hepatic hormones affecting uptake of blood glucose by muscle, and indeed a hormone liberated by working skeletal muscle which affects the metabolism of resting muscle in the same animal.

Whereas a number of the hormones which arise in the specialized endocrine glands, e.g., the pituitary, the adrenal, etc., have been purified and characterized structurally, this has not been accomplished for hormones arising from such tissues as liver or intestinal mucosa. Consequently, the structural information presented is confined to products of the so-called glands of internal secretion.

2. A second characteristic of hormones is that they normally circulate and exert their regulatory roles at low molar concentrations. On the basis of published estimates of the normal concentration of insulin in blood, it would appear that this agent is effective at concentrations of about 10^{-11} to 10^{-12} molar, and epinephrine, glucagon, and thyroxin all appear to exert recognizable effects at similar levels of concentration.

3. Some, but not all, hormones exert their effects upon highly specific target organs. Thus, adrenocorticotropic hormone of the pituitary operates essentially uniquely upon the adrenal cortex, while the activity of thyrotropic hormone is restricted largely to the thyroid. The sole convincingly demonstrated action of glucagon is upon the liver. On the other hand, epinephrine exerts actions upon liver and muscle, insulin has been shown to operate in many tissues including skeletal muscle, adipose tissue, and mammary gland, whereas the effects of adrenocortical steroids and thyroxin may be demonstrated in a wide variety of tissues.

4. If a hormone is to exert a regulatory effect, clearly the rate of its release into the blood stream must be variable and should be determined by some function of the mechanism which it regulates. Such variation in rate of discharge has been demonstrated for certain but not for all hormones. For example, one may cite insulin, which regulates the level of glucose in the blood and the release of which by the islet cells of the pancreas is determined directly by the concentration of glucose in the pancreatic blood supply. Analogously, ACTH, released by the pituitary, specifically stimulates the adrenal cortex to discharge steroid hormones, which, if injected, cause a prompt suppression of ACTH produc-

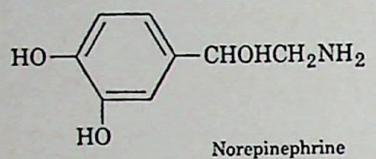
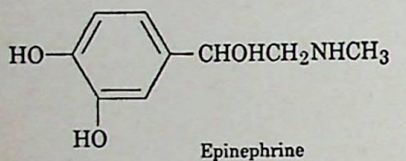
Thyroxine



Norepinephrine



Epinephrine

FIG. 1. Structures of certain phenolic hormones.

tion. Many other such examples of negative feedback, more or less well-documented, might be cited.

It may be profitable to consider briefly some of the structural types which are represented among the hormones. These include a variety of substances, among the simplest of which are certain phenols (Fig. 1). Under the regulation of thyrotropic hormone derived from the anterior pituitary gland, a protein, thyroglobulin, is elaborated in the thyroid gland, which contains the unique amino acid thyroxin, 3,5,3′,5′-tetraiodothyronine. This amino acid, accompanied by triiodothyronine, is discharged into the bloodstream where it circulates, largely protein-bound, in the plasma. Epinephrine and norepinephrine derived from adrenal medulla are related closely both metabolically and structurally. There is a considerable amount of information at hand defining the biosynthetic origins of these compounds. Tyrosine contributes the phenolic portions, in each case. With these, as well as with certain other hormones, secondarysites of origin exist. The synthesis of thyroxin-like materials in the totally thyroidectomized animal[1] is perhaps not surprising in view of the fact that tyrosine-containing proteins, after incubation with iodine in alkali, in the absence of enzymes, exhibit thyroxin activity.

Steroidal hormones comprise a large and much-studied group. They often are classified structurally according to the number of carbon atoms contained. Thus, the C_{18} steroids include the estrogens (Fig. 2), estrone, α- and β-estradiol, estriol, as well as the less familiar equilin and equilenin. All of these compounds have phenolic—i.e., acidic—properties. The methyl group born on carbon atom 10 of most other steroids is lacking in these compounds, as a consequence of the unsaturation. Arising predominantly in the Graafian follicle of the ovary, under regulation by pituitary gonadotropin, estrogens are generated also by testis and possibly also by adrenal cortex. They are detoxified normally in the liver by conjugation with glucuronic or sulfuric acids, and the loss of this function in hepatic failure results in feminizing symptoms and signs.

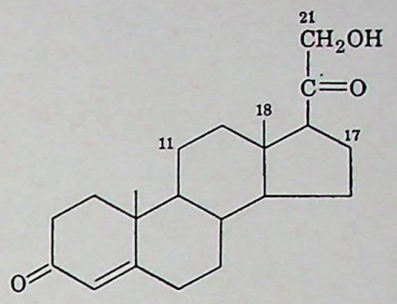
FIG. 3. Structures of certain C_{19} steroid hormones.

The C_{19} steroids include (Fig. 3) the androgens, testosterone and its congeners. There are a number of steroids with androgenic activity and these may arise in the adrenal cortex as well as in the testis. The C_{21} steroids (Fig. 4) include not only the several adrenocortical steroids but also progesterone, the hormone of the ovarian corpus luteum. The generation of these hormones is under direct control of specific anterior pituitary hormones. Testicular production of androgens is regulated by pituitary gonadotropin, adrenocortical activity is determined by pituitary adrenocorticotropin, and progesterone production depends upon a luteinizing hormone of the pituitary gland.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

The structural similarities of the several steroid hormones are explained by the fact that they are all biogenetically closely related. Cholesterol appears to be a parent compound to all of them, and many of the individual enzyme-catalyzed steps whereby they arise have been elucidated. It is, of course, of great interest that specific and important biological activities of a wide variety are associated with steroids. In addition to the steroid hormones, other biologically important steroids are vitamin D, the cardiac aglycones of the digitalis group of drugs, the toad poisons, and certain carcinogens. What it is in the steroid structure which imparts to the members of this class these various activities is not known.

The remaining groups of hormones about which there is structural information are polypeptides. Of these, insulin (Fig. 5) is probably the best-studied. Beef insulin, whose chemical structure was given by Sanger,[2] is made up of two polypeptides, an *A*- or acidic chain comprising 21 amino acids and a *B*- or basic chain containing 29 amino acids. The intramolecular disulfide bridges have been described previously by Oncley (p. 30), and their integrity is essential to the physiological activity. The C-terminal alanine in the *B*-chain is apparently not essential, however, and indeed the eight C-terminal amino acids of this chain may be eliminated without complete inactivation. The question of what constitutes the essential center of physiological activity of insulin, if indeed there is such, remains unanswered. When this structure first was published, attention was attracted to the pentapeptide closed ring in the *A*-chain, particularly since rings of similar size were found by du Vigneaud[3,4] to be present in both of the hormones of the posterior pituitary gland, vasopressin and oxytocin. The curious run of three adjacent aromatic amino acids in the *B*-chain also was pointed out.



Deoxycorticosterone

Compound	Substituent at C Numbers 11	17	18
Corticosterone	—OH	—H	—CH_3
11-Dehydrocorticosterone	=O	—H	—CH_3
17-Hydroxycorticosterone	—OH	—OH	—CH_3
Cortisone	=O	—OH	—CH_3
Aldosterone	—OH	—H	—CHO

FIG. 4. Structures of certain C_{21} steroid hormones (N. B. Progesterone differs from deoxycorticosterone only in that $-CH_2OH(21)$ is reduced to $-CH_3$.

No evidence has been presented implicating either of these sites specifically in insulin function.

The posterior pituitary hormones present striking similarities and, as might be expected, some degree of cross-reactivity physiologically. There is some reason to believe that these compounds may be parts of a larger polypeptide arising in the hypothalamus and transmitted down the pituitary stalk, to be stored in and released from the posterior lobe of the pituitary gland.

Attention is directed now to amino acids 8, 9, and 10 in the *A*-chain of insulin. Insulins of several species have been prepared; all are very similar in physical properties and are essentially identical in physiological assay, about 27 units per mg. Chemical differences do exist,

FIG. 6. Species variations in insulin structure.

however, but thus far the sole differences that have been detected reside within these 3 amino acids (Fig. 6). Although the sample studied is confessedly too small to permit firm conclusions to be drawn, a few suggestive findings have turned up. In each position, 8, 9, or 10, only one of 2 amino acids has been found. Thus, in position 8, there is either alanine or threonine; in position 9, serine or glycine; in position 10, valine or isoleucine. If this binary replacement proves general, and no other alterations are found, only 8 insulins are possible. There may be, however, an additional restriction. On comparison of positions 8 and 10, it appears that, whenever the former is alanine, the latter is valine; whenever the former is threonine, the latter is isoleucine. Should this represent a firm link in the coding to these 2 positions, only 4 insulins would occur, and indeed all types now are known. It is not surprising, then, that pig and whale insulins prove to be identical (Fig. 6†).

Insulin is generated in the β cells of the islets of Langerhans. Its function, as is discussed later, is to favor the utilization of blood glucose by muscle, to restrict glucose formation by liver. It is noteworthy, therefore, that the release of insulin by β cells is favored by a high concentration of blood glucose.

Intimately associated anatomically with the β cells are the α cells of the islets which are the source of glucagon. This polypeptide (Fig. 7) was for many years an unsuspected contaminant of the best available insulin from American commercial sources although, because of differences in manufacturing procedure, it was lacking in Danish insulin. Chemically and physiologically it is

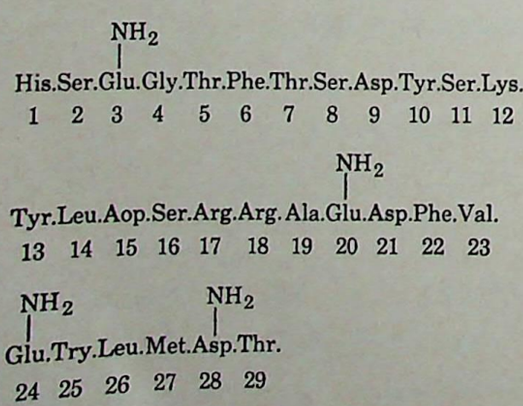

FIG. 7. Structure of glucagon.

unrelated to insulin.[5] The sole sequential similarity between insulin and glucagon that has been pointed out is the series 22–24 in glucagon (Phe. Val. Glu NH_2) which resembles Phe. Val. Asp NH_2 (1–3 chain B) of insulin. Whereas both glucagon and insulin affect the level of blood glucose, they do so by influencing quite different processes, and appear to be antagonists only on very superficial inspection.

The last group of hormones about which there is useful structural information are the polypeptides of the anterior pituitary gland. There are at least six of these, thyrotropin, adrenocorticotropin, somatotropin (growth hormone), follicle stimulating, luteinizing, and melanophore stimulating hormones. Other activities have been suspected in the past and may be revealed in the future. Complete structural information is available, for certain species, in regard to corticotropin and melanotropins. The formulas for certain of these have been given by Oncley (p. 30). Here, attention is directed only to certain salient points of similarity and dissimilarity (Fig. 8). Amino acids 4 through 10 of all corticotropins studied are identical with amino acids 7 through 13 of all known melanotropins. This identity of a series of seven amino acids is sufficiently startling

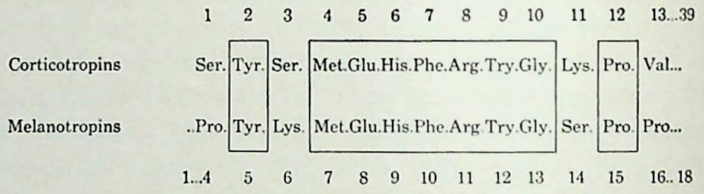

FIG. 8. Structural relationships of ACTH and melanophore stimulating hormone.

to attract attention. Li[6] has pointed out that the identical sequences would have been eleven rather than seven, but for a curious confusion about positions 3 and 11 of corticotropins, or 6 and 14 in melanotropins. An interchange between the serine and lysine in the appropriate positions of either of these peptides would prolong the identical sequences from seven to eleven.

This observation, as well as the previously mentioned species variations in insulin, suggests the occurrence of certain blunders in the transmission of the coded information pertaining to amino-acid sequences. Such blunders, if indeed so they be, may themselves be informative. Thus, the present figure suggests that the code is such as to permit interchange of information about 2 amino acids 8 positions remote in a polypeptide.

To date, accumulating knowledge of hormone structure has, for the most part, revealed little about how these compounds function. Only within the past few years have reasonable hormone effects been observed in biological preparations disorganized below the cellular level. Several of these now may be mentioned.

Thyroxin has been suspected for some time of exerting an effect similar to that of 2,5-dinitrophenol, a suspicion dating back to the early clinical observations of the

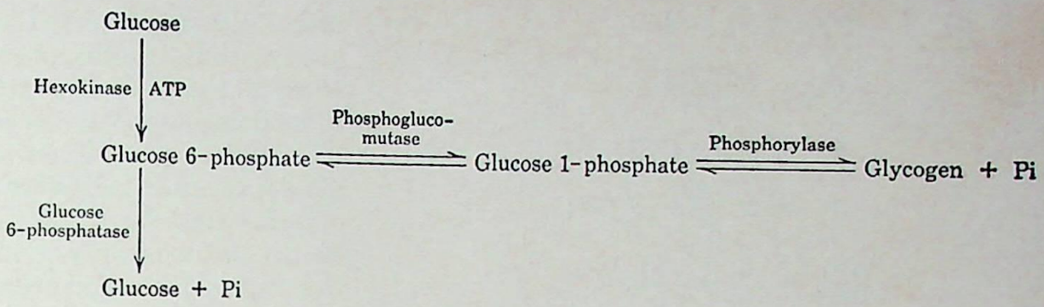

FIG. 9. Certain phases of the metabolism of glucose.

toxicology of the latter drug during World War I. When it was ascertained that dinitrophenol effected an uncoupling of oxidative phosphorylation, permitting respiration to proceed without obligatory and coincident phosphorylation, a similar effect was attributed to, and soon found with, thyroxin. This effect has been demonstrated with isolated mitochondria by Lehninger.[7] Such uncoupling, and consequent escape of glycolysis from the restraining influence of the Pasteur effect, would explain many of the clinical manifestations of thyrotoxicosis.

Estrogens have been shown by Villee[8] to activate the isocitric-acid dehydrogenase of placenta and this effect has been demonstrated in homogenized preparations (cell-free). More recently, Talalay[9] has indicated that the enzyme of placenta directly affected is a transhydrogenase which regenerates the TPNH required by the dehydrogenase in question. It is possible that, in this transhydrogenase reaction, the estrogen serves as a self-regenerating co-substrate.

Two hormones about which there is partial mechanistic information are epinephrine and glucagon. It is perhaps remarkable that these two substances, wholly unrelated structurally and biogenetically, should both exert, at equimolar concentrations, virtually identical effects. These effects, elucidated by Sutherland,[10] relate to the activation of hepatic phosphorylase. This enzyme, required for glycogen breakdown and probably also for its synthesis, is itself enzymatically inactivated with the loss of inorganic phosphate. Its reactivation also may be accomplished enzymatically, but this requires a novel cofactor, an anhydride of AMP. The synthesis of this cofactor, by yet another enzyme, proceeds only in the presence of epinephrine and/or glucagon. The two hormones, though acting identically in liver, are quite different in their effects upon muscle glycogen. Here, whereas epinephrine is highly active, glucagon is without effect.

Insulin, which has received the attention of many excellent investigators since its isolation, is in a more confused state than some of the other hormones which have been considered. The dramatic capacity to lower blood sugar apparently is the result of effects upon two processes. To evaluate these two effects, one should consider briefly some of the sources and fates of blood glucose (Fig. 9). Here are represented in abbreviated form some of the reactions of concern. In the absence of insulin, as in the severely diabetic human or as in the pancreatectomized animal, the conversion of extracellular glucose into intracellular glucose 6-phosphate, an essential first step in glucose utilization, is impaired. This impairment is especially demonstrable in muscle tissue and characteristically is seen in the isolated diaphragm. The basis for the impairment is still somewhat obscure but the bulk of current evidence favors the view, first propounded by Levine,[11] that insulin favors the entry of glucose into the intracellular compartment of muscle. Insulin demonstrably performs this function in relation to a number of other sugars. Possibly significant is the fact that the sugars most responsive to insulin in this regard are configurationally identical with glucose about carbon atoms 1, 2, and 3.

A second pertinent insulin effect is defined best by the fact that the activity of glucose 6-phosphatase is greatly enhanced in the liver of the diabetic animal, an effect reversible by administration of insulin. The importance of this enzyme is revealed by the fact that it catalyzes the reaction responsible for the majority of glucose contributed to the blood by animal tissues.

Consider the dilemma of the diabetic animal in the light of these two defects. With the conversion of glucose to glucose 6-phosphate restricted, and with the hydrolysis of this ester exaggerated, there results a curtailment of glucose phosphate needed for a variety of important processes, including glycolysis, oxidation, generation of reduced coenzymes, preparation of essential intermediates. Many, but certainly not all, of the late consequences of untreated diabetes are referable directly to this combination of biochemical defects. The question of which of the two defects is most significant is in a state of flux at the present time. Data from Hastings[12] and others suggest that the increase in utilization of glucose by muscle occurs much more promptly in response to insulin than does a decrease in glucose 6-phosphatase activity. On the other hand, Weinhouse and his collaborators[13] have data indicating that the reverse is true.

In relation to this figure, one can consider also the purported "antagonism" between insulin and glucagon. Glucagon, as mentioned previously, effects favorably the activity of hepatic phosphorylase, promotes breakdown of liver glycogen, and produces a resulting rise in blood glucose. Insulin, by its actions, produces a fall in blood glucose. If one's vision is restricted to the glucose of the blood, these two hormones act antagonistically. The blood glucose, however, is really relatively un-

FIG. 10. Expected arithmetical relationship between concentrations of free hormone, H, of bound hormone, HT, and of acceptor sites on target organ, Q.

important, except insofar as it nourishes the several tissues of the body, and the major consuming tissue is skeletal muscle. With respect to the nutrition of skeletal muscle, glucagon and insulin, far from being antagonists, are synergists. Glucagon supplies to the blood the glucose which muscle requires, and insulin facilitates the entry of this glucose into the cells so that it may be utilized.

It was mentioned at the outset that many endocrines, insulin among these, are physiologically active at remarkably low concentrations. The finding of Stadie[14] that several tissues responding to insulin *in vitro* are endowed with the capacity to bind insulin to their surfaces, and that the response to insulin is, under appropriate circumstances, proportional to the amount of insulin bound, is perhaps relevant. If the target organ has the capacity to bind the hormone to itself, local concentrations of hormone may be built up far in excess of the concentrations occurring in the blood. The dose-response relationship for several hormones is compatible with this idea in that, whereas the response is approximately proportional to dosage at low dosage levels, for many hormones a maximal response is attained asymptotically at high dosage levels. This suggests that something, possibly the acceptor site on the target organ, is being saturated with hormone. This situation may be treated arithmetically[15] by assuming a reversible association between hormone (H) and target-organ acceptor site (T). If K is the dissociation constant and Q is the total concentration of acceptor sites (Fig. 10), the problem may be treated as Lineweaver and Burk treated the Michaelis-Menten problem, to yield the final expression on the figure. If now it be assumed tentatively that the concentration of hormone H is proportional to dosage and that the response is proportional to the concentration of bound hormone HT, the reciprocals of these two quantities should be related linearly. In a limited number of cases where this relationship has been tested, the expected linear relationship indeed has been found. Values for K and Q can be estimated from the slopes and intercepts of such plots. The usefulness of the relationship diminishes insofar as some quantity other than the concentration of bound hormone limits the observed response.

It is perhaps unfortunate to terminate this distinguished series upon such an unsatisfactory note. In earlier papers on macromolecular structure and interaction, biological fine structure, information storage and retrieval, etc., one was left with the idea that there is a narrowing gap between the biological description and the physical model, or even explanation. In the matters presently under consideration, the gap is so wide that I, for one, am unable to see across it. Of such a gap, one may hope, but one can not know, that it is being narrowed. Certainly many experiments will have to be performed before the hormones, their origins, their modes of action, and their interrelationships can be defined in physical terms.

I. INTRODUCTION

RESEARCH on line broadening, though often regarded as pedestrian and unlikely to lead to new fundamental insights, is nonetheless inspired by a vision. One dreams that in a distant star or in some other inaccessible region filled with matter a few atoms, perhaps hydrogen atoms, emit lines whose structure can be analyzed in terrestrial laboratories. These lines carry in many cases information we have already learned to understand: red shifts revealing masses, Doppler shifts revealing motions, and sometimes Doppler widths revealing temperatures. It is clear that in principle all physical properties of the medium containing the radiating atoms are somehow reflected in the line structure, since they affect the forces between the radiating atom and its neighbors, the distances over which these forces are exerted, and the times during which they act. One hopes, therefore, that when the language of the spectral lines has been fully learned, a radiating atom in a distant material environment can serve as a noninterfering probe conveying significant data regarding pressure, temperature, or, more generally, the distribution of molecular speeds, and states of ionization in the surrounding medium. Such hope is now far from fulfillment, and this article attempts but a modest contribution to its realization.

This survey is limited to a small part of the line-width problem, a problem whose scope and complexity is not widely appreciated and which has suffered perhaps from an excessive optimism of authors who, on proposing a partially successful simple model yielding to mathematical treatment, have served enthusiastic notices that the whole problem is solved. When, as often happens, experimental observations fit the special model, the matter is easily regarded as closed despite logical difficulties, and it sometimes takes severely critical appraisals to set the problem on the path of progress again.

The part treated here is plasma broadening, a group of effects peculiar to lines emitted in a medium that is strongly ionized but has no net charge. Hence we do not consider the results of impacts between neutral molecules, nor any of the theories suitable principally for their description. Other review[1] articles fill this need. In a plasma, the heavy positive charges and the light electrons often require different treatment, as the following discussion shows. Attention is restricted to emission because in ionized media absorption is not often directly observable and the problems connected with phenomena of reabsorption necessitate considerations unrelated to the broadening agencies here reviewed. Nor are microwaves specifically included in our work; optical lines are our chief concern.

Applications of the theory are found in four widely separated fields of investigation: in astrophysics, gas discharges, strong shocks, and flames or explosions. Some practical urgency attaches to line-width studies because of the importance which all of these researches currently enjoy.

This introductory section surveys two very general methods that have found application to plasma line-broadening problems. One is called statistical theory; the other is variously called impact theory, velocity broadening or phase-shift broadening theory. They refer to different models that cannot easily be compared. Because of the intuitive difference of the models the effects they generate are sometimes regarded as separate or even additive, and oversimplifications have appeared as a result of this seductive fallacy. Statistical and impact theories are certain limiting instances of a more general theory, each having its own range of application, and each losing its validity in a large domain of physical conditions of interest to the experimenter. There are also situations in which both theories apply and give identical answers. But it happens that in plasma broadening the integrity of the two methods is rather better preserved than under almost any other circumstances, the reason being that the heavy ions exert long-range and slowly varying forces which satisfy the statistical theory, whereas the light and swift electrons are very often tractable by impact methods.

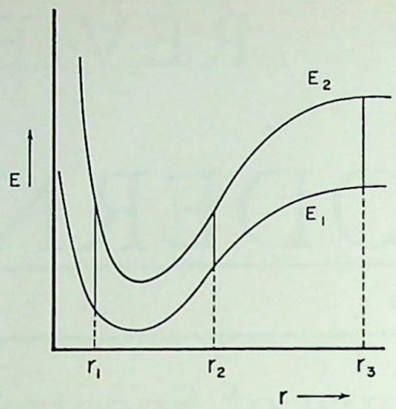

FIG. 1. Dependence of energies on interparticle distance.

A. Statistical Theory[2–4]

A spectral line arising from a transition between an upper level of energy E_2 and a lower of energy E_1, has its normal (radian) frequency $(E_2-E_1)/\hbar$. But E_2 and E_1 are not constants; they vary as a result of perturbations caused by other molecules, the "perturbers." In the presence of only one perturber the dependence of E_2 and E_1 on the distance, r, between the centers of the radiating and perturbing particle is given by the well-known potential energy curves, of which a typical set is drawn in Fig. 1. A transition occurring at a large distance r_3 has a normal ω, at r_2, ω is smaller and at r_1 larger than normal. Thus to every r there corresponds an $\omega(r)\equiv(E_2(r)-E_1(r))/\hbar$ and some ω's are more likely than others. In a statistical sense, the probability $P(\omega)$ equals the fraction of configuration space in which $E_2-E_1=\hbar\omega$ or, more precisely, that fraction times the Boltzmann factor, $\exp\{-[E_2(r)-E_2(\infty)]/kT\}$. It has been customary to neglect the Boltzmann factor on the supposition that it is practically 1 where $P(\omega)$ is large. This may sometimes lead to serious errors; yet we assume it here.

In the presence of N perturbers, the frequency distribution $I(\omega)$ is still given by $P(\omega)$, but configuration space now has $3N$ dimensions, and

$$I(\omega)d\omega=P(\omega)d(\omega)$$

$$=(4\pi/V)^N\int\cdots\int r_1^2r_2^2\cdots r_N^2dr_1\cdots dr_N. \quad (1.1)$$

The integration extends over the restricted domain in which

$$\omega-d\omega\leqslant\omega(r_1,r_2\cdots r_N)\leqslant\omega+d\omega.$$

Usually, in application of statistical theory, additivity is assumed for the contributions to ω:

$$\omega(r_1 \cdots r_N) = \sum_i \omega(r_i).$$

This is often true for large r, but never for small r, where the main contribution to the interaction comes from the exchange forces. In a plasma, $\hbar\omega(r)$ for large r is the difference in atomic energy resulting from the Coulomb forces which are exerted by the passing ions and electrons. Mathematical techniques for evaluating the integrals in (1.1) involve the use of δ functions (Dirichlet's method) now so common as not to require review (see Margenau[2c] and Chandrasekhar[5]).

B. Impact Theory

An infinitely sharp line implies a radiating process of infinite duration. Natural line width arises from the fact that the upper state of the atom has a finite life time, and can be obtained by carrying out a Fourier analysis of the sinusoidal vibration for a finite time. According to the reasoning of Lorentz,[6] impacts of perturbers shorten the lifetime below the natural duration and thereby increase the width of the emitted line. Mathematical representation of this process is very simple: Suppose an atom is allowed to emit radiation of frequency ω' between times 0 and T. Then the distribution of Fourier amplitudes is given by

$$J(\omega,T) \propto \int_0^T e^{i(\omega-\omega')t} dt = \frac{e^{i(\omega-\omega')T}-1}{i(\omega-\omega')}.$$

If this were the only radiative act observed, the frequency distribution would be $|J(\omega,T)|^2$. The observed line, however, is a composite of radiations from many atoms radiating for different lengths of time, but with a mean time equal to τ, the reciprocal of the collision frequency ν_c. The probability that a given atom radiate for T seconds is $\tau^{-1}e^{-T/\tau}$. Hence the intensity at ω is

$$I(\omega) = \tau^{-1}\int_0^\infty |J(\omega,T)|^2 e^{-T/\tau} dT \propto \frac{1}{(\omega-\omega')^2+\nu_c^2}. \quad (1.2)$$

This is the famous Lorentz "dispersion" curve whose full width at half-maximum is $2\nu_c$ on the radian frequency scale. In this article the "half-width" $\omega_{\frac{1}{2}}$ is defined as full width of the line at a height equal to $\frac{1}{2}$ its maximum intensity. Formula (1.2), despite its simplicity, meets with singular success in predicting that a "pressure-broadened" line has a width proportional to the collision frequency, and since

$$\nu_c = nqv \quad (1.3)$$

in terms of the number density of perturbers n, the collision cross section q, and their velocity v, this width turns out to be proportional to the pressure at a constant temperature. Hence the name, pressure broadening.

The meaning of an impact is clear only if the molecules are rigid spheres, an hypothesis of the worst sort for ions. Even for neutral structures, Eq. (1.2) is not wholly satisfactory, for if used in conjunction with (1.3) q must take on values quite different from gas-kinetic cross sections, usually larger values. To hide the difficulty a new phrase was coined; theorists began to speak of *optical* cross sections, to the delight of experimenters who now had a brand new quantity to measure. The unpleasant fact is, however, that Lorentz' theory in its simple form breaks down when the perturbers are surrounded by force fields, i.e., when impacts are "soft".

Qualitatively speaking, collisions affect the radiative process in two ways:

(1) Some actually terminate it, quenching the upper state by transferring the energy of excitation prematurely to another place. Precisely under what conditions an impact will quench is not easy to say because this process requires a delicate balance of energies within perturber and radiator. But it is known that quenching occurs, because it manifests itself in an added line width *and* a reduction in the total line intensity.

(2) The other collision effect is a phase change in the emitted radiation accompanying the detuning of its frequency by a passing particle. If the phase change connected with a collision is large enough the passage will effectively divide the wave train into two incoherent ones, and this is tantamount to termination so far as line width is concerned. In this case no change in intensity accompanies this interruption because the atom goes on radiating a similar line during each successive free period. Lorentz did not distinguish between quenching and phase-altering impacts.

Lenz and Weisskopf[7] incorporated the idea of phase changes in the impact theory and achieved thereby a measure of success in giving meaning to an optical cross section, or an "optical impact radius." In the absence of perturbations, Weisskopf reasoned, ω=constant=ω' and the phase is a linear function of t, $\omega' t$. This corresponds to a sharp line. If an appreciable change $\Delta\varphi$ is added to this linear trend during a perturbation, that perturbation acts like Lorentz's impact. Now

$$\Delta\varphi = \int(\omega-\omega')dt = \hbar^{-1}\int(\Delta E_2 - \Delta E_1)dt, \quad (1.4)$$

where $\Delta E(r)$ is the departure of the E curves in Fig. 1 from their final values. Writing $\epsilon(r)$ for the second difference $\Delta(E_2-E_1)$ and assuming ΔE_2 to be so small

that the perturber is deflected but very little from its straight-line path, then, if it flies by at a closest distance ρ from the radiator and has a speed v,

$$\Delta\varphi=\hbar^{-1}\int\epsilon(\rho^2+v^2t^2)^{\frac{1}{2}}dt=\Delta\varphi(\rho,v). \qquad (1.5)$$

The added phase depends on ρ and v. An *effective* impact, i.e., one which kills coherence, is an impact for which $\Delta\varphi\gtrsim\varphi_0$, a quantity presumably of order of magnitude 1. Thus the relation $\Delta\varphi=\varphi_0$ divides all impacts into two ideal classes, those which broaden and those which do not. Since a smaller ρ leads in general to a larger $\Delta\varphi$, the relation $\Delta\varphi=\varphi_0$ defines a $\rho_c(v)$ *below* which all impacts broaden the line. Therefore $\pi\rho_c^2(v)$ plays the role of Lorentz' q and may be introduced in (1.3) and (1.2). Here then is a qualitative reason why optical cross sections may differ from gas kinetic ones, and why they depend on v.

We shall often encounter the equation $\Delta\varphi=\varphi_0$ as a limiting condition separating the ranges in which different kinds of treatment are necessary. The precise value of φ_0 never matters, but we assume it to be of order magnitude 1 (or $\pi/2$, or even π) and call it the *critical phase.* If $\Delta\varphi$ arises from single impacts, the critical phase defines an *optical radius* or *critical impact distance* ρ_c, which depends on v and on the form of ϵ, i.e., the law of interaction. Likewise, there results an *optical cross section* $\pi\rho_c^2$.

Numerous refinements of this theory have been proposed.[4b,8] One of them is treated later in some detail because of its success in applications even under circumstances in which its *a priori* validity is not evident (see Sec. IV).

C. Relation Between Statistical and Impact Theories

The two physical pictures underlying the treatments in parts A and B of this section are so completely unrelated that a decision as to their domains of validity cannot be made on simple intuitive grounds. Attempts to combine the results in phenomenological ways, by merely saying that both are present independently and thus "folding" one distribution into the other[2d,4b] have had some success,† but lack fundamental justification. It is necessary to fall back upon a mathematical formalism more general than either treatment A or B, and to see under what conditions it reduces to these species of description.

Such a formalism is available in the Fourier integral for the line width, suitably generalized.[9,10] A classical observable Q, which is a function of momenta and coordinates of some physical system, is represented in quantum mechanics by a matrix with elements Q_{ij}. The classical intensity distribution within a line,

$$I(\omega)=\frac{2\omega^4}{3\pi c^3}\left|\int_{-\infty}^{\infty}\mu(t)e^{-i\omega t}dt\right|^2, \qquad (1.6)$$

is such an observable involving momenta and velocities of the radiating atom through the varying dipole moment μ and the atomic frequency ω. The observed value of Q for the state of the system which is represented by the statistical matrix $\mathbf{S}$ is

$$\bar{Q}=\text{trace}(SQ).$$

Thus the quantum mechanical intensity distribution (we omit the bar) is, because of (1.6),

$$I(\omega)\propto\text{trace}\left\{S\int dt\mu(t)e^{-i\omega t}\int dt'\mu(t')e^{i\omega t'}\right\}, \qquad (1.7)$$

where S, $\mu(t)$, and $\mu(t')$ are matrices, the latter two in the so-called moving system or in "the Heisenberg form" (see the following). From (1.7), statistical and impact theories can both be derived as certain limiting cases.[8d,11]

The Hamiltonian H for the emitting atom is a function of t because of the perturbations that broaden the line. Introducing a time-development matrix U which satisfies the Schrödinger equation,

$$i\hbar\dot{U}=HU, \qquad (1.8)$$

then

$$\mu(t)=U^\dagger\mu U,$$

μ being the time-constant (Schrödinger) matrix $\mu_{ij}^0=\int\psi_i^*(\sum_n er_n)\psi_j d\tau$. Now suppose the perturbers are fixed in space. Then H does not depend on t and (1.8) has the solutions $U_{lm}=\exp[(-i/\hbar)E_l t]\delta_{lm}$, where E_l is a stationary eigenvalue of H. This approximation is too drastic and yields no line width; however, almost as simple and quite significant is the answer obtained by making the *adiabatic hypothesis.*‡

The adiabatic hypothesis in its quantum mechanical form says that, under conditions specified forthwith, Eq. (1.8) has a solution of the form

$$U_{lm}=\exp\left[-\frac{i}{\hbar}\int_0^t E_l(t')dt'\right], \qquad (1.9)$$

‡ The word "adiabatic" has come to be almost meaningless through unprincipled use in modern physics. This becomes evident in Sec. IIB, where various specific senses of "adiabatic" and its opposite, "diabatic" (or its atrocious, pleonastic synonym, non-adiabatic), are discussed. In the present context, the meaning should be clear from the discussion.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

where the $E_l(t)$ are solutions of

$$H\psi_l(t)=E_l(t)\psi_l(t), \tag{1.10}$$

an equation sometimes called the adiabatic Schrödinger equation. The hypothesis is valid if, during the perturbation interval t, and for all states m,

$$\left|\int_0^t \frac{(dH/dt')_{lm}}{E_l(t')-E_m(t')}\left\{\exp\frac{i}{\hbar}\int_0^{t'}[E_l(t'')-E_m(t'')]dt''\right\}dt'\right|\ll 1. \tag{1.11}$$

Here l is the atomic state initially present, m some other state. With (1.9) and (1.10) $\mu(t)$ takes a simple form:

$$\left.\begin{aligned}\mu_{lm}&=\mu_{lm}{}^0\exp[i\varphi_{lm}(t)]\\ \varphi_{lm}&=\hbar^{-1}\int_0^t[E_l(t')-E_m(t')]dt'\end{aligned}\right\}. \tag{1.12}$$

We now introduce this into (1.7) and assume that S is diagonal, a form which can always be brought about by proper choice of state functions. Then, after a few steps (among them the replacement of the variables $t'-t$ by τ) there results

$$I(\omega)\propto\int d\tau e^{i\omega\tau}C(\tau), \tag{1.13a}$$

$$C(\tau)=\sum_{if}S_i|\mu_{if}{}^0|^2\int_{-\infty}^{\infty}\exp\{-i[\varphi_{if}(t+\tau)-\varphi_{if}(t)]\}dt. \tag{1.13b}$$

The function $C(\tau)$, whose Fourier transform is the intensity distribution, is called the correlation function; its general features form the substance of an elegant mathematical discipline called the statistics of time series; hence, this manner of writing $I(\omega)$ is finding increasing favor with theorists. Qualitatively, the meaning of C is clear: $\varphi_{if}(t+\tau)$ and $\varphi_{if}(t)$ are certainly equal when $\tau=0$; hence, $C(0)$ is large. If φ has a short "memory" so that it quickly loses correlation with its previous values, $C(\tau)$ will fall off rapidly with τ. It is then something like a δ function and $I(\omega)$ is broad. If, on the other hand, $\varphi(t)$ remains correlated with itself (in the absence of interaction there is a linear correlation for all time: $\varphi=\text{const}\cdot t$) during an appreciable period, $C(\tau)$ will differ from 0 for that period, and $I(\omega)$ will be correspondingly narrow. One may indeed show that the half-width of $I(\omega)$ is approximately the reciprocal of the half-width of $C(\tau)$.

In arriving at (1.13), which is suggestive of the starting point of the Lorentz theory, we have used only the adiabatic hypothesis. Its correctness is tied to inequality (1.11).

An analysis of the conditions under which that inequality is true is given in the next section. We observe here primarily that (1.11) contains both the nondiagonal element $(dH/dt)_{lm}$ and the energy difference $E_l(t)-E_m(t)$; its validity depends on the relation between them. The remainder of this section takes (1.11) for granted and concerns itself with the manner in which E_l-E_m changes in time, for the applicability of statistical and impact theories depends on the behavior of that difference alone.

The statistical theory results if the difference changes slowly. The quantity φ may then be expanded in a Taylor series

$$\varphi(t+\tau)=\varphi(t)+\varphi'(t)\cdot\tau+\cdots,$$

and all terms in higher powers of τ may be neglected. The convergence here is generally good if only $\varphi''(t)(\tau^2/2)\ll 1$ for all values of t and those values of τ which matter in the integration of (1.13a), i.e., for which $C(\tau)\neq 0$. In (1.13b) we assume for simplicity that only one atomic state $i=1$ was initially present ($S_i=\delta_{i1}$) and that only one $\mu_{1f}{}^0$, namely $\mu_{12}{}^0$, is of appreciable magnitude. Then

$$C(\tau)\propto\int e^{i\varphi'_{12}(t)\tau}dt=\int\exp\{-i[E_2(t)-E_1(t)]\tau/\hbar\}dt;$$

hence,

$$I(\omega)\propto\int d\tau e^{i\omega\tau}\int\exp\{-i[(E_2-E_1)/\hbar]\tau\}dt.$$

The integral over τ now leads to a δ function which is different from zero only at those times t when ω, the line frequency under consideration, equals $[E_2(t)-E_1(t)]/\hbar$, our former $\omega(r_1\cdots r_N)$. By the rules of statistical mechanics (ergodic theorem) these times have probabilities equal to the fractional volume of configuration space in which $\omega(r_1\cdots r_N)=\omega$. The exact formal analysis here involves ranges $d\omega$, near equalities and probability densities, which we suppress, placing thereby a heavy burden of infinities and zeros upon the proportionality signs. With a little care the reader can supply these purely mathematical details. In sum

$$I(\omega)\propto\int\cdots\int\delta[\omega,\omega(r_1\cdots r_N)]d\mathbf{r}_1\cdots d\mathbf{r}_N, \tag{1.14}$$

and this is the $P(\omega)$ of Eq. (1.1).

An extension of the reasoning here outlined permits proof of two propositions of interest in the use of the statistical method.[1f,8a,11]

1. Far in the wings of a line, i.e., as $|\omega-\omega'|\to\infty$, ($\omega'$ is again the normal frequency) the statistical theory is always applicable. The value of $|\omega-\omega'|$ beyond which this is true depends on the form of the interaction and cannot be generally specified.

Later we have occasion to return to this proposition (which we call for short the *wing theorem*) and therefore give its more detailed proof, which closely follows

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Sobel'man. Substituting Eq. (1.13b) into (1.13a) and dropping the subscripts and the sum we have

$$I(\omega) \propto \int d\tau e^{i\omega\tau} \int e^{-i[\varphi(t+\tau)-\varphi(\tau)]} dt,$$

with the understanding, however, that this quantity must be averaged over different collisions.

Let us *redefine* φ *(without bothering to change notation) to mean only the variable part of the phase which is contributed by the perturbation.* We then have for the second integral

$$\int e^{-i[\omega'\tau+\varphi(t+\tau)-\varphi(t)]} dt.$$

On interchanging the order of integrations, we have

$$I(\omega) \propto \int e^{i\varphi(t)} dt \int d\tau e^{i[\Delta\omega\tau-\varphi(t+\tau)]},$$

where $\Delta\omega=\omega-\omega'$. We now set $t+\tau=s$ in the second integral and obtain

$$I(\omega) \propto \int e^{i(\varphi-\Delta\omega t)} dt \int e^{-i[\varphi(s)-\Delta\omega s]} ds.$$

In the wings of the line, i.e., for sufficiently large $\Delta\omega$ the contributions to

$$\int e^{i(\varphi-\Delta\omega t)} dt$$

come from intervals Δt_k around the points t_k, defined by $\varphi'(t_k)=\Delta\omega$ since in other regions the rapid oscillations of the integrand tend to cancel. We can then write

$$\int e^{i(\varphi-\Delta\omega t)} dt \doteq \sum_k \int_{\Delta t_k} e^{i[\varphi-\Delta\omega t]} dt.$$

We next expand the exponent in a Taylor series about t_k obtaining

$$\sum_k e^{i[\varphi(t_k)-\Delta\omega t_k]} \int_{\Delta t_k} \exp i\left[\frac{\varphi''(t_k)}{2!}(t-t_k)^2 + \frac{\varphi'''(t_k)}{3!}(t-t_k)^3+\cdots\right] dt.$$

The important range of the integration, Δt_k, is of the order

$$\sqrt{2}[\varphi''(t_k)]^{-\frac{1}{2}}.$$

If, in this range, the term proportional to $(t-t_k)^3$ is small, the integration can be extended to infinity. This condition is

$$\varphi'''(t_k)[\varphi''(t_k)]^{-\frac{3}{2}} \ll 1. \qquad (1.15)$$

We then obtain for the integral,

$$\sum_k e^{i[\varphi(t_k)-\Delta\omega t_k]}[\varphi''(t_k)]^{-\frac{1}{2}},$$

and, for $I(\omega)$,

$$I(\omega) \propto \sum_{kl} e^{i[\varphi(t_k)-\varphi(t_l)-\Delta\omega(t_k-t_l)]}[\varphi''(t_k)\varphi''(t_l)]^{-\frac{1}{2}}.$$

The average over all collisions causes the terms for which $k \neq l$ to cancel, and we find

$$I(\omega) \propto \sum_k [\varphi''(t_k)]^{-1}.$$

The sum here can be interpreted as proportional to the length of time during which

$$\Delta\omega = \varphi'(t_k)$$

or

$$\omega = \omega' + \varphi' \equiv \hbar^{-1}[E_i(t_k) - E_f(t_k)].$$

Thus $I(\omega)$ is proportional to the time that the atom spends in the perturbed condition with the energy separation between levels given by $\hbar\omega$. This leads again to Eq. (1.14) by arguments already presented; hence the wing theorem.

2. If a spectral line is broadened by *single impacts* of perturbers (low density) and Δt is the time during which the passing particle moves a distance equal to the impact parameter ρ, the statistical theory is applicable provided

$$\omega_{\frac{1}{2}} \cdot \Delta t \gg 1. \qquad (1.16)$$

Here $\omega_{\frac{1}{2}}$ is the actual, measured half-width. Proof of theorem 2 rests upon the assumption that for an individual impact the perturbation can be written in the form

$$E_2 - E_1 = \text{const} r^{-\sigma},$$

where r is the distance between radiator and perturber and σ a small positive integer, so that $\varphi(t)$ can be constructed for any impact, If one then employs inequality (1.15) noticing that, by virtue of (1.13a), the half-width of $C(\tau)$ is the reciprocal of the half-width of $I(\omega)$, a little algebra leads to formula (1.16).

This formula has been proved for individual impacts only, and $\omega_{\frac{1}{2}}$ is the actual half-width of the line; in the wing theorem, the value of ω beyond which the statistical theory holds bears no general relation to the half-width and differs in different situations.

Next, we demonstrate that (1.13) leads to the impact results when the phase changes $\Delta\varphi$ occur suddenly and are therefore separated in time. We use (1.13) later on to obtain impact formulas more refined than those of Lorentz or Weisskopf, following the work of Foley, Lindholm, and others. At present we retrace the step that led to (1.13) and write

$$I(\omega) \propto \left| \int \mu_{12}^0 e^{-i[\omega t-\varphi_{12}(t)]} dt \right|^2, \qquad (1.17)$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

assuming again that the atom has only two levels. If sudden impacts occur at times $t=T_i$, and if these impacts add amounts $\hbar a_i$ to the phase of the atom,

$$E_2-E_1=\hbar[\omega'+\sum_i a_i\delta(t,T_i)]$$

so that

$$\varphi_{12}\equiv\varphi(t)=\omega' t+A_j \quad \text{for } T_j\leqslant t<T_{j+1},$$

where $T_1<T_2<T_3\cdots$ and

$$A_j=\sum_{i=1}^{j} a_i.$$

Then the integral in (1.17) is

$$\mu_{12}{}^0\sum_j e^{iA_j}\int_{T_j}^{T_{j+1}} e^{-i(\omega-\omega')t}dt.$$

When the square of the absolute value of the sum is taken, there will appear the terms

$$|\mu_{12}{}^0|^2\sum_j\left|\int_{T_j}^{T_{j+1}} e^{-i(\omega-\omega')t}dt\right|^2 \tag{1.18}$$

and, in addition, cross terms with factors $e^{i(A_k-A_j)}$. If the a_i are unrelated, the sum of these will effectively banish. The remaining summation in (1.16) extends over different free times $T_{j+1}-T_j=T$ and is equivalent to the integration over T in Eq. (1.2). Under these assumptions the Lorentz formula is therefore established.

The wings of a line rarely follow the Lorentz formula, whereas the central core often conforms to it. The reason for this is not hard to see.

We spoke of sudden phase changes $\Delta\varphi$. In quantitative terms, "sudden" means that the change in $\varphi(t)$ occurring in the integrand of Eq. (1.17) as the result of a collision is limited to a time interval Δt small compared to the period of the other exponential factor of the integrand, i.e.,

$$\Delta t\ll 2\pi/\omega. \tag{1.19}$$

Unless the collisions overlap completely (long-range forces, high density of perturbers) this inequality is satisfied for sufficiently *small* ω, that is to say, near the center of the line. This result might be called the "core theorem" in contradistinction to the wing theorem. The former says that the core of a line "results from impacts," while the latter *claims that the wings* "are statistical."

These considerations allow these qualitative inferences: impact theories describe lines at high temperatures and for sudden perturbations, i.e., at low densities; statistical theories meet success at low temperatures and for heavy perturbers, especially at high densities where many interactions coincide and produce small net fluctuations of energy at the radiating atom.

To account for the contour of a given spectral line when neither impact nor statistical theory can be fully trusted, the center of the line can usually be interpreted as resulting from impacts, the wings as statistically broadened. More is said about this in Sec. IV.

We should comment on the consequences of Eq. (1.7) when the adiabatic hypothesis cannot be made, that is, when condition (1.11) is violated. This contingency is most likely to arise when the spacings, E_l-E_k, are small, hence in the microwave region, and under other more special circumstances. The story is then somewhat involved: the best account of it is to be found in Anderson's article.[9]

In the plasma situation the statistical theory promises a satisfactory description of the ion effects, and it would seem that impact theories might be suited to treat the swift electrons. But in this latter task, unfortunately, a fundamentally new problem arises. All theories here surveyed require the use of a potential energy of interaction ϵ, which is a function of the perturber position. Basically, then, they assume that the perturber has a classical path. This is not true in general for electrons, whose position is quite diffuse when the speed is definite because of the uncertainty principle. To operate with an $\epsilon(r)$ may therefore be meaningless, and a new approach is needed. In the next section, we offer qualitative arguments designed to permit some discrimination of conditions under which classical path theories are useful, and related considerations.

II. CLASSICAL-PATH HYPOTHESIS AND CRITERIA FOR ADIABATICITY

A. Classical Path

Essential to the foregoing analysis of spectral line broadening are two assumptions: first, that the perturber has a classical path, i.e., is a point particle with spatial coordinates that are functions of the time; and, secondly, that adiabaticity prevails, so that the perturber disturbs (without mixing) only the two states between which the system is radiating. The lack of a completely general workable approach to the broadening problem confers a good deal of importance upon a knowledge of the conditions under which such assumptions hold. As instances of treatments where these assumptions are not invoked we note the quantum theories of Jablonski[12] and of Kivel, Bloom, and Margenau[13]; another example is the theory of dielectric relaxation of Debye,[14] which treats the broadening induced by reorientation transitions in the radiator during collisions. The broadening mechanisms pertaining to these latter theories are quite different from those discussed in Sec. I. The two classes of results arise from opposite extremes in the physical model for the

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

interaction. We now formulate some simple criteria for the validity of the description of Sec. I. Special consideration is given to the interaction of a radiating hydrogen atom with electrons and protons.

Quantum mechanics yields an accurate account of atomic phenomena, and, through the uncertainty principle, also defines the limits of classical mechanics. This principle focuses attention on our inability to describe certain details of an event, such as the collision between two systems, without introducing finite disturbances in the parameters necessary for such description. When these disturbances compete in magnitude with the events one wishes to investigate, the event imagined cannot be observed in the degree of detail demanded, for then a classical picturization is without basis, and we must use quantum mechanics.

Classical-path theories assume that the distance of separation r between the perturber and the radiator is expressible as

$$r(t)=(\rho^2+v^2t^2)^{\frac{1}{2}}, \tag{2.1}$$

which requires exact specification of both its position and velocity at each instant of time. For this is to be meaningful the uncertainties in these quantities, as derived from quantum considerations, must be small in comparison with their actual magnitudes.

Numerous authors base their use of (2.1) on the magnitude of the angular momentum involved in a collision,[1c,8d,15] relying on the correspondence principle to validate classical analysis for large orbits. If $\mathbf{L}$ is the angular momentum of the perturber with respect to a radiator at rest, then, $L\approx l\hbar$. For large values of the integer l we may identify $\mathbf{L}$ with $m\mathbf{r}\times\mathbf{v}$, which during the collision may be taken to be $\approx mrv$.

The relation above in the form

$$mrv\approx l\hbar$$

and the uncertainty principle,

$$m\Delta r\Delta v=\hbar,$$

yield on division

$$(\Delta r/r)\cdot(\Delta v/v)=1/l, \tag{2.2}$$

and this is much smaller than 1 if l is large.

Equation (2.2) implies that for sufficiently large l any specified relative accuracy in r and v can be accomplished without violating the uncertainty principle, i.e., without need for abandoning the assumption of a classical path. For example, if $l\approx 100$ we may choose the orbit of the perturber such that $\Delta r/r\approx\Delta v/v\approx 1/10$, which ratios represent an acceptable percentage accuracy in the specification of these parameters.[9]

The preceding argument leaves many detailed questions unanswered. Let us consider the problem with a measure of skepticism which, fortunately, will later prove excessive. For the process of collision broadening to be tractable by means of a classical path we must require that the inequality

$$(\Delta r/r)\cdot(\Delta v/v)\ll 1 \tag{2.3}$$

holds throughout the time of any collision and for all impact radii of importance. When the classical path is derived properly as the limiting form of a quantum mechanical description these requirements lead to relations more specific than (2.3), relations which depend upon the mass of the perturbers, the density and temperature of the gas, and the type of interaction which pertains to the problem.

Collisions with large angular momenta, as shown by Eq. (2.2), can be described classically; this means that the perturbing particles correspond to wave packets, well localized both in coordinates and momentum, the limits of this localization being Δr and Δv. We now imagine a wave packet with a mean spatial extension a and a mean momentum mv, this latter quantity being equal to the actual momentum of the classical particle. In addition, we let r be the distance between the radiator and the center of the packet; it therefore corresponds to the collision distance previously denoted by the same symbol. For the validity of the classical description we demand that

$$a\leqslant r, \tag{2.4}$$

the ultimate limit of the classical description being $a\approx r$.

In all applications of the theory the interaction is taken to be vanishingly small outside of a finite region of space, the linear dimension of which is designated by d. Physically, this distance represents the extent of penetration of the field of the radiator into its surroundings. For the case of a neutral plasma this distance is the Debye length[16]

$$d=6.90(T/n)^{\frac{1}{2}}, \tag{2.5}$$

where d is given in centimeters, T in degree absolute, and n in cm^{-3}.

We consider the interaction region to be a cube of dimensions d, oriented for convenience with an axis parallel to the perturber's path. The time during which the perturbation is in effect, τ_p, is then of the order of d/v, a constant for all values of r up to approximately d, beyond which distance it vanishes.

In a classical description of the passage of the perturber through the interaction region, the collision time must be shorter than the time during which the perturber diffuses quantum mechanically through the distance r. This diffusion results from the initial localization of the packet and proceeds with a velocity of the order of $\hbar/ma$. It is therefore necessary that

$$r/(\hbar/ma)\gg d/v. \tag{2.6}$$

Because of (2.4) this inequality must hold for, $a\approx r$;

[15] (a) L. Spitzer, Phys. Rev. 55, 699 (1939); (b) E. Lindholm, Arkiv Mat. Astron. Fysik 32A, No. 17 (1945).

[16] L. Spitzer, *The Physics of Fully Ionized Gases* (Interscience Publishers, Inc., New York, 1956).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

hence, we get from (2.6)

$$a \gg (d\lambda)^{\frac{1}{2}}, \tag{2.7}$$

where λ is the mean de Broglie wavlength of the perturber, $\hbar/mv$.

Applying this basic inequality to the most distant collisions with least momentum uncertainty for which $r \approx d \approx a$, we obtain $a \gg \lambda$, which (since $a \approx r$) is nothing more than the condition that $l \gg 1$. Thus, the criterion (2.7) reduces to the conditions that the angular momentum be large when applied to the most distant collisions; in general, (2.7) is more restrictive than $l \gg 1$.

In addition to the condition that the passage of the perturber through the interaction region retain its meaning in view of the diffusion of wave packets, we might also require that the interaction itself be classical in terms of precise momentum exchanges.

The interaction energy between the perturber and the radiator is $V(r)$ in the classical description. This can usually be expressed in the form

$$V(r) = C_\sigma / r^\sigma,$$

C_σ being some constant. The momentum exchange for the collision is then

$$\Delta p = -\int \nabla V(t) dt.$$

Another quantity of interest in this connection is the phase change per collision

$$\Delta\varphi = \hbar^{-1} \int V(t) dt.$$

In both these integrals we replace dt by dx/v and $V(t)$ by $C_\sigma(\rho^2 + v^2t^2)^{-\sigma/2}$. The integrations should then extend from $-d/2$ to $d/2$, but a sufficient approximation results when they are performed from $-\infty$ to $+\infty$. Curvature of the path is neglected in this procedure. Elementary calculation yields

$$\Delta p = \frac{\sigma C_\sigma}{v\rho^\sigma} \pi^{\frac{1}{2}} \frac{\Gamma[(\sigma+1)/2]}{\Gamma[(\sigma+2)/2]} \approx \frac{V(\rho)}{v}$$

and

$$\Delta\varphi = \frac{C_\sigma}{\hbar v \rho^{\sigma-1}} \pi^{\frac{1}{2}} \frac{\Gamma[(\sigma-1)/2]}{\Gamma(\sigma/2)}.$$

The critical impact distance ρ_c is that value of ρ for which $\Delta\varphi = 1$ (see the end of Sec. IB). Solving this equation for C_σ in terms of ρ_c and inserting in Δp, we find

$$\Delta p = (\rho_c/\rho)^{\sigma-1}(\sigma - 1/\rho)\hbar. \tag{2.8}$$

To regard the perturber wave as a classical particle is to neglect its momentum uncertainty $\hbar/a$. The same uncertainty is thus introduced also in the states of the radiator system during and after the collision. The validity of the classical interaction is certainly assured if we require that all momentum (and ther corresponding energy) exchanges between the pe and the radiator exceed this neglected uncertain classical picture therefore holds only when:

$$\Delta p \approx V(\rho)/v \gg \hbar/a.$$

This places an *upper* limit on the magnitude o which the interaction may be treated classically.

When the opposite inequality

$$\Delta p \approx V(\rho)/v \ll \hbar/a$$

holds, the momentum uncertainty in the syste exceeds the momentum exchanges of the cl description, and the spread in momenta must be porated into the description of the perturber (or, is equivalent, the spatial spread of the packet m taken into account). Then the classical picture collision breaks down.

From (2.9a) using the more accurate expressio Δp, from Eq. (2.8), we have

$$\rho \ll \alpha_\sigma \rho_c (a/\rho)^{1/(\sigma-1)},$$

where $\alpha_\sigma = (\sigma-1)^{1/(\sigma-1)}$ is of the order of unity, a in the correlation of σ with α_σ below:

$\sigma =$	2	3	4	6
$\alpha_\sigma =$	1.00	1.41	1.44	1.38

Since $a \leqslant r$ for all r during the collision, and r can on the value ρ, (2.10) seems to imply

$$\rho \ll \alpha_\sigma \rho_c. \quad (2.11)$$

This is essentially the condition $\Delta\varphi \gg 1$. We con that only collisions within the optical radius amenable to a classical-path treatment and all which occur outside of ρ_c must be treated by mea quantum mechanics. We return to this somewhat prising conclusion at the end of this section.

Letting $a \approx \rho$ as the least stringent condition fo classical path we obtain in place of (2.10)

$$a \ll \alpha_\sigma \rho_c. \quad (2.12)$$

The validity of the classical description for colli within ρ_c is also contingent on the enforcement of On combining (2.7) and (2.12), there results on nating,

$$(d\lambda)^{\frac{1}{2}} \ll \rho_c. \quad (2.13)$$

This condition for the validity of the classical pa effectively independent of the actual size of the packet describing the perturber. Margenau and Ki actually computed the dimension of a one-dimens packet [see Eq. (2.23)] and required it to be less the size of the radiator. In this way they found the width of the Lyman-α line of hydrogen ma computed classically at $T \approx 6000°$K if the pertu mass $> 10^{-26}$ g, which is true for protons but no

10^{16}	10^{15}	10^5
10^{18}	10^{16}	10^8

electrons. All this is in keeping with the present result, which is derived in a more general way.

After substituting (2.5) along with the definitions of λ and ρ_c into (2.13) one finds

$$\frac{T^{1/(\sigma-1)}}{n^{\frac{1}{2}}M^{\frac{1}{2}+1/(\sigma-1)}} \ll \frac{[\gamma_\sigma(C_\sigma/\hbar)]^{2/(\sigma-1)}}{6.90\hbar(3k)^{-\frac{1}{2}+1/(\sigma-1)}}, \tag{2.14}$$

where v, the perturbers' velocity, has been taken to be its rms value

$$v=(3kT/M)^{\frac{1}{2}},$$

M is the mass of the perturber, either a proton or an electron, and the γ_σ are numbers of order unity (e.g., $\gamma_2=\pi$).

This result has the advantage of containing no reference to ρ, which has no experimental meaning. However, inequality (2.14) is a sufficient condition which is in some instances too severe. For hydrogen, the first order Stark effect ($\sigma=2$) involves[18]

$$C_2\approx\tfrac{3}{4}(\hbar^2/m)n'(n'-1),$$

where n' is the principal quantum number of the excited state of the radiating atom and m is the electron mass. This is a sufficient approximation. Accurately, $n'(n'-1)$ should be replaced by $N_{n'}$ such that

$$N_3=4.5,\quad N_4=9.9,\quad N_5=23.6,\quad N_6=31.8.$$

Hence (2.14) becomes

$$\frac{T}{n^{\frac{1}{2}}M^{\frac{1}{2}}} \ll \frac{(\pi C_2)^2}{6.90\hbar^3(3k)^{\frac{1}{2}}}.$$

For the first Balmer line (H_α, $n'=3$), the inequality (2.14) gives Table I. For the higher Balmer lines the temperatures appearing here are multiplied by the factor $[n'(n'-1)/6]^2$, $n'>3$. Hence, for the higher series members the classical-path treatment is valid over a greater temperature range. This increase has practical significance only for the electrons, since they alone are severely limited by the values of the temperature. For a pure hydrogen plasma, thermal ionization begins at about 7000°K, so that appreciable broadening by electrons and protons does not occur at temperatures below this value. Thus much of Table I is purely academic.

For a typical second-order Stark effect in the optical region ($\sigma=4$) $C_4\hbar^{-1}\approx2\times10^{-12}$ esu. Here we obtain from (2.14) $T^{1/3}\ll n^{1/2}M^{5/6}(\gamma_4C_4/\hbar)^{2/3}(3k)^{1/6}/6.9\hbar$ and $\gamma_4=\pi/2$. This leads to the values of n and T shown in Table II. Table II shows that electrons may be treated classically for $n>10^{15}$ cm^{-3} in the second-order Stark effect, while protons and heavier ions always permit such treatment.

B. Criteria for Adiabaticity

We now transfer attention to the radiating system. Perturbation of its states can be treated adiabatically when the inequality (1.11) holds. The state of the system is then maintained throughout a collision except for its alteration through the radiation process. There are two cases of interest: (1) the states of the unperturbed radiator may be classified into groups of degenerate states and (2) the states of the unperturbed radiator are all nondegenerate. In case 1, two questions can be asked: (1a) Does the perturbation cause transitions between two states containing within the same group of degenerate levels? (1b) Does the perturbation cause transitions between a degenerate state in one group and a degenerate state in another group separated from the first by a finite energy? The perturbation may well be adiabatic in the sense of 1b, diabatic in the sense of 1a. In this section, we treat only case 1a, leaving 1b, which is more difficult, for the most part until Sec. V. Only a brief qualitative remark concerning 1b is presented at the end of this part of Sec. II. Existence is assumed of a finite perturbation time τ_p, the rate of change of the perturbation dV/dt being different from zero only during that time which, as we have seen, is of the order d/v. In addition, we here treat single impacts only.

For case 1a the energy differences of the instantaneous states appearing in the condition for adiabaticity are due solely to the perturbation itself, since all other states of the radiator may be ignored because of their much larger energy separations.

As the simplest example, we consider a radiator whose excited initial state has a two-fold degeneracy, and this degeneracy is removed in the first order of the per-

[18] A. Unsöld, *Physik der Sternatmosphären* (Springer-Verlag, Berlin, Germany, 1955), second edition, p. 321.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

turbation theory. The adiabatic condition then becomes

$$\left|\int_{-\infty}^{+\infty}\frac{d/dt'\,|V_{12}(t')|}{2|V_{12}(t')|}\times\exp\left[-\frac{i}{\hbar}\int_{-\infty}^{t'}2|V_{12}(t'')|\,dt''\right]dt'\right|\ll 1, \quad (2.15)$$

where $V_{12}(t)=\langle 1|V(t)|2\rangle$, the indices 1 and 2 designating the two states in question.

The phase shift between the states is given by

$$\Delta\varphi(t)=\frac{2}{\hbar}\int_{-\infty}^{t}|V_{12}(t')|\,dt'.$$

When $|\Delta\varphi(t)|\gg 1$, there have been many oscillations of the exponential part of the integrand in (2.15) at time t. These oscillations cause the integral to be quite small provided that

(α) $(d/dt)|V_{12}(t)|/|V_{12}(t)|$ is a slowly varying function of the time during an average period of the oscillation $\hbar/2\langle|V_{12}|\rangle$ (where $\langle|V_{12}|\rangle$ is a time average of $|V_{12}|$ for the whole perturbation,

$$\langle|V_{12}|\rangle=\int_{-\tau_p/2}^{\tau_p/2}|V_{12}(t)|\,dt/\tau_p);$$

and

(β) the perturbation time is much greater than $\hbar/2\langle|V_{12}|\rangle$.

The first requirement α reduces to the second β when the classical-path procedure is used. In that case

$$V_{12}(t)\equiv C_{12}/(\rho^2+v^2t^2)^{\sigma/2}, \quad \tau_p\leqslant t\leqslant\tau_p/2$$
$$\equiv 0, \quad |t|>\tau_p/2$$

and $(d/dt)|V_{12}|/|V_{12}|=(-\sigma v^2t)/(\rho^2+v^2t^2)$. We wish this to vary slowly within an interval of the order of $\hbar/\langle|V_{12}|\rangle$. This can occur only when $|t|\gg\hbar/\langle|V_{12}|\rangle$. To maintain condition α, therefore, the contribution of $(d/dt)\ln|V_{12}|$ coming from small $|t|$ must be inappreciable, and this requires that $\tau_p\gg\hbar/\langle|V_{12}|\rangle$, which is condition β. The two conditions are not independent.

When the degree of degeneracy is greater than 2, E_l-E_m is no longer to be identified with $2|V_{lm}|$, but it is still of the same order of magnitude. The result just obtained is therefore quite general in degenerate situations, and we must depend entirely on long, slow collision processes for the validity of the adiabatic assumption. Our criterion for adiabaticity in case 1a, when written in a more general way, is, therefore,

$$\hbar^{-1}\langle|E_l-E_m|\rangle\tau_p\gg 1. \quad (2.16)$$

But $\hbar^{-1}\langle(E_l-E_m)\rangle$ is the average frequency shift of the initial state during the collision. Neglecting the frequency shift in the lower state of the radiative transition, condition (2.16) takes the form

$$\Delta\varphi\gg 1. \quad (2.17)$$

Hence, in the presence of degeneracy, collisions which fall within the optical radius are adiabatic, others are diabatic. This result has been derived by Spitzer[19] in more detailed calculations for the L_α line.

In the absence of degeneracy, case 2, the energy differences (E_l-E_m) are much larger than those which were considered in case 1. We may thus take $E_l-E_m\approx E_l^0-E_m^0$, where E_l^0 and E_m^0 are the unperturbed states of the radiator. With this understanding, inequality (1.11) reads

$$\frac{1}{|E_l^0-E_m^0|}\left|\int_{-\infty}^{+\infty}\left(\frac{d}{dt'}V_{lm}(t')\right)\times\exp\left[-\frac{i}{\hbar}(E_l^0-E_m^0)t'\right]dt'\right|\ll 1. \quad (2.18)$$

Here it is convenient to distinguish between slow and fast collisions with respect to the oscillatory period $\hbar/|E_l^0-E_m^0|$. For slow collisions, $\tau_p\gg\hbar/|E_l^0-E_m^0|$.

Integrating (2.18) by parts and making use of the fact that $V(\pm\infty)=0$ we have

$$\frac{1}{\hbar}\left|\int_{-\infty}^{+\infty}V_{lm}(t')\exp\left[-\frac{i}{\hbar}(E_l^0-E_m^0)t'\right]dt'\right|\ll 1. \quad (2.19)$$

Therefore, when $V_{lm}(t)$ varies insignificantly over the period $\hbar/|E_l^0-E_m^0|$ the inequality (2.19) will certainly be true provided $\tau_p\gg\hbar/|E_l^0-E_m^0|$, which is our premise. This assumption about V_{lm} holds for times such that $|t|>\hbar/|E_l^0-E_m^0|$ and that the adiabatic criterion reduces merely to $\tau_p\gg\hbar/|E_l^0-E_m^0|$. Hence, all slow collisions are adiabatic.

For fast collisions, $\tau_p\ll\hbar/|E_l^0-E_m^0|$, and we may take the exponential appearing in (2.18) equal to unity. This yields, upon integration of (2.18),

$$|V_{lm}(\infty)-V_{lm}(-\infty)|/|E_l^0-E_m^0|<1,$$

and the quantity on the left is always zero. The adiabatic criterion is therefore satisfied also when the perturbation time is short, provided the radiator has large energy separations.

Thus both very slow and very fast collisions are adiabatic when degeneracy (or near degeneracy) is absent in the levels concerned. In the case of degeneracy only the slow collisions are adiabatic. In this latter instance the condition for adiabaticity is similar to one of the conditions for the classical-path approximation, namely $\Delta\varphi\gg 1$.

Under the subject of degeneracy, case 1a, special attention must be given to *space* quantization, the fact that different orientations of the total angular mo-

[19] L. Spitzer, Phys. Rev. **58**, 348 (1940).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

mentum vector correspond to the same energy of the radiating system. The meaning of the term adiabatic is a little confusing in this case, as the following consideration shows.

Suppose the atom is radiating in a $^3P_1$ state, and assume first that an external magnetic field is present. The orientations in space for which $m=-1$, 0, 1 will then have slightly different energies. The passage of a perturber past the atom is said to be adiabatic if the interaction with the perturber does not transfer the radiator from one m value to another or, classically speaking, if the radiator's orientation remains fixed in space during a perturber passage. If we retain this meaning of the word adiabatic even in the absence of an external field, then an adiabatic perturbation is one which does not succeed in turning the radiator about, or in altering the value of m.

The interaction between the radiator and the perturber depends on the value of a quantum number m. However, this m is not identical with the foregoing, which refers to some fixed direction: the interaction depends on space quantization with respect to the line joining radiator and perturber, and this line moves in space as the latter flies by, turning through an angle of 180° during a complete passage. We call the space quantum number relative to this *moving* line, m'. Adiabaticity with respect to m' is clearly different from the former version because it implies rotation of the radiating atom. Spitzer,[19] Lindholm,[20] and Unsöld[18] use the term in the latter sense.

For the present problem this choice is more appropriate because in the derivation of our criterion we have taken $|E_1-E_2|$ to be $|V_{12}|$, and this implies that the radiator is in a state for which the linear combination of m eigenfunctions changes in time while m' remains fixed. With this understanding, inequalities (2.15) and (2.16) tell us under what conditions m' is unaltered by an impact.

But if m' is not changed, so that the impact is adiabatic in the second sense, then, since the radiation has to be analyzed in a fixed coordinate system (the spectrograph does not revolve about the radiating atom), an adiabatic impact corresponds to a phase change of magnitude π. This seems to imply that simple impact theories, like those of Lorentz and Weisskopf, which ignore phase changes resulting from this rotation but consider phase changes of magnitude π produced by dynamic effects as singularly important, contain grave errors. Distant impacts, for example, are not counted in these impact theories; yet they should produce a phase change π if they are adiabatic in the second sense. Physical intuition argues that this cannot be. The resolution of this apparent dilemma is simple: criterion (2.16) shows clearly that distant impacts are *not* adiabatic in the second sense. This means they do not succeed in swinging the radiator around. They *are* adiabatic in the first sense.

This problem, which is practically of minor importance but presents points of fundamental interest, is considered carefully by Spitzer.[19] He shows how the impact theories manage to obtain a reasonable result by compensating errors, the errors being an unwarranted claim of adiabaticity and a neglect of the rotation effect. Further light is shed on the "rotation problem" by an analysis[21] having an entirely different aim, but which indicates nonetheless how and why the Lorentz theory takes correct account of the change in orientation of Debye dipoles induced by collisions.

Before concluding the analysis of adiabatic conditions we take a brief look at case 1b and inquire how one should deal with transitions between one set of degenerate states and another set, separated from the first by a finite energy interval. Suppose that for transitions between any two states of the initial set and also the final set,

$$\Delta\varphi\ll 1.$$

Then the perturbation is diabatic with respect to the (perturbed) degenerate states. In that case a consideration of Unsöld[1c] makes it appear plausible that an optical transition between the two separated level sets can be handled as though each were nondegenerate. The reason is that within the limit of the uncertainty principle the degenerate levels do form a single level even after they have been split by the perturbation.

To see this we remember that the adiabatic hypothesis for transitions between the originally degenerate states of one energy level breaks down when the reverse of (2.16) is true, *viz.*

$$|E_l-E_m|\,\tau_p\hbar^{-1}\ll 1.$$

This implies that the energy uncertainty in the system, of the order of $\hbar/\tau_p$, exceeds the discrete energy shifts due to the instantaneous perturbation $|E_l-E_m|$. The states which are split by the field are therefore not revealed individually through radiation processes involving them since they overlap in energy by large amounts and form what amounts to a single diffuse energy band.

The use of the impact theory when coupled with the suggestion of Unsöld is roughly equivalent to a procedure which takes account of the diffuseness in energy of these states by solving the time-dependent perturbation equations for the probabilities of states formed through quantum transitions that are caused by the collisions. Foley[8d] and Kolb[22] have done this using the classical-path assumption, while Kivel, Bloom, and Margenau,[13] and also Landwehr[23] have carried through the calculation without this assumption.

In conclusion we call attention to an early calculation by D. Blochinzew[24] who investigated the transition from diabatic to adiabatic behavior of an atom perturbed by a harmonic electric field, $E_0 \cos\omega t$.

C. Construction of Wave Packets

Since the classical-path assumption (Sec. IIA) is not always easy to justify for electron-broadening applications, we discuss this problem in quantum terms.

How can the state function of the perturbing electron be constructed? Inequality (2.9b) is the necessary condition for success of the Born approximation, which is so useful in scattering theory. But (2.9b) is normally satisfied for the plasma electrons, and as (2.9a) leads to (2.10), so (2.9b) leads to its contrary which can roughly be written $\rho \gg \rho_c$. Therefore, when densities are very low and encounters as close as the critical radius are rare, conditions under which one ordinarily employs a plane wave in describing the perturbing electron seem to be satisfied. Nevertheless, the plane wave description, which has received extensive use in problems where collimated beams of particles are directed at scattering centers, is inappropriate to our problem for several reasons.

First, we are here concerned with a single electron encountering the radiator, or, as the density is increased sufficiently, with a number of electrons statistically distributed in momenta and acting simultaneously on the radiator. The single electron hardly acts like a plane wave because the latter is stationary throughout the radiation time, and where in reality the electron has a spectrum of momenta the plane wave possesses a single value. Furthermore, the plane wave does not yield any momentary asymmetry in the charge distribution about the radiator, a situation which practically eliminates the possibility of a Stark effect.[11a] As a description of the many-electron perturbation the plane wave has similar disadvantages for the treatment of broadening, except that in this case the assumption of stationarity of the perturbation is more acceptable. At large densities one would expect the fluctuations in the perturbation to be small and the plane wave picture to become more accurate.

In stellar atmospheres where $n \approx 10^{13}$/cc, the critical radius is only about 10^{-4} times the Debye cutoff at temperatures between 5×10^3 and 10^4 °K. Thus we might expect something like single impacts by the electrons, and strong objections to the use of a plane wave for the electron must arise. For such cases Margenau and Kivel[17] employed a wave packet state function. For simplicity, they construct wave packets in one dimension and determine the width of the packet from the condition of thermal equilibrium.

The quantum-statistical density matrix for the system in a volume V and for states labelled by wave numbers κ and κ', is taken to be

$$S_{\kappa,\kappa'} = P_\kappa \delta_{\kappa,\kappa'},$$
$$P_\kappa = \frac{(2\pi mkT)^{\frac{1}{2}}}{V^{\frac{1}{3}}} \exp\left[-\frac{\hbar^2\kappa^2}{2mkT}\right], \tag{2.20}$$

and the wave packet is defined by

$$\psi(x,t) = \sum_\kappa C(\kappa,t) e^{i\kappa x}. \tag{2.21}$$

Correspondence is established between the description (2.20), which is a stationary mixed case, and (2.21), which is a nonstationary pure case, by equating expectation values for the momenta

$$P_\kappa = |C(\kappa,t)|^2, \tag{2.22}$$

This procedure yields the amplitudes but not the phases of the coefficients $C(\kappa,t)$. These are chosen on the basis of a physical argument. If the collision occurs at the time $t=0$, then because at this instant the electron involved in collision has a maximum energy uncertainty, the packet should have its minimum concentration about the radiator at that time. But minimum concentration means equality of all phases, i.e., $P_\kappa = C(\kappa,0)^2$. From (2.22) and (2.21) one then finds (upon carrying out the summation over κ as an integration)

$$\psi(x,0) \leq \exp[-mkTx^2/\hbar^2], \tag{2.23}$$

which represents a Gaussian probability packet whose width is equal to $\hbar/(2mkT)^{\frac{1}{2}}$. This is precisely the mean momentum of the ensemble described by (2.20), and the *diffusion* velocity of this packet is, satisfying enough, the *root-mean-square velocity* of the ensemble. The action of such an electron is to squeeze itself about the atom at the instant of collision and then to diffuse away again after the impact time. More general wave packets of this type, centered about points distant from the radiator and having finite mean momenta, so that they move bodily and diffuse, are even better representations of the electron which may be of assistance in broadening calculations. A paper by the present authors[25] shows how the classical formula for Stark broadening arises out of a wave packet treatment as the wave packets become more and more concentrated.

D. Summary and Appraisal

Section II has dealt with rather basic and intricate matters, and has led to some slightly surprising conclusions which, if true, restrict the validity of classical approaches more severely than might have been anticipated. It may also seem amazing that inequalities of the form $\Delta\varphi > 1$ and $\Delta\varphi < 1$ decide so many different issues. The first defines the range of validity of the classical-path description as well as the domain of adiabaticity (in the case of degeneracy). We also meet

[24] D. Blochinzew, Physik. Z. Sowjetunion 4, 501 (1933).

[25] H. Margenau and M. B. Lewis, Phys. Rev. **106**, 244 (1957).

it again in Sec. IV, as a criterion for the correctness of statistical theories.

The typical structure of the arguments used in this chapter is the following. We carefully specified conditions under which certain conclusion (e.g., "The classical path is a valid assumption") are true. Then we said, quite without logical justification, that when the conditions are violated the conclusion will not be true. All we should have said is that we did not prove it to be true. We did not investigate the conclusions of more general conditions, and have, therefore, no assurance that more general premises will not lead to the interdicted conclusions. Hence all inequalities here encountered are permissive, are sufficient conditions, and mean to say that, under their terms, the type of description in question is certainly adequate. They do not strictly rule out the possibility that the description may be appropriate even when the inequality fails. The logic outlined is not peculiar to our treatment but characterizes most of the arguments found in the literature. They provide guides, but no final solutions.

Fortunately, the criterion derived for classical-path description is at times too limited. But there is no way of discovering this, or of assuring it, short of proceeding with more general premises. This means actually starting with quantum theory in the initial phases of the calculation to show that such treatment does, in fact, yield the same results as the classical-path description.

III. HOLTSMARK THEORY

A. Review of Conventional Treatment

The oldest and, within its limits, most successful theory of line broadening by the particles of a plasma is Holtsmark's; it treats the diffusion of intensities within a line as if each part of the line arose from a Stark effect caused by the electric field associated with a temporary configuration of the moving ions. Most of the older review articles and newer texts deal with this theory in considerable detail; we, therefore, merely sketch its features and develop as much as is needed for present purposes.

A simple approximation gives the frequency distribution at large distances from the line center extremely well. This takes into consideration only close binary encounters between the radiating atom and one ion, leaving out of account the numerous—and therefore highly probable—collaborative but weaker perturbations of many ions further away. Thus it falsifies the center but describes adequately the wings of the line. We call this approximation the *binary* form of the Holtsmark theory and present it as follows.

Selecting the radiating atom as center, we describe a sphere of radius r about it. Denote by $P(r)$ the probability that there is at least one ion within it. To obtain $P(r)$ we first focus attention on its complement $P_-(r)$, namely, the probability that there shall be *no* particles at all within r. Clearly, $P(r)=1-P_-(r)$. By the laws of combination of probabilities,

$$P_-(r+dr)=P_-(r)\cdot p_-, \tag{3.1}$$

where p_- is the probability that there be no ion between r and $r+dr$. But we know p_-: it is 1 less the probability for the presence of particles, one or more, within the shell dr. Hence, if n is the number density of ions,

$$p_-=1-4\pi nr^2dr-(4\pi nr^2dr)^2-\cdots,$$

and the powers of dr beyond the first, which represent the probabilities for the occurrence of 2, $3\cdots$ particles in dr, can be omitted for sufficiently small dr. Thus Eq. (3.1) takes the form

$$P_-(r)+P_-'(r)dr=P_-(r)[1-4\pi nr^2dr],$$

whence on integration $P_-(r)=C\exp[-(4\pi/3)nr^3]$. The constant C must be adjusted so that $P_-(0)=1$ and is therefore 1. Hence $P(r)=1-\exp[-(4\pi/3)nr^3]dr$ and the probability that the shell contain at least one ion is

$$dP(r)=4\pi nr^2\exp[-(4\pi/3)nr^3]dr. \tag{3.2}$$

It is also apparent that this is the *nearest* ion, for the factor $4\pi nr^2dr$ expresses the indiscriminate likelihood of the presence of an ion between r and $r+dr$, while the factor $\exp[-(4\pi/3)nr^3]$ conjoins it with the condition that there be *no* ion *within* r. The latter factor is often insignificant numerically and is sometimes omitted; however, it is necessary if P is to be correctly normalized. Equation (3.2) leads to $\int_0^R dP(r)=1-e^{-N}\to 1$ if R is the volume containing $N=n(4\pi/3)R^3$ particles, whereas $\int_0^R 4\pi nr^2dr=N$.

Introducing the abbreviation

$$(4\pi/3)n=r_0^{-3}. \tag{3.3}$$

Equation (3.2) may be written

$$dP(r)=\exp[-(r/r_0)^3]d(r/r_0)^3. \tag{3.4}$$

The distance r_0 thus defined is the radius of a sphere whose volume equals the mean volume per ion; it is a little smaller than the mean distance between ions, $n^{-\frac{1}{3}}$.

Equation (3.4) is the probability distribution in r. Since a given r defines an electric field, F, and an electric field defines a frequency displacement via the Stark effect, that equation also represents the distribution of the last two quantities. F is given by $F=Ze/r^2$; so substitution $r^2=Ze/F$ in (3.4) converts it to a probability distribution in F

$$\begin{aligned} dP(F)&=\exp[-(F_0/F)^{\frac{3}{2}}]d(F_0/F)^{\frac{3}{2}}\\ &=(3/2F)(F_0/F)^{\frac{3}{2}}\exp[-(F_0/F)^{\frac{3}{2}}]dF. \end{aligned} \tag{3.5}$$

Here $F_0=Ze/r_0^2$, and the minus sign was inserted in order that the normalization be correct relative to F, not F_0/F. That is to say, the normalization is such that

$$\int_0^{F=\infty} dP(F)=1.$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

In the *linear* Stark effect,

$$\Delta\omega = sF,$$

s being a constant. Writing $\Delta\omega_0 = sF_0$, Eq. (3.5) leads to

$$dP(\Delta\omega) = -\exp\left[-\left(\frac{\Delta\omega_0}{\Delta\omega}\right)^{\frac{3}{2}}\right] d\left(\frac{\Delta\omega_0}{\Delta\omega}\right)^{\frac{3}{2}}$$

$$= \frac{3}{2\Delta\omega}\left(\frac{\Delta\omega_0}{\Delta\omega}\right)^{\frac{3}{2}} \exp\left[-\left(\frac{\Delta\omega_0}{\Delta\omega}\right)^{\frac{3}{2}}\right] d(\Delta\omega). \quad (3.6)$$

By the fundamental assumption of the statistical theory $dP(\Delta\omega)$ is identical with the intensity distribution:

$$dP(\Delta\omega) = I(\Delta\omega)d(\Delta\omega). \quad (3.7)$$

Hence,

$$I(\Delta\omega) = \frac{3}{2\Delta\omega}\left(\frac{\Delta\omega_0}{\Delta\omega}\right)^{\frac{3}{2}} \exp\left[-\left(\frac{\Delta\omega_0}{\Delta\omega}\right)^{\frac{3}{2}}\right]. \quad (3.8)$$

In the *quadratic* Stark effect,

$$\Delta\omega = tF^2, \quad \Delta\omega_0 = tF_0^2,$$

t being another constant. When this is substituted in (3.5) we obtain, again with the use of (3.7),

$$I(\Delta\omega) = \frac{3}{4\Delta\omega}\left(\frac{\Delta\omega_0}{\Delta\omega}\right)^{\frac{1}{2}} \exp\left[-\left(\frac{\Delta\omega_0}{\Delta\omega}\right)^{\frac{1}{2}}\right]. \quad (3.9)$$

The "normal" frequency $\Delta\omega_0$, though denoted by the same symbol, has different values in the linear and the quadratic Stark effect.

The foregoing elementary considerations, which yield the binary approximations to the intensity distribution Eqs. (3.8) and (3.9), have been superseded by the work of Holtsmark,[26] Verwey,[27] Schmaljohann,[28] and others, who included the cooperative effect of many ions. Their results are most easily derived by a method introduced by Markoff, a good presentation of which is available in a review by Chandrasekhar[5] while its application to other line-width problems is to be found in reference 2e. The treatment under review ignores the Boltzmann factor which attaches to the configuration probability of the moving ions. Effects of this simplification are considered later.

The field F, which appears in Eq. (3.5), must here be written as a vector sum when it is compounded from the fields of many ions in different places:

$$F = |\sum_i \mathbf{F}_i|. \quad (3.10)$$

The analysis leading to (3.5) must be carried out in a configuration space of $3N$ dimensions. In place of (3.5),

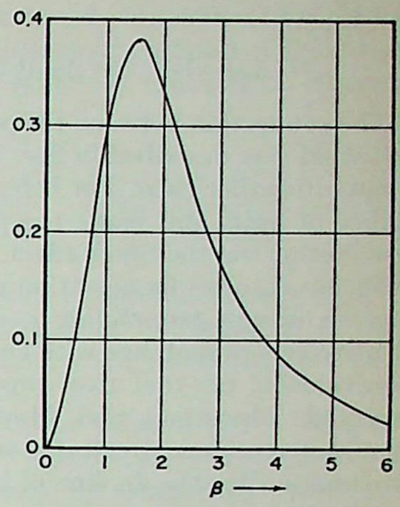

FIG. 2. Graph of $W(\beta)$ *vs* β. See Eq. (3.11b).

it yields

$$dP(F) = W(\beta)d\beta; \quad \beta = F/F_0, \quad (3.11a)$$

$$W(\beta) = \begin{cases} (4/3\pi)\beta^2(1-0.463\beta^2+0.1227\beta^4\cdots) \\ 1.496\beta^{-\frac{5}{2}}(1+5.107\beta^{-\frac{3}{2}}+14.93\beta^{-3}+\cdots). \end{cases} \quad (3.11b)$$

The two alternate expressions are useful for small and large values of β, respectively. Near $\beta=3$, both series converge slowly. According to Schmaljohann and Unsöld $W(3)=0.175$; $W(3.5)=0.122$. In Fig. 2, the function $W(\beta)$ is plotted, showing that

$$\lim_{\beta\to\infty} W = 1.496\beta^{-\frac{5}{2}} = 1.496\left(\frac{F_0}{F}\right)^{\frac{5}{2}}.$$

This is very nearly the same as the limit of Eq. (3.5),

$$\lim_{\beta\to\infty} \frac{dP(F)}{dF}\frac{dF}{d\beta} = \frac{3}{2}\left(\frac{F_0}{F}\right)^{\frac{5}{2}},$$

as asserted earlier.

These statements are not quite correct. In the binary theory F_0 was defined as

$$Ze/r_0^2 = Ze[(4\pi/3)n]^{\frac{2}{3}} = 2.60eZn^{\frac{2}{3}}.$$

The many-ion calculation involves a slightly different parameter,

$$F_0 = 2.61Zen^{\frac{2}{3}},$$

but the change is so small that its importance is quite academic, so we do not trouble to alter notation because of it.

From Eqs. (3.11) we pass to the frequency distribution in the same way as before. In the linear Stark effect $\Delta\omega/\Delta\omega_0 = F/F_0 = \beta$, and since in general

$$I(\Delta\omega)d(\Delta\omega) = W(\beta)d\beta, \quad (3.12)$$

we find

$$I(\Delta\omega) = W(\Delta\omega/\Delta\omega_0)(1/\Delta\omega_0). \quad (3.13)$$

In the *qradratic Stark effect*

$$(\Delta\omega/\Delta\omega_0)^{\frac{1}{2}} = F/F_0 = \beta,$$

and Eq. (3.5) gives

$$I(\Delta\omega)=W[(\Delta\omega/\Delta\omega_0)^{\frac{1}{2}}]\cdot\tfrac{1}{2}(\Delta\omega_0\cdot\Delta\omega)^{-\frac{1}{2}}. \quad (3.14)$$

The connection between the preceding considerations and what was described in Sec. I as a statistical theory is not altogether clear. For here, we calculate the probability of *fields* and make the passage to an intensity distribution via the Stark effect, whereas the statistical quantum theories fix attention upon the probability of a given *energy perturbation* ϵ, a scalar quantity, and identify this probability with the line intensity at $\hbar\Delta\omega$. Equivalence of the two procedures is intuitively expected. Margenau and Meyerott,[11a] who made a quantum mechanical calculation using the binary approximation for the L_α line of hydrogen, indicate how the equivalence comes about mathematically. Among other things ϵ is not the sum, $\sum_i \epsilon_i$ for individual perturbers but is composed very much like $\mathbf{F}$ from the vectors $\mathbf{F}_i$; hence the Holtsmark theory does not depart from the statistical pattern.

This treatment includes the effect of the nonuniformity of the Stark field produced by ions. In the ordinary theory of the Stark effect, $\mathbf{F}$ is treated as a constant, whereas the ions produce a field which depends on r, the dependence being greater the smaller r. In general the nonuniformity effect is small, increasing in magnitude with ion density, $W(\beta)$ as given by (3.11b) no longer has the asymptotic form $1.5\,\beta^{-\frac{5}{2}}$, but $1.5\,(\beta^{-\frac{5}{2}}+2\beta^{-2}a'/r_0)$, a' being the radius of the lower atomic state (first Bohr radius for L_α). The nonuniformity also causes shifts and widths in Stark components which do not show a first-order effect, the "forbidden" half-widths being of the order a'/r_0 times the regular Holtsmark widths.

B. Effect of Perturber Interactions

In part (A) of this section the probability of a given ion configuration was taken to be proportional to the volume of configuration space assignable to it, the Boltzmann factor $\exp[-V(\mathbf{r}_1,\mathbf{r}_2\cdots,\mathbf{r}_N)/kT]$ being neglected. This factor confers smaller weight upon configurations in which several ions are close together and therefore reduces the probability that many ions shall be situated near the radiating atom. Hence the Holtsmark theory overestimates the likelihood of strong perturbations and therefore the intensity in the wings of a line.

An accurate calculation with inclusion of the Boltzmann factor has not been made. Broyles[29] considers the problem most carefully, but his results are relevant primarily for the case where the radiator, too, is ionized and repels the perturbing ions by a Coulomb field of its own. His results are examined in the next section. Here we summarize a contribution by Ecker,[30] which deals directly with the problem. He relies upon the Debye-Hückel screening mechanism to provide a semiquantitative solution, which introduces the electrons as well as the ions into the picture.

In the presence of a cloud of ions and electrons the Coulomb field produced by an ion is given by

$$\mathbf{F}=(Ze\mathbf{r}/r^2)[(1/r)+(1/D)]e^{-r/D},$$

as may be seen by differentiating the expression for V, Eq. (5.4). According to (5.5),

$$D=[kT/4\pi ne^2(1+Z^2)]^{\frac{1}{2}}.$$

Analysis of the line-broadening problem even with this simplified potential remains formidable; Ecker chooses as an approximation to $\mathbf{F}$ the form§

$$\mathbf{F}=\begin{cases} Ze^2\mathbf{r}/r^3 & \text{if } r<D \\ 0 & \text{if } r\geq D. \end{cases}$$

Machine computation by the method of part (A) leads to a dependence of the line shape on the parameter

$$\delta=(4\pi D^3/3)n,$$

whose physical meaning is the number of ions within the Debye radius D. Clearly, if $D\to\infty$, the result must agree with Holtsmark's. Figure 3 shows the results of Ecker's calculations for three values of δ. The expected effect, reduction of the intensity in the wing is clearly in evidence.

In principle, a further correction must be made in the Holtsmark distribution. The Debye-Hückel cutoff modifies the effective field at large r. For small r, the Coulomb field breaks down because of *atomic* screening, the potential going to a finite value as $r\to 0$. The theory of this effect is easily developed[31] and predicts a flattening of the Holtsmark curve far from the center of the line. In the region affected, the frequency is pro-

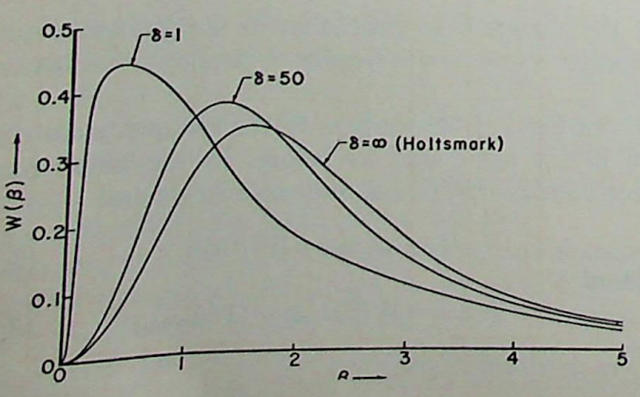

FIG. 3. Graph of $W(\beta)$ for different values of δ.

[29] A. A. Broyles, Phys. Rev. **100**, 1181 (1955).

[30] (a) G. Ecker, Z. Physik **148**, 593 (1957); (b) **149**, 254 (1957); (c) Z. Naturforsch. **12**, 346, 517 (1957).

§ A calculation of the shielding correction which avoids this cutoff was made by H. Hoffman and O. Theimer, Astrophys. J. **127**, 477 (1958). Ecker (private communication) has performed a careful machine calculation based on the correct potential and obtains results in substantial agreement with his former approximation and differing from those of Hoffman and Theimer.

portional approximately to β^{-1}, not to $\beta^{-\frac{1}{2}}$. But this region lies so far outside the measured range of line widths (hundreds of angstroms for the Balmer lines, as a simple estimate, based on the assumption that the breakdown radius is of atomic dimensions, shows) that this correction is at this time academic.

C. Treatment for Radiating Ions

The analysis leading to Eq. (3.5) is further defective in assuming no potential energy between the moving ions, and none between the radiating atom and the ions. The former is always present but has ordinarily no very profound effect on the frequency distribution. The second potential energy is present when the radiator itself is ionized; in that case its effect is more important. Attention has been called to these shortcomings by Mayer[32] and Broyles,[29] whose interest is primarily in highly ionized exploding plasmas where the ions themselves emit the lines. A completely adequate theory of these effects is not at hand. We develop here first the binary approximation to the many-ion analysis and compare the results with Eq. (3.4). (Our development completes somewhat the treatment of the aforenamed authors who omitted the condition that there be no ion within r and obtained an unnormalized distribution.)

The perturbing ion of charge Z_2e will repel the radiating ion of charge Z_1e with the Coulomb energy $Z_1Z_2e^2/r$. The former p_- will then be $1-4\pi ne^{-a/r}r^2dr$, provided

$$a=(Z_1Z_2e^2)/(kT). \tag{3.15}$$

In place of (3.2) we obtain

$$dP(a,r)=4\pi n\,\exp[(-a/r)-4\pi nA(a,r)]r^2dr, \tag{3.16}$$

where

$$A(a,r)=\int_0^r e^{-a/r}r^2dr. \tag{3.17}$$

Hence, the ratio of (3.16) to the Holtsmark distribution (3.4) is

$$S=dP(a,r)/dP(0,r)$$
$$=\exp\{-(a/r)+4\pi n[A(0,r)-A(a,r)]\}. \tag{3.18}$$

The function $A(a,r)$ is easy to calculate; it may be written

$$A(a,\xi a)=\tfrac{1}{3}a^3\mathfrak{F}(\xi);$$
$$\mathfrak{F}(\xi)\equiv(\xi^3-\tfrac{1}{2}\xi^2+\xi)e^{-1/\xi}+\tfrac{1}{2}Ei(-1/\xi). \tag{3.18a}$$

the function $\mathfrak{F}$ is plotted in Fig. 4. Clearly,

$$A(0,r)=r^3/3.$$

For the binary approximation to be valid, the ratio $(r_0/r)^2=\beta$ must be greater than about 7. On the other hand, $r_0=0.62n^{-\frac{1}{3}}$. The last results, then, begin to be useful at values of r in the neighborhood of $1/4n^{-\frac{1}{3}}$ and remain so for smaller radii. At this critical distance, Eq. (3.18) becomes

$$S=\exp\left\{-4an^{\frac{1}{3}}+\frac{\pi}{48}-\frac{4\pi}{3}na^3\mathfrak{F}\left(\frac{1}{4an^{\frac{1}{3}}}\right)\right\}. \tag{3.19}$$

The terms in the exponent become important when $an^{\frac{1}{3}}\approx 1$. This is the condition for equality of mean kinetic energy and Coulomb energy at the mean distance of separation of the ions.

If $4an^{\frac{1}{3}}=0.1$, $S=e^{-0.09}$, the value of $\mathfrak{F}(10)$ being 845. For $4an^{\frac{1}{3}}=1$, $S=e^{-0.952}$ (since $\mathfrak{F}(1)=0.258$), and for larger values of $4an^{\frac{1}{3}}$ only the term $\exp(-4an^{\frac{1}{3}})$ of S remains, the others being negligible.

In the light of these numerical results we consider two cases, first the perturbation of singly ionized helium atoms by protons in a star or a discharge plasma. Here $Z_1=Z_2=1$. The condition that the binary approximation be significant, namely $r<0.62n^{-\frac{1}{3}}$, is easily compatible with the requirement that r be greater than a helium ion, $r>5\times10^{-9}$ cm, since these inequalities merely imply $n<10^{24}$ cm^{-3}. But to have S appreciably smaller than 1, $an^{\frac{1}{3}}$ must be near 1. This means that $T\approx(e^2/k)n^{\frac{1}{3}}=1.7\times10^{-3}n^{\frac{1}{3}}$ °K, which can occur in a shock front or in an arc.

The situation is quite different for atomic explosions. At amosphere of iron ions, each with $Z=23$, and with $T\approx10^7$ °K implies $a=8.4\times10^{-8}$ cm. At normal density

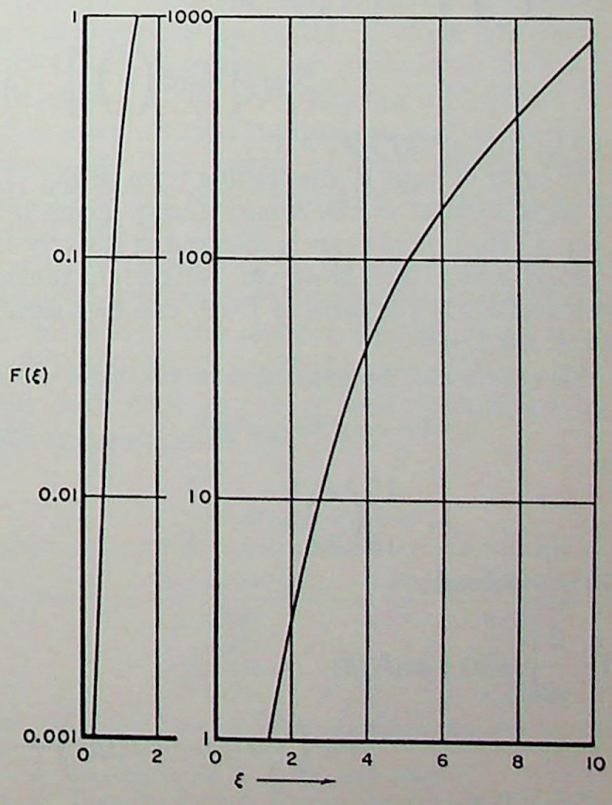

FIG. 4. Graph of $F(\xi)$ *vs* ξ. See Eq. (3.18a).

[32] H. Mayer, Los Alamos Scientific Laboratory Report LA-647, 1947.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

$n \approx 10^{23}$ cm^{-3} and the condition upon r is $r < 10^{-8}$ cm. Because of the small size of the iron core this leaves a considerable range in which the binary approximation is correct. Indeed at $r = 1/4n^{-\frac{1}{3}}$, for which (3.19) was computed $S \approx 10^{-15}$, indicating that the Holtsmark formula is enormously in error.

We now treat the many-ion problem[33] using the following model: the free electrons form a uniformly smeared out negative charge, and interactions are considered only between the radiating ion and the plasma ions; interaction between plasma ions themselves is ignored. This method avoids some uncertainties inherent in the approximations using the Bohm-Pines approach (see the following), for the approximations are clear in their physical meaning and the analysis is otherwise exact.

With this model, the probability $P(\mathbf{F})$ for an electric field F is given by

$$P(\mathbf{F}) = \frac{\int \cdots \int \exp(-a \sum_{i \to N} r_i^{-1}) \delta_i(\mathbf{F} - \sum_{i \to N} Q_2 \mathbf{r}_i / r_i^3) d\mathbf{r}_1 \cdots d\mathbf{r}_N}{\int \cdots \int \exp(-a \sum_i r_i^{-1}) d\mathbf{r}_1 \cdots d\mathbf{r}_N}, \tag{3.20}$$

where a is defined by Eq. (3.15). Equation (3.20) can be written in a more convenient form, best obtained through use of Chandrasekhar's method.[5] As before, we denote by $W(\beta)$ the probability of finding a field of strength $\beta = F/F_0$ [see Eq. (3.11a)]

$$F_0 = 2.61 Z_2 e n^{\frac{2}{3}}.$$

F_0 is the quantity introduced previously and represents essentially the field produced on one ion by another ion at the average spacing between ions, and n is the number density of ions. Then

$$W(\beta) = \frac{2}{\pi\beta} \int_0^\infty \exp\left[-\left(\frac{x}{\beta}\right)^{\frac{3}{2}} \eta\right] x \sin x dx, \tag{3.21}$$

$$\eta = \frac{15}{8}\left(\frac{2}{\pi}\right)^{\frac{1}{2}} \int_0^\infty dz z^{-7/2}(z - \sin z) \times \exp\left[-\alpha z^{\frac{1}{2}} \left(\frac{\beta}{x}\right)^{\frac{1}{2}}\right], \tag{3.22}$$

and $\alpha = [Z_1 e (Z_2 e)^{\frac{1}{2}} (kT)] F_0^{-\frac{1}{2}}$.

In the limit of large β, the leading term in Eq. (3.21) is the same as that of the binary theory given before [see Eq. (3.16)]. $W(\beta)$ can be computed directly from Eqs. (3.21) and (3.22). However, for certain ranges of α ($\alpha \ll 1$ and $\alpha \gg 1$) the form of $W(\beta)$ can be simplified.

Case 1: $\alpha \ll 1$, $\alpha\beta^{\frac{1}{2}} \ll 1$.

In this case η can be expanded in the ratio $y = x/\beta$:

$$\eta = 1 - c_1 \alpha y^{-\frac{1}{2}} + c_2 \alpha^2 y^{-1} \cdots, \tag{3.23}$$

where

$$c_1 = \frac{15}{16}\left(\frac{\pi}{2}\right)^{\frac{1}{2}}, \quad c_2 = \frac{5}{4}.$$

$W(\beta)$ then becomes

$$W(\beta) = \frac{2}{\pi\beta}\left[I_0(\beta) + \alpha c_1 I_1(\beta) + \alpha^2\left(\frac{c_1^2}{2} I_2(\beta) - c_2 I_{\frac{3}{2}}(\beta)\right) + \cdots\right],$$

where

$$I_p(\beta) = \int_0^\infty \exp\left[-\left(\frac{x}{\beta}\right)^{\frac{3}{2}}\right] x \left(\frac{x}{\beta}\right)^p \sin x dx. \tag{3.24}$$

It is seen that $(2/\pi\beta) I_0(\beta)$ is the Holtsmark distribution, to which Eq. (3.24) reduces in the limit, $T \to \infty$ ($\beta \to 0$).

The integrals in Eq. (3.24) can be expanded in a series and evaluated for $\beta \leqslant 3$ and $\beta \geqslant 6$. The range from 3 to 6 is difficult because of the slow convergence of the series. The coefficients of the first two terms in Eq. (3.24) are listed in Table III.

Case 2: $\alpha \gg 1$, $\beta \ll \alpha$.

For this case, η is expanded in an asymptotic series in y:

$$\eta = \frac{15}{4}\left(\frac{2}{\pi}\right)^{\frac{1}{2}}\left(\frac{1}{3!} y^{\frac{3}{2}} \alpha^{-1} - \frac{4!}{5!} y^{\frac{5}{2}} \alpha^{-5} + \frac{8!}{7!} y^{9/2} \alpha^{-9} - \cdots\right). \tag{3.25}$$

If only the first term is retained, one finds

$$W(\beta) = \frac{\alpha^{\frac{3}{2}} \beta^2 \exp(-\beta^2 \alpha (2\pi)^{\frac{1}{2}}/5)}{2\pi^{\frac{1}{2}}[(5/8)(2/\pi)^{\frac{1}{2}}]^{\frac{3}{2}}} = \frac{\alpha^{\frac{3}{2}} \beta^2 \exp[-0.5\alpha\beta^2]}{1.25}. \tag{3.26}$$

Equation (3.26) is identical with a formula proposed by Mayer[32] on the basis of a different, simpler physical

TABLE III. Coefficients of the first two terms of Eq. (3.24). Values of $(2/\pi\beta) I_0(\beta)$ from reference 5.

model. Why the two models lead to the same result is not clear.

Broyles[29] has proposed another way of computing the probability $P(F)$ of finding an electric field of magnitude F at a radiating *ion* in a plasma. He uses the method of Pines and Bohm[34] to separate the potential energy and the electric field into a short and a long-range component.

The work is based on a model in which the free electrons are represented as a uniformly smeared out negative charge. The following units are used: unit length is the radius of a sphere whose volume is the volume per ion r_0; unit field strength is F_0, and unit energy is that of two ions separated by unit distance, and the temperature is expressed in the above energy units.

The probability density for occurrence of a field β is [see Eq. (3.11a) for definition of β] in analogy to Eq. (3.20),

$$P(\beta)=\frac{\int\cdots\int \exp(-V/\theta)\delta(\beta-\sum_i \mathbf{r}_i/r_0^3)d\mathbf{r}_1\cdots d\mathbf{r}_N}{\int\cdots\int \exp(-V/\theta)d\mathbf{r}_1\cdots d\mathbf{r}_N}, \tag{3.27}$$

provided V is the potential energy, and δ the Dirac "function." On using the Dirichlet representation for δ one obtains

$$P(\beta)=(2\pi)^{-3}\int T(\mathbf{l})\exp(i\beta\cdot\mathbf{l})d\mathbf{l}, \tag{3.28}$$

$$T(\mathbf{l})\equiv\frac{\int\cdots\int \exp[-(V/\theta)+i\mathbf{l}\cdot\sum_j \mathbf{r}_j/r_j^3]d\mathbf{r}_1\cdots d\mathbf{r}_N}{\int\cdots\int \exp(-V/\theta)d\mathbf{r}_1\cdots d\mathbf{r}_N}.$$

Since $P(\beta)$ depends only on the magnitude of β we have

$$W(\beta)=4\pi\beta^2P(\beta). \tag{3.29}$$

We now employ the Pines-Bohm method to split the potential energy and the electric field into short and long-range components. The *ion* charge density ρ_i is written as

$$\rho_i=\sum_j \delta(\mathbf{r}-\mathbf{r}_j). \tag{3.30}$$

But the total charge density ρ can be expanded into a Fourier series (unit volume per particle) to give

$$\rho=\sum_k{}' \rho(\mathbf{k})\exp(i\mathbf{k}\cdot\mathbf{r}), \tag{3.31}$$

with

$$\rho(\mathbf{k})=\sum_j \exp(-i\mathbf{k}\cdot\mathbf{r}_j),$$

where the prime indicates the omission of $k=0$ from the sum in order that the net charge be zero. The potential and the electric field when expressed as functions of k can each be written as a sum of two terms, one for high and one for low values of k. The high k terms are functions of the individual $\mathbf{r}_i$ and are referred to as the particle or short-range part, the low k terms are expressible as functions of the $\rho(\mathbf{k})$ and are called the wave or long-range part of the respective quantity. With this separation, $T(\mathbf{l})$ can likewise be approximated in consistent fashion; it becomes a product of T_w (wave parts) and T_p (particle part). The wave part can easily be evaluated; the particle part is approximated by Broyles in two ways:

(1) Short-range central interactions (SRCI). In this approximation only the interactions between the radiating ion and the perturbing ions are retained, the interactions among the perturbing ions being neglected. This approximation is similar to the one in the previous section, except that it was there applied to the full Coulomb interactions of the ions whereas it is here restricted to the short range components which arise in the Bohm-Pines method.

(2) Short-range nearest neighbor (SRNN) interactions. Interactions are considered only between the radiating ion and its nearest neighbor.

Broyles[29] has employed his method for iron ions at normal densities, with a charge of 23 electron charges at a temperature of 1 kev, a case already considered earlier in this section. This corresponds to $\theta=0.186$. Under these conditions, α as defined in the previous part of this section [Eq. (3.22)] has a value of 5.5. It is therefore possible to use Eq. (3.26) for $\beta\ll 5.5$. The error attending the use of Eq. (3.26) is less than 10% for $\beta=1$ and decreases for decreasing β. Table IV compares Eq. (3.26) with Broyles' SRNN for $0.3\leqslant\beta\leqslant 1.5$ A more detailed comparison is given in Fig. 2 of reference 29. The curve marked "simple harmonic oscillator" is the result of Mayer's calculation and is identical with Eq. (3.26).

A separate publication by Broyles[35] deals extensively with the approximations involved in using the Pines-Bohm method for this problem and devises an improved procedure[36] which is applicable for $\theta\geqslant 0.6$. It is concluded that $P(\beta)$ is rather well determined by the SRNN approximation for $\theta\geqslant 0.6$.

TABLE IV.

IV. REFINED IMPACT THEORY. FUSION OF IMPACT AND STATISTICAL THEORIES

A. Impact Theory

A consistent and ingenious development of the impact method was carried out by E. Lindholm[8c,15b] who was preceded in several important respects by W. Lenz[8a] and G. Burkhardt.[37] In deriving Lindholm's results we use recent stochastic methods.

Let us return to Eq. (1.13), which represents the true line form, provided only the adiabatic hypothesis holds [see formula (1.11)]. The immediate problem is to calculate the correlation function C. To strip it of irrelevancies, we continue to suppose that the radiator has only two states, and that only one of these is occupied: $S_1=1$, $S_2=0$. We also omit subscripts. Then,

$$C(\tau)=\mu^2\int_{-\infty}^{\infty}e^{-i[\varphi(t+\tau)-\varphi(t)]}dt. \tag{4.1}$$

The phase φ is defined by (1.12). In that expression, E_l and E_m contain constant parts, E_l^0 and E_m^0, plus the perturbations. The constant parts contribute to φ_{lm} the amount $[(E_l^0-E_m^0)/\hbar]t\equiv\omega' t$, ω' being the normal frequency of the line. In this section, *we redefine φ (without changing notation) to mean only the variable part which is contributed by the perturbations*. As a result, we change Eq. (1.13a) to read

$$I(\omega)\propto\int d\tau e^{i(\omega-\omega')\tau}C(\tau). \tag{4.2}$$

Positive φ corresponds to a positive difference ΔE (upper state)$-\Delta E$ (lower state). There is some confusion on this point in the cited literature.

The quantity $\varphi(t+\tau)-\varphi(t)$ represents the perturbational phase change which has occurred in the interval $(t, t+\tau)$. The integrand in Eq. (4.1) is a time series in which this quantity changes from instant to instant t, and we are integrating over t. As is customary (ergodic hypothesis) the one time series is replaced by an ensemble of time series and the *time integral* is identified with an *ensemble average* (except for a constant factor). Thus

$$C(\tau)\propto\langle e^{-i\varphi(\tau)}\rangle_{Av}\equiv\int_{-\infty}^{\infty}e^{-i\varphi}P_\tau(\varphi)d\varphi, \tag{4.3}$$

where $P_\tau(\varphi)$ is the probability of a phase change φ in the interval τ. It is convenient to make the assumption characteristic of the impact approach, namely that the collisions are sudden and occur singly. The value of φ is then the sum of a whole number of individual phase changes φ_i, each associated with one collision. By the rules of probability, $P_\tau(\varphi)$ is related to the probability $P_\tau(k)$ that k collisions have taken place in τ, by

$$P_\tau(\varphi)=\sum_{k=0}^{\infty}P_\tau(k)\sum_{1,2\cdots k}\left[\prod_{j=1}^{k}P(\varphi_j)\right]\delta\left(\varphi-\sum_{j=1}^{k}\varphi_j\right) \tag{4.4}$$

and

$$P_\tau(k)=(\tau\nu_c)^k e^{-\nu_c\tau}/k!, \tag{4.5}$$

which is Poisson's law. As before, ν_c is the collision frequency $P(\varphi_j)$ the probability for the occurrence of a phase change of magnitude φ_j, and δ is the well-known Dirac "function" which may be replaced by its Dirichlet representation

$$\delta\left(\varphi-\sum_{j=1}^{k}\varphi_j\right)=\frac{1}{2\pi}\int_{-\infty}^{\infty}dy\exp\left[iy\left(\varphi-\sum_{1}^{k}\varphi_j\right)\right]. \tag{4.6}$$

The symbol $\sum_{1,2\ldots k}$ is meant as a summation over all $\varphi_1, \varphi_2, \cdots, \varphi_k$ in every factor that follows it. With the aid of (4.5) and (4.6), one may write Eq. (4.4) in the form

$$P_\tau(\varphi)=\frac{e^{-\nu_c\tau}}{2\pi}\int_{-\infty}^{\infty}dy e^{iy\varphi}\sum_{k=0}^{\infty}\frac{\nu_c\tau}{k!}[\sum_i P(\varphi_j)e^{-iy\varphi_j}]^k,$$

and this may be expressed as

$$P_\tau(\varphi)=\frac{e^{-\nu_c\tau}}{2\pi}\int_{-\infty}^{\infty}dy e^{iy\varphi+\nu_c\tau\alpha(y)}, \tag{4.7}$$

provided

$$\alpha(y)=\sum_i P(\varphi_j)e^{-iy\varphi_j}. \tag{4.8}$$

On substituting (4.7) in (4.3) we have

$$C(\tau)=\frac{e^{-\nu_c\tau}}{2\pi}\int_{-\infty}^{\infty}e^{-i\varphi}d\varphi\int_{-\infty}^{\infty}dy e^{iy\varphi+\nu_c\tau\alpha(y)}$$

$$=e^{-\nu_c\tau}\int dy e^{\nu_c\tau\alpha(y)}\left\{\frac{1}{2\pi}\int_{-\infty}^{\infty}e^{i(y-1)\varphi}d\varphi\right\}.$$

The factor { } is $\delta(y,1)$. Hence,

$$C(\tau)=e^{-\nu_c\tau[1-\alpha(1)]}. \tag{4.9}$$

This result is sufficient for many purposes and underlies most of the work on impact broadening. A generalization which allows the collision probability to depend on velocity, and which also gets rid of the usual assumption that the collisions are sudden and occur singly, is contained in Kolb's[22,38] report and is given below, following the lines of the preceding account. The result [Eq. (4.16)] is used in Sec. V.

Let us divide the time interval $(-\infty, \infty)$ into elements Δt_i. The phase change produced by *one* perturber in the time interval τ depends on the time of closest approach, the velocity v, and in general on some impact parameter l. Let us call this phase change $\varphi_{i,v,l}(\tau)$,

[37] G. Burkhardt, Z. Physik 115, 592 (1940).

[38] A. C. Kolb, AFOSR-TN-57-8, Astia Document No. AD115-400.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

where i refers to the time interval $\Delta\tau_i$ which contains the time of closest approach. If the perturbations are *scalarly additive*, the total phase change is

$$\varphi(\tau)=\sum_{iv}\varphi_{iv}(\tau),$$

where $\varphi_{iv}(\tau)$ is the phase change produced in the time interval τ by all perturbers described by (i,v). Clearly,

$$\varphi_{iv}(\tau)=\sum_{j=1}^{\mathfrak{N}(iv)}\varphi_{i,v,l_j}(\tau),$$

if $\mathfrak{N}(iv)$ is the number of perturbers characterized by (i,v) in some effective volume. We first compute $P(\varphi_{iv})$, the probability of a phase change φ_{iv} due to all perturbers in the class (i,v).

Assume that the effective volume of our system is a sphere of radius R and write $n(v)$ for the number per cubic centimeter of perturbers with velocity v (assumed at first to take on discrete values). We designate by $W(l)$ and $W[\mathfrak{N}(i,v)]$ the probability distributions for l and $\mathfrak{N}(i,v)$. The latter is given again by Poisson's distribution,

$$W[\mathfrak{N}(i,v)]=\frac{1}{\mathfrak{N}(i,v)!}(\nu_v\Delta t_i)^{\mathfrak{N}(iv)}e^{-\nu_v\Delta t_i}, \quad (4.10)$$

where ν_v is the collision frequency for particles with velocity v and is given by

$$\nu_v=\pi R^2 v n(v). \quad (4.11)$$

We then have

$$P(\varphi_{i,v})=\sum_{\mathfrak{N}(iv)=0}^{\infty}\int_{l_1}\cdots\int_{l_{\mathfrak{N}(i,v)}}W[\mathfrak{N}(i,v)]\times\left\{\prod_{j=0}^{\mathfrak{N}(i,v)}W(l_j)dl_j\right\}\delta\left(\varphi_{iv}-\sum_{j=1}^{\mathfrak{N}(iv)}\varphi_{i,v,l_j}\right). \quad (4.12)$$

Again we replace the δ function by its Dirichlet representation

$$\delta(x-x')=\frac{1}{2\pi}\int_{-\infty}^{\infty}dy e^{iy(x-x')}, \quad (4.13)$$

substitute (4.10) into (4.12) and obtain

$$P(\varphi_{iv})=\frac{1}{2\pi}\int_{-\infty}^{\infty}dy\exp\{iy\varphi_{iv}+\nu_v\Delta t_i[\alpha_{i,v}(y)-1]\}, \quad (4.14)$$

provided

$$\alpha_{i,v}(y)=\int W(l)e^{-iy\varphi_{iv}l}dl.$$

Now $P(\varphi)$ can be written

$$\int\cdots\int\left(\prod_{iv}P(\varphi_{iv})d\varphi_{iv}\right)\delta\left(\varphi-\sum_{iv}\varphi_{iv}\right).$$

On using Eqs. (4.13) and (4.14) this becomes, after rearrangement,

$$P(\varphi)=\frac{1}{2\pi}\int_{-\infty}^{\infty}e^{is\varphi}ds\left\{\prod_{iv}\int_{-\infty}^{\infty}dy e^{\nu_v\Delta t_i[\alpha_{i,v}(y)-1]}\cdot\frac{1}{2\pi}\int d\varphi_{iv}e^{i\varphi_{i,v}(y-s)}\right\}.$$

The last integral is $\delta(y-s)$, so that

$$P(\varphi)=\frac{1}{2\pi}\int_{-\infty}^{\infty}e^{is\varphi}ds\prod_{iv}e^{\nu_v\Delta t_i[\alpha_{iv}(s)-1]}=\frac{1}{2\pi}\int_{-\infty}^{\infty}\exp\{is\varphi+\sum_{i,v}\nu_v\Delta t_i[\alpha_{i,v}(s)-1]\}ds.$$

$C(\tau)$ then becomes proportional to

$$\int_{-\infty}^{\infty}ds\exp\{\sum_{iv}\nu_v\Delta t_i[\alpha_{i,v}(s)-1]\}\cdot\frac{1}{2\pi}\int_{-\infty}^{\infty}d\varphi e^{i(s-1)\varphi}$$

and, therefore,

$$C(\tau)\propto\exp\{\sum_{i,v}\nu_v\Delta t_i[\alpha_{i,v}(1)-1]\}.$$

This finally can be written with the use of Eq. (4.4) and replacement of the sum by integrals, as

$$C(\tau)\propto\exp\left\{\int dv\int_{-\infty}^{\infty}dl\pi R^2 v n(v)[\alpha_{l,v}(1)-1]\right\}. \quad (4.15)$$

We now apply this general formula to the special case of impacts. In this approximation, all collisions are assumed to be short enough so that those having their time of closest approach in τ are also completed in τ, and one may disregard the others. This means, in terms of $\varphi_{t,v,l}$, that

$$\varphi_{t,v,l}\begin{cases}=0 \text{ if } t \text{ is not in } \tau\\ =\varphi_{v,l} \text{ if } t \text{ is in } \tau.\end{cases}$$

In the second instance $\varphi_{t,v,l}$ is independent of time, and therefore $\varphi_{v,l}$ represents the total phase change produced by *one* particle with time of closest approach in τ and with impact parameter l. Under these conditions

$$\alpha_{t,v}(1)=1 \text{ if } t \text{ is not in } \tau$$

$$\alpha_{t,v}(1)=\alpha_v(1)=\int dl W(l)e^{-i\varphi_{vl}} \text{ if } t \text{ is in } \tau.$$

Equation (4.15) then leads to

$$C(\tau)\propto\exp\left\{\pi R^2\int dv v n(v)[\alpha_v(1)-1]\tau\right\}. \quad (4.16)$$

This is the general form of $C(\tau)$ for an impact theory

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

based on scalarly additive perturbations. We return to this equation later (Sec. V). Equation (4.16) reduces to (4.9) under the proper conditions. To show this we first assume that all perturbers have the same velocity v'. This means we replace $n(v)$ by $n\delta(v-v')$, where n is the number of particles per cubic centimeter. In view of Eq. (4.11) and because ν_v is now identical with our former ν_c, we then recover Eq. (4.9)

$$C(\tau) \propto e^{\nu_c[\alpha(1)-1]\tau}.$$

This is the correlation function for perturbers all of which have the same velocity. This derivation shows that its validity rests on the premise of scalarly additive perturbations and does not require the restriction that the impacts fail to overlap in time; this feature was not evident from the simpler proof which led to Eq. (4.9).

We return to calculation of the line intensity, employing the correlation function given by Eq. (4.9). We split $\alpha(1)$ into its real and its imaginary part, $\alpha=\alpha_1+i\alpha_2$ and put

$$\nu_c(1-\alpha_1)\equiv u_1, \quad -\nu_c\alpha_2\equiv u_2 \tag{4.17}$$

so that

$$C(\tau)=e^{-(u_1+iu_2)\tau}. \tag{4.18}$$

The calculation of I in accordance with Eq. (4.2) is then easy. One further detail has to be remembered. It follows from (4.1) that $C(-\tau)=C^*(\tau)$, a relation necessary for the reality of $I(\omega)$ but obscured by the explicit form (4.18) which is valid for $\tau>0$. Thus

$$C(\tau)=C^*(-\tau)=e^{(u_1-iu_2)\tau} \quad \text{for } \tau<0$$

and by (4.2)

$$I(\omega)\propto\left[\int_{-\infty}^{0} e^{u_1\tau+i(\omega-\omega'-u_2)\tau}d\tau+\int_{0}^{\infty} e^{-u_1\tau+i(\omega-\omega'-u_2)\tau}d\tau\right]$$
$$=2u_1[u_1^2+(\omega-\omega'-u_2)^2]^{-1}.$$

To make $\int_0^\infty I(\omega)d\omega=1$ we must write

$$I(\omega)=u_1/\pi[u_1^2+(\omega-\omega'-u_2)^2]^{-1}. \tag{4.19}$$

This represents a dispersion curve with a shift

$$u_2=\nu_c\sum_j P(\varphi_j)\sin\varphi_j \tag{4.20}$$

to the blue of the normal peak at ω', and a half-width

$$\omega_{\frac{1}{2}}=2u_1=2\nu_c[1-\sum_j P(\varphi_j)\cos\varphi_j]. \tag{4.21}$$

Lindholm now falls back upon Eq. (1.5) for a computation of the φ_j, which he identifies with the $\Delta\varphi(\rho,v)$ of that expression. This proficient and simple step is warranted under two conditions: (*a*) The impacts are sudden and do not coincide; (*b*) the perturber has a classical path, so that $\epsilon[(\rho^2+v^2t^2)^{\frac{1}{2}}]$ is meaningful. The first of these had already been discussed; the second is an additional restriction to be examined in the light of Sec. II.

Equation (4.21) distinguishes between phase changes by the arbitrary index j; Eq. (1.5) classifies them by the impact parameter ρ which is the closest distance of approach. The connection is this: If φ_j is taken to be $\varphi(\rho)$ then $P[\varphi(\rho)]=2\pi\rho d\rho/q$, where q is the total collision cross section. On the other hand, $\nu_c=nqv$. Therefore (4.20) and (4.21) become

$$u_2=nv\int 2\pi\rho d\rho\,\sin\Delta\varphi(\rho,v), \tag{4.22}$$

$$\omega_{\frac{1}{2}}=2nv\left[q-\int 2\pi\rho d\rho\,\cos\Delta\varphi(\rho,v)\right]$$
$$=2nv\int(1-\cos\Delta\varphi)2\pi\rho d\rho=4\pi nv\int\sin^2\Delta\varphi\rho d\rho. \tag{4.23}$$

The integrations over ρ are to be carried from 0 to $(q/\pi)^{\frac{1}{2}}$. Because of the rapid decline of $\Delta\varphi$ with ρ it is often permissible to replace the upper limit by ∞. In the case of long-range Coulomb interactions there is the added difficulty of giving a meaning to q.

The evaluation of $\Delta\varphi$ proceeds in accordance with (1.4); it is profitable only for simple force laws of the form

$$\epsilon(r)=\hbar\Omega_\sigma/r^\sigma. \tag{4.24}$$

Here we have replaced the former C_σ by $\hbar\Omega_\sigma$ to save writing. For our purposes the form (4.24) is satisfactory, for we shall be dealing mainly with linear Stark effects (where $\epsilon=\hbar sF=\hbar se/r^2$, whence $\sigma=2$) and quadratic Stark effects (where $\epsilon=\hbar tF^2=\hbar te^2/r^4$, whence $\sigma=4$). Here ϵ is the difference in the Stark displacements of the two states; it refers to the line, not to a given state.

With (4.24) Eq. (1.5) yields

$$\Delta\varphi=\Omega_\sigma\int_{-\infty}^{\infty}dt(\rho^2+v^2t^2)^{-\sigma/2}=\pi^{\frac{1}{2}}\frac{\Gamma[(\sigma-1)/2]}{\Gamma(\sigma/2)}\frac{\Omega_\sigma}{v\rho^{\sigma-1}}.$$

In particular, for $\sigma=2$

$$\Delta\varphi=(\pi\Omega_2)/(v\rho) \tag{4.25}$$

and for $\sigma=4$

$$\Delta\varphi=(\pi\Omega_4)/(2v\rho^3). \tag{4.26}$$

We now compute (4.22) and (4.23) for these two cases.

The shift for the linear Stark effect is not observable as such because the splitting pattern as a whole is symmetric. Lindholm and Unsöld do not compute it for that reason. Nevertheless, it is meaningful as a measure of the shift of each Stark component, and it does manifest itself in each wing of such lines as H_β and H_δ, which have zero intensity at the center. Since q is not well defined, the upper limit in the integrations of (4.22) and (4.23) will be taken as r_0 (see Sec. III: $(4\pi/3)r_0^3n=1$), this being the order of distance beyond which the

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Coulomb force is effectively screened.‖ When $\sigma=4$ the convergence is fast and the integrations may be carried to ∞. For $\sigma=2$ both integrations are straightforward (see Lindholm); the forms below involve an expansion of the integral sine and cosine. For $\sigma=4$ a graphical integration is necessary to determine the numerical factors. Thus one finds:

Linear Stark effect, $\sigma=2$

$$\text{Shift}=u_2=2\pi^3\Omega_2^2\frac{n}{v}\left(\frac{vr_0}{\pi\Omega_2}-\frac{\pi}{4}+\frac{\pi\Omega_2}{2vr_0}-\cdots\right), \quad (4.27)$$

$$\text{Half-width}=\omega_{\frac{1}{2}}=2\pi^3\Omega_2^2\frac{n}{v}\left(0.923-\ln\frac{\pi\Omega_2}{vr_0}-\frac{\pi^2\Omega_2^2}{24v^2r_0^2}+\cdots\right). \quad (4.28)$$

Quadratic Stark effect, $\sigma=4$

$$\text{Shift}=u_2=9.8\Omega_4^{\frac{2}{3}}v^{\frac{1}{3}}n, \quad (4.29)$$

$$\text{Half-width}=\omega_{\frac{1}{2}}=11.4\Omega_4^{\frac{2}{3}}v^{\frac{1}{3}}n. \quad (4.30)$$

In these formulas v is the speed of the perturbing particle (in the center of gravity system).

Equation (4.27) is somewhat embarassing: it makes the shift depend directly upon the cutoff radius and thereby emphasizes the uncertainty of our assumptions. Numerical considerations even show that for electrons as perturbers, (4.27) is generally much greater than (4.28), and this exposes an inconsistency of the present method. Table V shows the ratio $u_2/\omega_{\frac{1}{2}}$ from (4.27) and (4.28) for different temperatures and electron densities.

Burkhardt,[37] Lindholm,[8c,15b] and particularly Unsöld[18] couple an interesting consideration with the analysis leading to Eqs. (4.29) and (4.30), where no convergence difficulties are encountered. If $\sigma=4$, Eqs. (4.22) and (4.23) read

$$u_2=nv\int \sin(\rho_0/\rho)^3\cdot 2\pi\rho d\rho, \quad (4.31)$$

$$\omega_{\frac{1}{2}}=4nv\int \sin^2\tfrac{1}{2}(\rho_0/\rho)^3\cdot 2\pi\rho d\rho, \quad (4.32)$$

because in this instance $\Delta\varphi$, given by (4.26), takes the form $(\rho_0/\rho)^3$ if we put $\rho_0=(\pi\Omega_4/2v)^{\frac{1}{3}}$. This, is the value of ρ (always in terms of our single-impact analysis) for which the phase change $\Delta\varphi=1$ and therefore corresponds to Weisskopf's critical radius ρ_c.

Consider the integrands in (4.31) and (4.32). Clearly $\sin(\rho_0/\rho)^3$ fluctuates rapidly about zero for small ρ and becomes monotone and decreasing for large ρ. The initial fluctuations practically make u_2 depend on the contributions it gets from large ρ. But as for (4.32), its integrand is never negative; hence, the initial fluctuations contribute greatly to $\omega_{\frac{1}{2}}$ while the small contributions from large ρ are less significant. Now the division between large and small ρ comes at $\rho=\rho_0$, the point beyond which neither integrand oscillates.

‖ The Debye-Hückel radius would be a better limit; but the results should not depend critically on this choice if they are to be believed.

TABLE V. Electron broadening. Ratio of shift to half-width in the linear Stark effect.

T(°K)$\backslash n$	10^{12}	10^{13}	10^{14}	10^{15}	10^{16}
10^2	8.6	3.5	2.6	1.4	1.05
10^3	22	11.7	6.3	3.5	1.9
10^4	58	30	16	8.6	3.5
10^5	158	81	42	22	11.7

All this suggests that perhaps a useful simplification results if we integrate (4.31) from ρ_0 to ∞, and (4.32) from 0 to ρ_0. Furthermore, we replace the sine in (4.31) by its argument and revert to the original form for u_2, Eq. (4.20). It reads

$$u_2=\nu_c\sum_j P(\varphi_j)\varphi_j\equiv\nu_c\bar{\varphi}_j. \quad (4.33)$$

The line shift, which arises primarily from small $\Delta\varphi$ (large ρ) is in effect the average number of phase shifts per second.

The integration of (4.32) from 0 to ρ_0 changes the numerical factor in (4.30) very little; hence, we may conclude that, under conditions in which (4.32) is valid, contributions from $\Delta\varphi$ smaller that 1 may be ignored. This, however, is not the same as saying that (4.32) is valid when $\Delta\varphi\gg 1$. Within the limits set by the example of the second-order Stark effect, and for force-law parameters σ greater than 4, one arrives at the qualitative rule that impacts within the optical radius broaden, impacts outside the optical radius shift the line. This somewhat precarious generalization is belied by Eqs. (4.27) and (4.28), and by Table V; hence it has no meaning for first-order Stark effects.

What are the conditions for validity of (4.22) and (4.23) of which (4.31) and (4.32) were special cases? We have derived them by assuming the impacts to be sudden. A little reflection shows that the derivation is essentially unchanged provided the collisions do not overlap, i.e., are binary. The case of multiple collisions has been treated by Lindholm (though in a way which makes no allowance for the *vector* superposition of fields in the Stark-effect problem and which remains within the "classical path" approximation) who succeeded in showing that the foregoing results of this section have wider validity than the present analysis suggests. Some further consideration is given by Krogdahl[39] and, by Kolb.[38]

B. Core and Wing Theorems for Individual Collisions

Under the assumption of binary collisions the criteria for the impact and the statistical theory take special forms.

[39] M. Krogdahl, Astrophys. J. 110, 355 (1949).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

1. Core Theorem

The impact theory (see Sec. I) was established on the assumption that the impacts are sudden and separated in time. The general form for the intensity distribution depends on integrals of the form $\int e^{i[\varphi(t)-\Delta\omega\cdot t]}dt$. A single impact, and therefore the change in φ corresponding to a single impact, are completed in a time of the order of ρ/v. If the change in $\Delta\omega\cdot t$ over this time interval is small compared to unity, i.e., if $\Delta\omega\rho/v\gg 1$ the impact can be considered to be sudden. This inequality can always be satisfied for sufficiently small $\Delta\omega$, hence the impact theory is valid in the core of the line (core theorem).

For *single impacts* the phase change is (see Sec. IIA)

$$\Delta\varphi=\frac{C_\sigma\pi^{\frac{1}{2}}}{\hbar v\rho^{\sigma-1}}\frac{\Gamma[(\sigma-1)/2]}{\Gamma(\sigma/2)}.$$

With the result we can derive[1f] a more specific criterion for validity of the impact theory. If we assume that the important impacts are those that occur within the optical radius ρ_c for which $\Delta\varphi\approx 1$, we have

$$\rho_c\approx(C_\sigma/\hbar v)^{1/\sigma-1}.$$

Combining this equation with the foregoing inequality we have for the range of validity of the impact theory in isolated collisions

$$\Delta\omega\ll v(\hbar v/C_\sigma)^{1/\sigma-1}.$$

In certain cases Kolb[22,38] has shown that this relation is valid under more general conditions than the restrictive ones imposed for this simple derivation.

2. Wing Theorem

The wing theorem, Sec. I, shows that for sufficiently large $\Delta\omega$ (measured from the normal line position) the statistical theory holds, but it does not say beyond what frequency it may be applied. *When the line arises from individual impacts*, a very simple argument covers this point. For there appears in the entire formalism only one time (and hence one frequency) that is characteristic of an impact namely, the duration of the perturbation τ_p. Hence, there is only one frequency τ_p^{-1} to which appeal can be made as a critical limit. The condition, $\Delta\omega\to\infty$, may therefore be replaced by

$$\Delta\omega\cdot\tau_p\gg 1. \qquad (4.34)$$

A more pictorial demonstration of the meaning of this inequality has been given by several authors, among whom Burkhardt[37] seems most explicit and circumspect. He pictures different collisions as producing different rectangles on a perturbation energy *vs* time plot, as drawn in Fig. 5. Distant passages have large τ_p but small $\Delta\omega$, for in this instance we may identify a specific $\Delta\omega$ within the observed line with a specific passage. A given passage is assumed to affect recorded frequencies in two ways, by virtue of the phase jumps occurring at the beginning and the end of a perturbation, and by the actual change of frequency during the perturbation. The former leads to a formula like (4.21) (in which ν_c is strictly *twice* the collision frequency). Empirically, the resulting width is usually small.

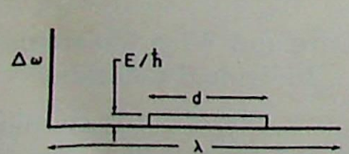

FIG. 5. Idealized representation of collisions. Long and flat rectangles represent gentle impacts of long duration; short and tall rectangle; represent energetic but brief impacts.

The detuning over an interval τ_p requires different treatment in different cases. Taken by itself, a given rectangle in Fig. 5 produces a line at the frequency $\Delta\omega$ and of Lorentz width $1/\tau_p$. Consecutive impacts yield superpositions of such lines, and these superpositions produce a statistical distribution about the different values of $\Delta\omega$ if $1/\tau_p\ll\Delta\omega$, i.e., if the different impact lines do not overlap. Here we discover again the inequality (4.34).

This reasoning is alone perhaps not quite convincing; for it will occur to those with experience in Fourier analysis that the replacement of a set of continuous perturbations by the rectangles of Fig. 5 is a risky practice. Still this demonstration possesses merits, even if rigor is not among them.

There is some likelihood of confusion in the criterion (4.34). We noted, in the text following Eq. (4.32), that the condition $\Delta\varphi\gg 1$ selects those encounters which make important contributions to the *impact* width of the line. This same condition is implied by (4.34). But (4.34) is also the condition for validity of the *statistical* theory. If impact broadening and statistical broadening were mutually exclusive or contradictory effects we should encounter here a paradox. This, however, is not the case. Inequality (4.34) means what it says: it permits the use of statistical theory. The earlier information is also true; it means simply that an impact theory, when carefully employed under these conditions (which is in general more difficult to do), must give approximately the same answer. The literature contains many instances showing this to be true.[8d] Lindholm's theory, for instance, leads to Margenau's statistical formula for Van der Waals broadening, a case which has been repeatedly discussed in this connection.

The overlapping of impact and statistical domains is further illustrated by the following coincidence. We saw that the line shift (4.33) arises from small phase changes, which violate the criteria $\Delta\varphi\gg 1$. But if we compute it under certain circumstances, it is nevertheless the statistical shift. Assume, for instance, that every φ_j arises from a perturbation ΔE_j lasting a time t' which is inversely proportional to the velocity v (so that the interaction distance, d, is constant). Then

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by eGangotri Foundation USA

$\varphi_j=(\Delta E_j/\hbar)(d/v)$. Also, $\nu_c=nqv$ and by (4.33), $u_2=nqd\Delta E/\hbar$, a result which displays the important characteristic of all statistical theories inasmuch as it does not depend on v. In fact, it is exactly the statistical result. In Fig. 6, λ is the mean free path. Along it $\Delta E=0$ except in a region of length d. Hence,

$$\Delta\omega=\frac{\langle\Delta E\rangle}{\hbar}=\frac{1}{\hbar}\frac{0\cdot\lambda+\Delta E\cdot d}{\lambda}=\frac{nqd\Delta E}{\hbar}$$

because $nq\lambda=1$.

C. Some Numerical Estimates, Mainly Regarding the Balmer Lines

The wing theorem for binary collisions says, in effect, that for $\Delta\omega$ greater than ω'', such that $\omega''\tau_p=1$, a statistical description is appropriate. But as we have seen, $\omega''\tau_p$ also equals $\Delta\varphi$ if this simple picture holds.

We now consider the *first-order Stark effect*. Here $\Delta\varphi$ is given by Eq. (4.25). Putting

$$\Delta\varphi=(\pi\Omega_2)/(v\rho_c)=1$$

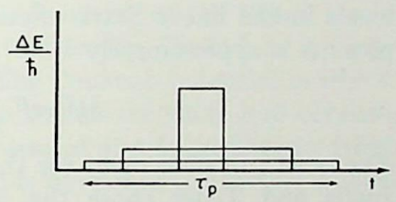

FIG. 6. $\Delta\omega$ *vs* distance travelled by perturber.

we have $\rho_c=\pi\Omega_2/v$. The frequency displacement for this ρ_c is

$$\omega''=\Omega_2/r^2=\Omega_2/\rho_c^2=v^2/(\pi^2\Omega_2). \qquad (4.35)$$

This "statistical frequency limit" within the line is independent of the perturber density.

Let us now consider the half-width of the line which would be calculated by means of impact theory, Eq. (4.28):

$$\omega_{\frac{1}{2}}\approx 2\pi^3\Omega_2^2 n/v. \qquad (4.36)$$

The dependence on v is interesting; the statistical frequency limit moves out farther with increasing v, whereas the impact width becomes smaller.

To make a comparison of (4.35) and (4.36) we need the values of Ω_2. These are discussed by Unsöld (whose C is our $\Omega_2/2\pi$) are are given for the Balmer lines:

	H_α	H_β	H_γ	H_δ	
Ω_2	3.96	10.35	20.5	27.6	(cgs units)

As a typical case we take the H_α line, emitted at a temperature of 10 000°K and an ion density $n=10^{15}$ cm^{-3}. At that temperature v (electron) $=6.23\times10^7$ cm/sec and v (H-ion) $=20.6\times10^5$ cm/sec. From (4.35) and (4.36) one then computes the following values.

TABLE VI. Statistical wavelength limit $\Delta\lambda''$ in Angstroms for the Balmer lines (after Unsöld).

$T=$		25 000°	10 000°	5000°	3000° (K)
H_α	Electrons	580	230	110	70
	Protons	0.63	0.25	0.12	0.08
H_β	Electrons	120	48	24	14
	Protons	0.13	0.05	0.03	0.02
H_γ	Electrons	48	19	9	6
	Protons	0.05	0.02	0.01	0.006
H_δ	Electrons	32	13	6	4
	Protons	0.03	0.01	0.007	0.004

H_α line broadened by

H ions: $\omega_{\frac{1}{2}}=4.8\times10^{11}$ sec^{-1}, $\omega''=1.1\times10^{11}$ sec^{-1}.

electrons: $\omega_{\frac{1}{2}}=1.6\times10^{10}$ sec^{-1}, $\omega''=9.8\times10^{13}$ sec^{-1}.

For all these cases the Holtsmark half width is $\approx10^{12}$ sec^{-1}. The ions, if their broadening effect were computed by the impact theory, would show a half-width greater than ω''. But since for $\Delta\omega\gg\omega''$ the statistical theory is valid one may, so long as one is not interested in the intensity distribution for smaller $\Delta\omega$, disregard $\omega_{\frac{1}{2}}$ for the ions. The electrons, however, produce an ω'' well beyond the limit of interest; hence, a statistical treatment for them is not proper. On the other hand $\omega_{\frac{1}{2}}$ for electrons is very small. The important contribution to the line structure comes from the statistical effects of the ions beyond ω'' and everything else, indeed the entire role of the electrons, can be ignored. The *actual* Holtsmark half width computed for the *ions* under the conditions here assumed is of course greater than ω'' (it is about 8×10^{11} sec^{-1}).

In cases of this sort it is sometimes claimed that the part of the line beyond ω'' can be treated statistically while the inner portion arises from impacts. There is no logical warrant for the second half of this statement despite the core theorem, for the limit of validity of the core theorem need not coincide with that of the wing theorem. Since the interior part has usually been of little interest in line analysis no damage is done by that pleasing supposition.

Table VI, taken from Unsöld,[18] shows the *wave length*, $\Delta\lambda''$, in angstroms from the line center, beyond which the statistical theory is applicable; $\Delta\lambda''=(\lambda^2\omega'')/(2\pi c)$ if λ is the normal frequency of the Balmer line. In all these instances the limit in question is close to the line center for proton broadening, so that Holtsmark's theory may practically be applied throughout the intensity distribution to the protons. The limit for electrons is so far out that they may not be treated statistically. But their impact widths are small, and presumably their entire effect is therefore negligible.

Our logic regarding the electrons contains a blind spot, which we hope the remainder of this article will in part remove. At this point we observe only the proportionality of $\omega_{\frac{1}{2}}$ with n in Eq. (4.36), a feature which

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

indicates that at higher densities the electrons do become important. Had we chosen $n=10^{16}$ cm^{-3} and $T=10\,000$°K in the example of H_α (see text following Eq. (4.36)) $\omega_{\frac{1}{2}}$ for electrons would have been greater than ω'' for protons.

Before concluding we take a glance at the *second-order* Stark effect. Here $\Delta\varphi$ is given by (4.26), and if this is to be 1, $\rho_c=(\pi\Omega_4/2v)^{\frac{1}{3}}$. The corresponding

$$\omega''=\Omega_4/\rho_c{}^4=(2v/\pi)^{\frac{1}{3}}\Omega_4{}^{\frac{1}{3}}.$$

A typical value of Ω_4 is 2×10^{-12} cgs units. Because of the dependence of ω'' on $v^{\frac{1}{3}}$ we encounter here a situation like that presented in Table VI: protons may be treated statistically fairly close to the center of the line, electrons only beyond a large, uninteresting distance from the center. But according to Eq. (4.30) the impact width $\omega_{\frac{1}{2}}=11.4\Omega_4{}^{\frac{1}{3}}v^{\frac{1}{3}}n$. It is proportional to $v^{\frac{1}{3}}$, not to v^{-1} as in the first-order Stark effect. Impact broadening therefore favors the electrons in the present instance.

A numerical example illustrates the situation. If $T=10\,000$°K, $\omega''=7\times10^{11}$ sec^{-1}. Assume again $n=10^{15}$ cm^{-3}. This makes $\Delta\omega_0$ in the Holtsmark theory [$\Delta\omega_0=\Omega_4(F_0{}^2/e^2)$, (compare Sec. III)] equal to 1.36×10^9 sec^{-1}. For the frequency ω'', where this theory becomes valid, the parameter $\omega''/\Delta\omega_0\approx500$, and at this value the function $W[(\omega''/\Delta\omega_0)^{\frac{1}{2}}]$ (see Fig. 2) is already quite small. Hence the Holtsmark theory has little to say about the case. The impact width for electrons, however, leads to $\omega_{\frac{1}{2}}=8\times10^{10}$ sec^{-1} which is the dominant contribution.

The formula for the electron contributed to the line width in the case of the quadratic Stark effect may be written more explicitly. For a hydrogen-like atom (if $Z=1$) or an ion of charge Z with principal quantum number g one finds, approximately,

$$\Omega_4\cong\frac{1}{2}\left(\frac{g}{Z}\right)^6\frac{a_0{}^3e^2}{\hbar}$$

$$=1.4\left(\frac{g}{Z}\right)^6\times10^{-17}.$$

Hence

$$\omega_{\frac{1}{2}}\approx6.6\times10^{-11}\left(\frac{g}{Z}\right)^4nv^{\frac{1}{3}}. \tag{4.37}$$

V. DISAPPEARANCE OF LINES WITH HIGH QUANTUM NUMBERS

Special consideration must be given to the Balmer lines involving high quantum numbers, and in general to lines emitted from highly excited states of atoms or ions within a plasma. The states near the continuum limit have a tendency to disappear for two reasons:

1. Broadening of the levels causes them to merge, which effect begins among the excited states which lie close together on the energy scale. We speak of this as the merging of states.

2. There is also an effective lowering of the continuum limit or, more precisely, an upward displacement of the higher levels because the electron in the atom does not move in a pure Coulomb field. The actual field in a plasma is subject to the Debye-Hückel cutoff. As a result, levels do not approach the energy zero with large quantum number g like $-1/g^2$, but there will be a finite distance between the energy of the level with the largest g (say g^*) and energy zero. This has been recognized in connection with the problem of calculating partition functions, where actually *both* effects, 1 and 2, are important.

Effect 1 has been treated by Inglis and Teller,[40] effect 2 most carefully by Unsöld[41] and by Ecker and Weizel.[42]

The best simple derivation of the formula for the merging of levels (differing only slightly from that of Inglis and Teller) and reliable comments on its precision are found in Unsöld, whose method is followed here. Our analysis will again be applied to the levels of hydrogen, for which $E_g=-e^2/2g^2a_0$ and therefore the undisturbed level separation at large g is

$$\Delta E=e^2/g^3a_0.$$

Here a_0 is the first Bohr radius. The splitting of the levels in the linear Stark effect for the extreme components is approximately

$$\tfrac{3}{2}g^2a_0eF.$$

The most probable value for the ionic field is $4.2\,e^2n^{\frac{2}{3}}$; Inglis and Teller chose the smaller value $3.7\,e^2n^{\frac{2}{3}}$. Merging will take place when the splitting equals $\approx\Delta E/2$. Hence the last discernible level will have the quantum number g^* which is defined by

$$\frac{1}{2}\frac{e^2}{a_0(g^*)^3}=\frac{3}{2}(g^*)^2a_0 3.7e^2n^{\frac{2}{3}}.$$

When logarithms are taken this becomes

$$\log_{10}n=23.3-7.5\log_{10}g^*. \tag{5.1}$$

This formula has often been used for the determination of the ion density n.

So far we have neglected the electrons. If only their statistical effect is considered (assuming that their impact width is small), Eq. (4.28), which represents the limit beyond which the statistical theory holds, tells what role is played by the electrons. For if $\hbar\omega''$ is much greater than the above $\Delta E/2$, they do not contribute to the ionic breadth when it equals $\Delta E/2$ and may therefore be neglected. But if

$$\hbar\omega''=(\hbar v^2)/(\pi^2\Omega_2)<\Delta E/2$$

[40] D. R. Inglis and E. Teller, Astrophys. J. **90**, 439 (1939). [For experimental verification see F. L. Mohler, Astrophys. J. **90**, 429 (1939).]

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

the electrons must be considered. For large g, the linear Stark constant [defined in Eq. (4.24)] has approximately the value $e^2a_0g^2/\hbar$. The value of v^2 for electrons is taken from

$$\tfrac{3}{2}kT=\tfrac{1}{2}mv^2.$$

Equation (5.1) is therefore subject to modification on account of the electrons when

$$\frac{\hbar}{\pi^2}\frac{3kT/m}{e^2a_0(g^*)^2/\hbar}<\frac{e^2}{2(g^*)^3a_0},$$

or

$$T<\frac{\pi^2me^4}{6\hbar^2kg^*}=\frac{5\times10^5\ ^\circ\mathrm{K}}{g^*}. \tag{5.2}$$

How to include the electrons when this condition holds —and it holds in many cases of physical interest—is, in principle, a difficult problem. The custom seems to be to accord them a role equal to that of the ions and to replace n in Eq. (5.1) by $2n$. Since this adds to $\log_{10}$ only the amount 0.3, and the number 23.3 on the right of (5.1) is hardly certain to within that amount, it is not reasonable to worry about the electrons in this connection.

The second effect, the drowning of the higher levels in the continuum, is treated by Unsöld in a very simple schematic way. The Coulomb potential in which an electron moves never reaches the value zero because another positive ion is situated at a finite distance from it. The electron may slide over into the trough of the other ion, even at a negative total energy, much in the manner in which high atomic levels are depleted by a strong electric field. If the depth of the transfer channel is made to correspond to the mean distance between atom and nearest ion, the highest permitted quantum g^* number is given by

$$(g^*)^2=(Z^{4/3}/6a_0)\left(\frac{4\pi}{3}n\right)^{-\frac{1}{3}}. \tag{5.3}$$

With this simple model, g^* does not depend on the temperature because it ignores the electrons.

The treatment by Ecker and Weizel involves a solution of the Schrödinger equation for an electron moving in a Debye field (or, if the reader is a nuclear physicist, a Yukawa field) of the form

$$V=-(Ze^2/r)\exp(-r/D)+\text{const.} \tag{5.4}$$

The Debye radius is

$$D=[kT/4\pi ne^2(1+Z)]^{\frac{1}{2}}\approx10^{-5}\text{ cm for }\begin{cases}T=10\,000^\circ\mathrm{K}\\ n=10^{16}\text{ cm}^{-3}\end{cases} \tag{5.5}$$

in terms of Z, the charge on an ion. The result obtained is simple and agrees with the plausible expectation that the largest orbit of the cited electron shall be smaller than D:

$$(g^*)^2a_0/Z\leqslant[kT/4\pi ne^2(1+Z)]^{\frac{1}{2}}. \tag{5.6}$$

For $Z=1$ this means

$$g^*\cong3\times10^4(n/T)^{-\frac{1}{4}} \tag{5.7}$$

if g^* is the greatest possible quantum number.

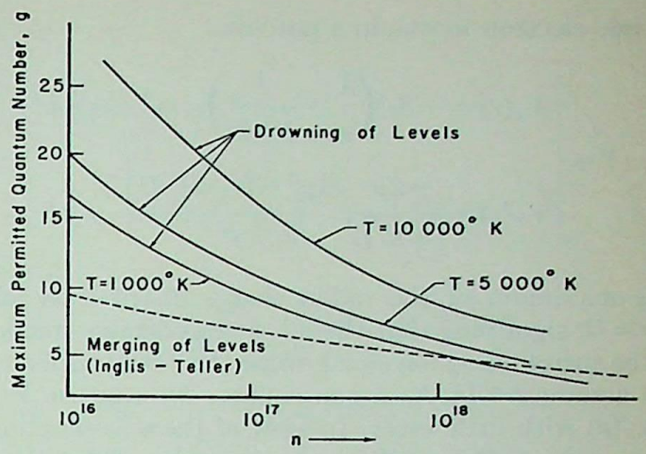

FIG. 7. Disappearance of levels in hydrogen.

Equation (5.7) is plotted for three different temperatures in Fig. 7. On the same figure we have drawn Eq. (5.1). Unsöld's Eq. (3) [Eq. (5.3) of this paper], which is not included, specifies values of g^* which fall slightly below the dotted curve. For high temperatures and low densities the merging of the levels according to Inglis and Teller determines the highest permitted quantum number, whereas in the other extreme the drowning of levels in the continuum is the decisive effect.

The latter has been studied in another way, employing straightforward perturbation theory, in a recent, unpublished calculation.[43] This led to the result

$$(g^*)^2=0.86D, \tag{5.8}$$

which reduces the limiting quantum number slightly below the value given by Eq. (5.6).

Perturbation theory is not strictly applicable since for the last level the perturbation energy is of the same order of magnitude as the unperturbed energy. For this reason we present here the essentials of a parallel variational calculation¶ in which an exponential screening factor $\mathfrak{Z}$ is employed as variable parameter in connection with hydrogen state functions of principal quantum number g. It may be asked why this method should be expected to work, since variation of $\mathfrak{Z}$ might push a hydrogen level initially assigned to the quantum number g down to energies corresponding to lower values of g. The answer is that variation of $\mathfrak{Z}$ does not alter the number of nodes, which is controlled by g, and that therefore a crossing from one g to another cannot occur.

In view of the Debye-Hückel shielding effect the

atomic electron moves in a potential

$$V=\begin{cases} V_i(r)=-Ze^2\left(\dfrac{1}{r}-\dfrac{1}{b+D}\right) & r\leqslant b \\ V_0(r)=\dfrac{-Ze^2}{1+b/D}\dfrac{\exp[-(r-b)/D]}{r} & r\geqslant b. \end{cases}$$

The maximum of the radial charge distribution falls at $r=D$, signifying that there is a considerable fraction of the surrounding ion cloud inside the "Debye sphere." We assume $b\ll D$. As a consequence we can use $V(r)=V_0(r)$ with little error. In view of these assumptions concerning b/D and $V(r)$ we write the Schrödinger equation for the optical electron in the form

$$H\psi=-(\hbar^2/2m)\nabla^2\psi-Ze^2(e^{-r/D}/r)\psi=E\psi. \quad (5.9)$$

Choosing functions ψ_g which satisfy the Schrödinger equation for the hydrogen atom of nuclear charge $\mathfrak{Z}$ for quantum number g we compute the integral

$$E_g=\int\psi_g^*H\psi_g d\tau$$

and requires $\partial E_g/\partial\mathfrak{Z}=0$. ($\mathfrak{Z}$ is the variable charge number, Z the fixed ion charge number.) Since

$$-(\hbar^2/2m)\nabla^2\psi_g=[E_g^0+(\mathfrak{Z}e^2/r)]\psi_g$$

and $E_g^0=\mathfrak{Z}^2E_H/g^2$ we have

$$E_g=\frac{\mathfrak{Z}^2}{g^2}E_H-2E_H\int\psi_g^*\left(\frac{\mathfrak{Z}-Ze^{-r/D}}{r/a_0}\right)\psi_g d\tau, \quad (5.10)$$

where $E_H=-e^2/2a_0=-13.53$ ev. Expanding $e^{-r/D}$ in a power series yields

$$\int\left(\frac{\mathfrak{Z}-Ze^{-r/D}}{r/a_0}\right)|\psi_g|^2d\tau$$

$$=(\mathfrak{Z}-Z)\frac{\mathfrak{Z}}{g^2}+\kappa\sum_{m=0}^{\infty}\frac{(-1)^m}{m!}\left\langle\left(\frac{\kappa r}{a_0}\right)^m\right\rangle \quad (5.11)$$

$$\kappa\equiv a_0/D$$

$$\langle(\kappa r/a_0)^m\rangle\equiv\int|\psi_g|^2(\kappa r/a_0)^m d\tau.$$

The values of $\langle(\kappa r/a_0)^m\rangle$ are given by Condon and Shortley.[44] For S states,

$$E_g=E_H\{[(-\mathfrak{Z}^2+2\mathfrak{Z}Z)/g^2]-2Z\kappa S(\beta)\}$$

$$\beta\equiv\kappa g^2/\mathfrak{Z} \quad (5.12)$$

$$S(\beta)\approx\frac{3}{4}\beta-\frac{5}{12}\beta^2+\frac{35\beta^3}{192}-\frac{63}{960}\beta^4+\cdots.$$

The variational constraint, $\partial E_g/\partial\mathfrak{Z}=0$, leads to

$$\mathfrak{Z}-Z+Z\beta^2\partial S(\beta)/\partial\beta=0. \quad (5.13)$$

The principal quantum number of the last level (g^*) is given by the equation $E_g^*=0$. This gives

$$2Z-\mathfrak{Z}-2Z\beta S(\beta)=0. \quad (5.14)$$

Elimination of Z through (5.10) and (5.11) gives an equation involving only β,

$$1-2\beta S(\beta)+\beta^2(\partial S(\beta)/\partial\beta)=0, \quad (5.15)$$

which has $\beta=1.27$ as a root. Thus

$$\beta=[(g^*)^2a_0]/\mathfrak{Z}D=1.27.$$

Reintroducing the true ion charge number, Z, we find

$$(g^*)^2=0.804(ZD/a_0), \quad (5.16)$$

which differs very little from the perturbation result, Eq. (5.8).

We might also inquire how the departure from the hydrogen level structure affects the merging of lines. For this purpose we can apply perturbation theory to all but the last few levels, using hydrogen state functions with $l=l_{\max}=g-1$, since it is for these substates that the Stark splitting is extreme. These functions prove to be very simple and it is not necessary to resort to to the expansion in $\langle(\kappa r/a_0)^m\rangle$. The calculation shows that the first order correction to the hydrogen levels is independent of g and the second order term is so small as to change g^* as given by (5.1) less than one percent.

There are other corrections. Edmonds[45] has calculated, for instance, how the effective mean distance between ions is altered by the Debye shielding effect. For present concerns, relating to the disappearance of the lines, this consideration is of secondary importance.

VI. BROADENING OF DEGENERATE LEVELS

Recently, Kolb[30] has treated the broadening of hydrogen lines in a manner which is more careful than previous treatments in its consideration of the difficulties of degeneracy and which furthermore attempts to include both ions and electrons in their simultaneous actions upon the radiating atom.

We present a synopsis of Kolb's calculations after first discussing certain fundamental ideas of the method and also its principal results. The details given here differ from Kolb's in this respect: our functions [see Eq. (6.8)] are solutions of the *unperturbed* Schrödinger equation, whereas Kolb's are said to be adiabatic functions. The latter choice leads to difficulties which our treatment avoids. Let us recall the meaning of "adiabatic" in the first and second sense discussed in Sec. IIB. The collisions a hydrogen atom can experience with an *electron* can be divided roughly into two extreme groups, namely, (1) *close collisions* that turn the atom around (adiabatic in the second sense) and (2) *distant*

[44] E. U. Condon and G. H. Shortley, *Theory of Atomic Spectra* (Cambridge University Press, London, 1957).

[45] F. N. Edmonds, Astrophys. J. **123**, 95 (1956).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

or weak collisions that do not turn the atom (adiabatic in the first sense). We assume that under certain specifiable conditions the weak collisions are mainly responsible for the broadening, so that the analysis can be restricted to collisions of type 2. One can now speak of adiabatic and diabatic in the following sense; an adiabatic collision leaves the atom in, or returns it to, its original state (permitting the energy to change while the collision is in process), a diabatic collision causes transitions to other final states.

Principal conclusions are (*a*) the electron effects are an important factor in the broadening of the hydrogen lines; (*b*) the adiabatic and diabatic electron effects are of comparable magnitude.

A. Mathematical Foundations

The energy radiated and absorbed per second due to transitions between states m and the state n (providing $E_n^0 > E_m^0$) is given by[10]

$$I_n(\omega) \propto \left\langle \sum_m [\rho_m(0)-\rho_n(0)] \times \lim_{T\to\infty} \frac{1}{T}\left|\int_0^T dt \mu_{nm}{}^c(t) e^{-i\omega t}\right|^2 \right\rangle_{\text{Av}}. \quad (6.1)$$

Here $\rho_m(0)$ and $\rho_n(0)$ are Boltzmann factors for the states having unperturbed energies E_m^0 and E_n^0; $\mu_{nm}{}^c(t)$ is the dipole matrix element defined by

$$\mu_{nm}{}^c(t) \equiv \int \chi_n{}^*(t) \mu \chi_n(t) d\tau, \quad (6.2)$$

where μ is the dipole moment operator. The functions χ_n satisfy

$$i\hbar \dot{\chi}_n(t) = [H_0 + H_1(t)]\chi_n(t), \quad (6.3)$$

provided H_0 is the Hamiltonian for the atom and $H_1(t)$ the interaction between the atom and the perturbing ions and/or electrons. Equation (6.1) is valid if $E_n^0 > E_m^0$. For states (m,n) such that $E_m^0 > E_n^0$, $e^{-i\omega t}$ must be replaced by $e^{i\omega t}$.

Equation (6.1) was derived by calculating the increase in population of the nth state due to the action of the light. Since $E_n^0 > E_m^0$ the first term, $\rho_m(0)\left|\int \mu_{nm}{}^c e^{-i\omega t}\right|^2$ is seen to represent absorption, i.e., transitions from m to n; the second term $\rho_n(0) \times \left|\int \mu_{nm}{}^c(t) e^{-i\omega t}\right|^2$ represents induced emission (electromagnetic field was not quantized) i.e., transitions from $n \to m$. Therefore $I_n(\omega)$ is the net absorption. The average in Eq. (6.1) is to be carried out over different collisions.

Suppose that the states n and m are degenerate in the absence of perturbations. For the level n, we call the collection of states f and label the individual states ϵ_f; for the states m we use i and α_i. Occasionally, we omit the subscripts on ϵ and α. Equation (6.1) thus becomes

$$I_{\epsilon f}(\omega) \propto \left\langle \sum_{i,\alpha_i} [\rho_{\alpha i}(0) - \rho_{\epsilon f}(0)] \frac{1}{2\pi} \times \lim_{T\to\infty} \frac{1}{T}\left|\int_0^T dt \mu_{\epsilon f \alpha i}{}^c(t) e^{-i\omega t}\right|^2 \right\rangle_{\text{Av}}. \quad (6.4)$$

Defining

$$I_{\epsilon f \alpha i} \equiv \frac{1}{2\pi} \lim_{T\to\infty} \left|\int_0^T dt \mu_{\epsilon f \alpha i}{}^c(t) e^{-i\omega t}\right|^2_{\text{Av}}, \quad (6.5)$$

we now sum over all degenerate f states, obtaining

$$\sum_{\epsilon f} I_{\epsilon f}(\omega) \propto \sum_i \{\sum_{\epsilon f \alpha i} [\rho_{\alpha i}(0) - \rho_{\epsilon f}(0)] I_{\epsilon f \alpha i}\}. \quad (6.6)$$

The term in brackets represents transitions between the groups of i and f states. The first term represents absorption, and we define the absorption coefficient I_{if} as

$$I_{if} \equiv \sum_{\epsilon f \alpha i} [\rho_{\alpha i}(0) I_{\epsilon f \alpha i}]. \quad (6.7)$$

In keeping with the weak-collision hypothesis, a solution of Eq. (6.3) is written as

$$\chi_\alpha(t) = \sum_{\alpha'} C_{\alpha'\alpha}(t) \varphi_{\alpha'}{}^0 \times \exp\left[-\frac{i}{\hbar}\int_0^t \{E_{\alpha'}{}^0 + (H_1)_{\alpha'\alpha'}\} dt'\right], \quad (6.8)$$

where $\varphi_{\alpha'}{}^0$ and $E_{\alpha'}{}^0$ are eigenfunctions and energies of H_0, and $(H_1)_{\alpha'\alpha'}$ is given by

$$(H_1)_{\alpha'\alpha'} \equiv \int \varphi_{\alpha'}{}^{0*} H_1 \varphi_{\alpha'}{}^0 d\tau.$$

When Eq. (6.8) is substituted into Eq. (6.3), we obtain

$$\dot{C}_{\alpha''\alpha}(t) = -\frac{i}{\hbar} \sum_{\alpha', \alpha' \neq \alpha''}{}' C_{\alpha'\alpha}(t)(H_1)_{\alpha''\alpha'} \times \exp[-i\{\omega_{\alpha'\alpha''}{}^0 t + P_{\alpha'\alpha''}\}] \quad (6.9)$$

upon using the following abbreviations:

$$\omega_{\alpha'\alpha''}{}^0 = \omega_{\alpha'}{}^0 - \omega_{\alpha''}{}^0; \quad \omega_{\alpha'}{}^0 = E_{\alpha'}{}^0/\hbar$$
$$P_{\alpha'\alpha''} = P_{\alpha'} - P_{\alpha''}; \quad P_{\alpha'} = \frac{1}{\hbar}\int_0^t (H_1)_{\alpha'\alpha'} dt. \quad (6.10)$$

We take as an initial condition that only the state α is present at $t=0$. With weak collisions only the initial state is appreciable at a later time, i.e.,

$$|C_{\alpha\alpha}(0)| \simeq |C_{\alpha\alpha}(t)| \simeq 1; \quad |C_{\alpha'\alpha}(t)| \ll 1 \quad \text{for } \alpha' \neq \alpha.$$

Hence, Eq. (6.9) can be written

$$C_{\alpha''\alpha}(t) = -\frac{i}{\hbar}\int_0^t (H_1)_{\alpha''\alpha} \times \exp[-i(\omega_{\alpha\alpha''}{}^0 t' + P_{\alpha\alpha''})] dt'. \quad (6.11)$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

In this approximation Eq. (6.8) takes the form

$$\chi_\alpha(t)=\varphi_\alpha{}^0\exp[-i(\omega_\alpha{}^0t+P_\alpha)]+\sum_{\alpha',\alpha'\neq\alpha}{}'C_{\alpha'\alpha}(t)\varphi_{\alpha'}{}^0\exp[-i(\omega_{\alpha'}{}^0t+P_{\alpha'})]. \quad (6.12)$$

When Eq. (6.12) and a similar one for $\chi_\epsilon(t)$ are used to calculate $\mu_{\epsilon\alpha}{}^c(t)$ the result is

$$\mu_{\epsilon\alpha}{}^c(t)=\mu_{\epsilon\alpha}{}^0\exp[i(\omega_{\epsilon\alpha}{}^0t+P_{\epsilon\alpha})]+\sum_{\epsilon'}{}'\mu_{\epsilon'\alpha}{}^0C_{\epsilon'\epsilon}{}^*(t)\exp[i(\omega_{\epsilon'\alpha}{}^0t+P_{\epsilon'\alpha})]+\sum_{\alpha'}{}'\mu_{\epsilon\alpha'}{}^0C_{\alpha'\alpha}(t)\exp[i(\omega_{\epsilon\alpha'}{}^0t+P_{\epsilon\alpha'})], \quad (6.13)$$

where $\mu_{\epsilon\alpha}{}^0=\int\varphi_\epsilon{}^0\mu\varphi_\alpha{}^0d\tau$ and terms of the order C^2 have been neglected. Equation (6.13) together with Eq. (6.5) determines the absorption coefficient. We are now ready to consider two special cases of interest.

B. Adiabatic Approximation

The off-diagonal elements are neglected in this approximation, only the first term in Eq. (6.13) being used. This simplifies the theory so that it can easily be applied to any two states (α,ϵ). The resulting approximation is general enough to include both electrons and ions and serves as a guide for the more complicated theory below, which includes the off-diagonal elements. On substituting Eq. (6.13) into Eq. (6.5) we have, neglecting the off-diagonal elements,

$$I_{\epsilon\alpha}=\frac{|\mu_{\epsilon\alpha}{}^0|^2}{2\pi}\lim_{T\to\infty}\frac{1}{T}\times\left|\int_0^T dt\exp[-i(\Delta\omega_{\epsilon\alpha}{}^0-P_{\epsilon\alpha})]\right|_{\text{Av}}^2, \quad (6.14)$$

where $\Delta\omega_{\epsilon\alpha}{}^0=\omega-\omega_{\epsilon\alpha}{}^0$. Equation (6.14) can be put into the usual correlation form (see Sec. IV)

$$I_{\epsilon\alpha}=\frac{|\mu_{\epsilon\alpha}{}^0|^2}{\pi}\operatorname{Re}\int_0^\infty d\tau\times\exp(i\Delta\omega_{\epsilon\alpha}{}^0\tau)\langle\exp[-iP_{\epsilon\alpha}(\tau)]\rangle_{\text{Av}}. \quad (6.15)$$

The term $P_{\epsilon\alpha}$ contains interactions involving the *ions* and *electrons*. We therefore write

$$P_{\epsilon\alpha}=P_{\epsilon\alpha}{}^i+P_{\epsilon\alpha}{}^e$$

and assume that the ion and electron averages can be calculated separately. The ions are to be treated in the statistical approximation and therefore permit the interaction to be written as time independent. With this understanding

$$P_{\epsilon\alpha}{}^i=(\Omega_2{}^{\epsilon\alpha}/e)F\tau, \quad (6.16)$$

where F is the instantaneous ion field, e the charge on the ion, and $\Omega_2{}^{\epsilon\alpha}$ are terms connected with the Stark shift of the states (ϵ,α).

The electrons are treated by the phase shift (impact) approximation. Consider

$$\langle\exp[-iP_{\epsilon\alpha}{}^e(\tau)]\rangle_{\text{Av}}=\left\langle\exp\left[-\frac{i}{\hbar}\int_0^\tau\{(H_1{}^e)_{\epsilon\epsilon}-(H_1{}^e)_{\alpha\alpha}\}dt\right]\right\rangle_{\text{Av}}, \quad (6.17)$$

where $H_1{}^e$ is the interaction of the atom with all the electrons in the plasma. In the evaluation of (6.17) we employ Eq. (4.15), following Kolb. This does not require that the impacts are sudden or isolated. It is applicable to scalarly additive perturbations, that is perturbations for which

$$H_1{}^e=\sum_p H_1{}^p. \quad (6.18)$$

The sum here is taken over all the electrons contained in some effective volume. The phase change during the time interval τ produced by a single electron depends on the velocity v, the time of closest approach t_i and on some other parameter l. Since

$$H_1{}^e=\sum_{i,v,l}\mathfrak{N}(i,v,l)H_1(i,v,l), \quad (6.19)$$

where $\mathfrak{N}(i,v,l)$ is the number of electrons characterized by (i,v,l) in the effective volume, $P_{\epsilon\alpha}{}^e$ becomes

$$P_{\epsilon\alpha}{}^e=\hbar^{-1}\sum_{i,v,l}\mathfrak{N}(i,v,l)\int_0^\tau[(H_1(i,v,l))_{\epsilon\epsilon}-(H_1(i,v,l))_{\alpha\alpha}]dt, \quad (6.20)$$

$$P_{\epsilon\alpha}{}^e=\sum_{i,v,l}\mathfrak{N}(i,v,l)\varphi_{i,v,l}(\tau),$$

$$\varphi_{i,v,l}(\tau)\equiv\hbar^{-1}\int_0^\tau[(H_1(i,v,l))_{\epsilon\epsilon}-(H_1(i,v,l))_{\alpha\alpha}]dt. \quad (6.21)$$

Using the results developed in Sec. IV we find

$$\langle\exp[-iP_{\epsilon\alpha}{}^e(\tau)]\rangle_{\text{Av}}=\exp\left[\pi R^2\int dvvn_e(v)[\alpha_v(1)-1]\tau\right], \quad (6.22)$$

$n_e(v)$ being the number of electrons with velocity v per cubic centimeter. The effective volume of the system is assumed to be a sphere of radius R and

$$\alpha_v(1)=\int dlW(l)e^{-i\varphi_{v,l}}. \quad (6.23)$$

Here $\varphi_{v,l}$ is the total phase change produced by an electron of velocity v and parameter l which has its time of closest approach in the time interval τ. Now suppose

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

that the parameter l labels two impact variables ρ and σ, ρ being the distance of closest approach and σ some other characteristic variable defined later. The probability distribution functions for these are

$$W(\rho)d\rho=2\pi\rho d\rho/\pi R^2;\quad W(\sigma)d\sigma=d\sigma/\Sigma, \tag{6.24}$$

where Σ is the total cross section for σ. Then

$$\alpha_v=\int\int W(\rho)W(\sigma)\exp(-i\varphi_{v,\rho,\sigma})d\rho d\sigma, \tag{6.25}$$

and hence

$$\langle\exp[-iP_{\epsilon\alpha}{}^c(\tau)]\rangle_{\text{Av}}=\exp\Big[2\pi\int vn_c(v)dv\int\rho d\rho \times\int(d\sigma/\Sigma)(\exp(-i\varphi_{v,\rho,\sigma})-1)\tau\Big]. \tag{6.26}$$

Finally, we replace $n_e(v)$ by $n_eW(v)$ understanding by n_e the number of electrons per cubic centimeter and by $W(v)$ the Boltzmann distribution function; we write $\varphi_{\epsilon\alpha}(\infty)$ for $\varphi_{v,\rho,\sigma}$, letting (ϵ,α) indicate the two states involved and omitting the (ρ,v,σ) dependence; the symbol (∞) means that the phase change produced by one particle is completed. One then finds

$$\langle\exp[-iP_{\epsilon\alpha}{}^c(\tau)]\rangle_{\text{Av}}=\exp[-(u_1{}^{\epsilon\alpha}+iu_2{}^{\epsilon\alpha})\tau], \tag{6.27}$$

where

$$\begin{pmatrix}-u_1{}^{\epsilon\alpha}\\-u_2{}^{\epsilon\alpha}\end{pmatrix}\equiv\begin{pmatrix}\text{Re}\\\text{Im}\end{pmatrix}2\pi n_e\int_0^\infty vW(v)dv\int_0^R\rho d\rho \times\int_0^\Sigma\frac{d\sigma}{\Sigma}\{\exp[-i\varphi_{\epsilon\alpha}(\infty)]-1\}. \tag{6.28}$$

Substitution of Eqs. (6.27), (6.16) and (6.15′) into (6.15) results in

$$I_{\epsilon\alpha}=\frac{|\mu_{\epsilon\alpha}{}^0|^2}{\pi}\text{Re}\Big\langle\int_0^\infty\exp\Big[i\Big(\Delta\omega_{\epsilon\alpha}{}^0-u_2{}^{\epsilon\alpha}-\frac{\Omega_2{}^{\epsilon\alpha}}{e}F\Big)\tau-u_1{}^{\epsilon\alpha}\tau\Big]d\tau\Big\rangle_{\text{Av(ions)}} \tag{6.29}$$

$$=\frac{|\mu_{\epsilon\alpha}{}^0|^2}{\pi}\Big\langle\frac{u_1{}^{\epsilon\alpha}}{(\Delta\omega_{\epsilon\alpha}{}^0-\Omega_2{}^{\epsilon\alpha}F/e-u_2{}^{\epsilon\alpha})^2+(u_1{}^{\epsilon\alpha})^2}\Big\rangle_{\text{Av(ions)}}. \tag{6.30}$$

We shall return to this equation. At present we wish to develop a formula including the off-diagonal elements, which are taken to be zero in the treatment above.

C. Diabatic Effects in Degenerate Systems

The ions are neglected, so that the atomic states are degenerate, in this approximation. The resulting formulas are useful because they indicate the magnitude of the diabatic effects as far as electron broadening is concerned. In particular, the results of the present development, when applied to the Lyman-α line, and then compared with the adiabatic approximation (when ions are neglected), clearly demonstrate that the adiabatic theory can contain large errors. The method of this section can be generalized to nearly degenerate systems, degeneracy being removed by inclusion of the ions, but the results are difficult to handle and have not been carefully studied.

In the weak collision approximation we assume that $|P_{\epsilon\alpha}{}^c|\ll1$ so that Eq. (6.13) can be written in the form

$$\mu_{\epsilon\alpha}{}^c(t)=\mu_{\epsilon\alpha}{}^0\exp(i\omega_{\epsilon\alpha}{}^0t)\Big\{1+iP_{\epsilon\alpha}{}^e+\sum_{\epsilon'}{}'\frac{\mu_{\epsilon'\alpha}{}^0}{\mu_{\epsilon\alpha}{}^0}C_{\epsilon'\epsilon}{}^*+\sum_{\alpha'}{}'\frac{\mu_{\epsilon\alpha'}{}^0}{\mu_{\epsilon\alpha}{}^0}C_{\alpha'\alpha}\Big\}. \tag{6.31}$$

Since $|P_{\epsilon\alpha}{}^e|\ll1$ and the sum are small, we can write

$$\mu_{\epsilon\alpha}{}^c(t)=\mu_{\epsilon\alpha}{}^0\exp(i\omega_{\epsilon\alpha}{}^0t)\exp(i\Phi_{\epsilon\alpha}), \tag{6.32}$$

with

$$\Phi_{\epsilon\alpha}\equiv P_{\epsilon\alpha}{}^e-i\Big[\sum_{\epsilon'}{}'\frac{\mu_{\epsilon'\alpha}{}^0}{\mu_{\epsilon\alpha}{}^0}C_{\epsilon'\epsilon}{}^*+\sum_{\alpha'}{}'\frac{\mu_{\epsilon\alpha'}{}^0}{\mu_{\epsilon\alpha}{}^0}C_{\alpha'\alpha}\Big]. \tag{6.33}$$

When this is substituted in Eq. (6.5) there results

$$I_{\epsilon\alpha}=\frac{|\mu_{\epsilon\alpha}{}^0|^2}{2\pi}\lim_{T\to\infty}\frac{1}{T}\times\Big|\int_0^T dt\exp(-i\Delta\omega_{\epsilon\alpha}{}^0t)\exp(i\Phi_{\epsilon\alpha})\Big|^2_{\text{Av}}. \tag{6.34}$$

In the weak collision approximation, then, Eq. (6.11) for $C_{\alpha'\alpha}$ becomes

$$C_{\alpha'\alpha}=-\frac{i}{\hbar}\int_0^t(H_1{}^e)_{\alpha'\alpha}\exp(-iP_{\alpha\alpha''}{}^e)dt'\cong-\frac{i}{\hbar}\int_0^t(H_1{}^e)_{\alpha'\alpha}dt'. \tag{6.35}$$

If one assumes, as in the adiabatic case, scalarly additive perturbations [see Eq. (6.19)] then, in view of Eq. (6.35),

$$\Phi_{\epsilon\alpha}\equiv\sum_{i,v,l}\mathfrak{N}(i,v,l)\kappa_{i,v,l},$$

$$\kappa_{i,v,l}(t)=\hbar^{-1}\int_0^t dt'\Big\{\sum_{\epsilon'}\frac{\mu_{\epsilon'\alpha}{}^0}{\mu_{\epsilon\alpha}{}^0}(H_1(i,v,l))_{\epsilon'\epsilon}-\sum_{\alpha'}\frac{\mu_{\epsilon\alpha'}{}^0}{\mu_{\epsilon\alpha}{}^0}(H_1(i,v,l))_{\alpha'\alpha}\Big\}. \tag{6.36}$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Equation (6.34) is formally the same as Eq. (6.14). On the other hand, Eqs. (6.36) are similar to Eq. (6.21). We can therefore use the results of the adiabatic treatment when the proper replacements are made. Our results in that case do not contain the effects of the ions. Instead of Eqs. (6.35) we thus find

$$I_{\epsilon\alpha}=\frac{|\mu_{\epsilon\alpha}{}^0|^2}{\pi}\frac{u_1{}^{\epsilon\alpha}}{(\Delta\omega_{\epsilon\alpha}{}^0-u_2{}^{\epsilon\alpha})^2+(u_1{}^{\epsilon\alpha})^2}, \tag{6.37}$$

$$\binom{-u_1{}^{\epsilon\alpha}}{-u_2{}^{\epsilon\alpha}}\equiv\binom{\mathrm{Re}}{\mathrm{Im}}2\pi n_e\int_0^\infty vW(v)dv\int_0^R\rho d\rho \times\int_0^\Sigma\frac{d\sigma}{\Sigma}[\exp[-i\kappa_{\epsilon\alpha}(\infty)]-1], \tag{6.38}$$

subject again to the use of the phase shift approximation, which accounts for our writing $\kappa_{\epsilon\alpha}(\infty)$ in place of the $\kappa_{i,v,l}$ appearing in Eq. (6.36). The condition $|P_{\epsilon\alpha}|\ll 1$ is violated after a long enough time, and Eq. (6.37) is valid *only* in the wings. In applications, since $|\kappa_{\epsilon\alpha}(\infty)|\ll 1$, we retain only the first two nonvanishing terms in the expansion of $e^{-i\kappa_{\epsilon\alpha}}$. In the wings (6.37) becomes

$$I_{\epsilon\alpha}=u_1{}^{\epsilon\alpha}/[\pi(\Delta\omega_{\epsilon\alpha}{}^0)^2], \tag{6.39}$$

and

$$u_1{}^{\epsilon\alpha}=2\pi n_e\int_0^\infty W(v)vdv\int_0^R\rho d\rho\int_0^\Sigma\frac{d\sigma}{\Sigma}\frac{1}{2\hbar^2} \times\left[\int_{-\infty}^{+\infty}dl\{\sum_{\epsilon'}\mu_{\epsilon'\alpha}{}^0(H_1)_{\epsilon'\epsilon}-\sum_{\alpha'}\mu_{\epsilon\alpha'}{}^0(H_1)_{\alpha'\alpha}\}\right]^2 \tag{6.40}$$

with the understanding that H_1 refers to one electron with specified ρ, v, σ. We shall now apply the formulas of this and the previous section to line broadening by electrons.

D. Electron Broadening in the Adiabatic Approximation

In this section, the adiabatic theory of part B is applied to broadening by electrons only. Here "adiabatic" means that we retain only the first term in Eq. (6.13). This calculation, although restrictive, is useful in estimating (*a*) the error introduced by the electron collisions that fail to satisfy the conditions for an impact theory; (*b*) the effects of close collisions. The value of $\varphi_{i,v,l}(\infty)$, defined by Eq. (6.21) except that the integration is now extended over all time, is (with suitable changes of indexes)

$$\varphi_{\epsilon\alpha}(\infty)=(2\Omega_2{}^{\epsilon\alpha}/\rho v)\cos\theta, \tag{6.41}$$

where

$$\Omega_2{}^{\epsilon\alpha}=\tfrac{3}{2}(e^2a_0/\hbar)\{[n^\epsilon(k_1{}^\epsilon-k_2{}^\epsilon)]-[n^\alpha(k_1{}^\alpha-k_2{}^\alpha)]\}. \tag{6.42}$$

In this expression n^ϵ, $k_1{}^\epsilon$, $k_2{}^\epsilon$ are quantum numbers, in parabolic coordinates, of the state ϵ and θ of Eq. (6.41) is the polar angle describing the location of the position vector of closest approach ϱ in some fixed coordinate system; θ is the σ parameter mentioned earlier. Equation (6.28) then gives

$$u_2{}^{\epsilon\alpha}=0$$

$$u_1{}^{\epsilon\alpha}=2\pi n_e\int_0^\infty vW(v)dv\int_0^{\rho_m}\rho d\rho \times\left[1-\frac{\sin(2\Omega_2{}^{\epsilon\alpha}/\rho v)}{(2\Omega_2{}^{\epsilon\alpha}/\rho v)}\right], \tag{6.43}$$

where ρ_m is a cutoff distance and is chosen as the Debye length of Sec. II. With the definition

$$\delta_m{}^{\epsilon\alpha}\equiv 2\Omega_2{}^{\epsilon\alpha}/\rho_m v,$$

Eq. (6.43) then becomes

$$u_1{}^{\epsilon\alpha}=8\pi n_e(\Omega_2{}^{\epsilon\alpha})^2\int_0^\infty\frac{W(v)}{v}dv\left[0.2094-\tfrac{1}{6}\ln\delta_m{}^{\epsilon\alpha}+\frac{(\delta_m{}^{\epsilon\alpha})^2}{240}+\cdots\right]. \tag{6.44}$$

The velocity average is approximated by replacing the v^{-1} outside of [ ] by its Boltzmann average $\langle v^{-1}\rangle=(4/\pi)(1/\langle v\rangle)$ in Eq. (6.44). We then obtain, finally,

$$u_1{}^{\epsilon\alpha}=(32/\langle v\rangle)n_e(\Omega_2{}^{\epsilon\alpha})^2G(\delta_m{}^{\epsilon\alpha}),\qquad G(x)\equiv(0.2094-\tfrac{1}{6}\ln x+x^2/240\cdots) \tag{6.45}$$

and $\delta_m{}^{\epsilon\alpha}$ is redefined as

$$\delta_m{}^{\epsilon\alpha}=2\Omega_2{}^{\epsilon\alpha}/(\rho_m\langle v\rangle). \tag{6.45a}$$

Let us now return to the two points mentioned at the beginning of this section.

(*a*) According to the criterion for the validity of the phase shift approximation (Sec. IV B), the velocity must satisfy

$$v\gg(\Omega_2{}^{\epsilon\alpha}\Delta\omega)^{\frac{1}{2}}\equiv v_c$$

for the present results to be acceptable. One can estimate the error resulting from extending the velocity integration from zero to infinity by computing the contribution to $\langle v^{-1}\rangle$ from velocities less than v_c. One obtains

$$\frac{\langle v^{-1}\rangle-\langle v^{-1}\rangle_{v<v_c}}{\langle v^{-1}\rangle}=1-\frac{m(\Delta\omega)\Omega_2{}^{\epsilon\alpha}}{4kT}+\cdots. \tag{6.46}$$

For 10 000°K, and for H_β (4861 A) at 30 A from the line center, 90% of $\langle v^{-1}\rangle$ comes from velocities which satisfy the phase shift approximation.

(*b*) It is reasonable to treat close collisions by the Lorentz formula [Eq. (1.2)]. This leads to an $I_{\alpha\epsilon}$ which is similar to Eq. (6.30) (the ion contribution is again neglected) except that $u_1{}^{\epsilon\alpha}$ is replaced by τ_c^{-1}, τ_c being the mean time between collisions. Hence the suggestion that $u_1{}^{\epsilon\alpha}$ can be represented, in an approxi-

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

mate way, as a sum of two terms

$$u_1^{\epsilon\alpha}=(u_1^{\epsilon\alpha})_{\rho>\rho_c}+(u_1^{\epsilon\alpha})_{\rho<\rho_c}, \tag{6.47}$$

where $(u_1^{\epsilon\alpha})_{\rho>\rho_c}$ is the contribution from the weak collision theory, computed according to Eq. (6.32) except that ρ is now allowed to vary from ρ_c to ρ_m. Here ρ_c is the value of ρ which roughly divides the impacts into strong (close) and weak ones, chosen so that

$$\delta_c^{\epsilon\alpha}\equiv 2\Omega_2^{\epsilon\alpha}/(\rho_c\langle v\rangle)=1 \tag{6.48}$$

or

$$\rho_c=2\Omega_2^{\epsilon\alpha}/\langle v\rangle. \tag{6.49}$$

In view of Eq. (6.41), $\delta_c^{\epsilon\alpha}$ is the maximum phase shift that an electron with velocity $\langle v\rangle$ and distance of closest approach ρ_c can produce. But

$$(u_1^{\epsilon\alpha})_{\rho<\rho_c}=\tau_c^{-1}\equiv\pi\rho_c^2 n_e\langle v\rangle=(4\pi/\langle v\rangle)(\Omega_2^{\epsilon\alpha})^2 n_e \tag{6.50}$$

and

$$\begin{aligned}(u_1^{\epsilon\alpha})_{\rho>\rho_c}&=(32n_e/\langle v\rangle)(\Omega_2^{\epsilon\alpha})^2[G(\delta_m^{\epsilon\alpha})-G(1)]\\&=(32n_e/\langle v\rangle)(\Omega_2^{\epsilon\alpha})^2\\&\quad\times[-0.0042-\tfrac{1}{6}\ln\delta_m^{\epsilon\alpha}+\cdots].\end{aligned} \tag{6.51}$$

Comparing (6.50) and (6.51), the contribution due to close collisions can be neglected if

$$\frac{(u_1^{\epsilon\alpha})_{\rho<\rho_c}}{(u_1^{\epsilon\alpha})_{\rho>\rho_c}}\simeq\frac{3}{4}\frac{1}{\ln(1/\delta_m^{\epsilon\alpha})}\ll 1, \tag{6.52}$$

that is, if

$$\ln(1/\delta_m^{\epsilon\alpha})\gg 1.5. \tag{6.53}$$

When (6.53) is satisfied, the quantities expressed by Eqs. (6.51) and (6.45) are approximately equal.

Example: If $n_e=10^{15}$, $T=20\,000$°K and $\Omega_2^{\epsilon\alpha}/A=1.1$ (where $A\equiv\frac{3}{2}e^2a_0/\hbar$) then $\ln(1/\delta_m^{\epsilon\alpha})\approx 6$.

E. Broadening of the Lyman-α Line by Electrons

In this section we treat the broadening of the Lyman lines by electrons only. Both adiabatic and diabatic effects are considered. The wave functions used are the Stark wave functions with the Z axis fixed in space

$$\varphi_+=\frac{1}{\sqrt{2}}(\varphi_{200}+\varphi_{210}),\quad \varphi_-=\frac{1}{\sqrt{2}}(\varphi_{200}-\varphi_{210}),$$

$$\varphi_{21\pm1},\quad \varphi_{100},$$

the subscripts on φ denoting, in spherical coordinates, the quantum numbers nlm.

We use Eqs. (6.39) and (6.40), dropping $\sum_{\alpha'}$ in Eq. (6.40) because of the nondegeneracy of the ground state (100). Letting α designate the state (100), ϵ the states

$$(21\pm1),\quad (+),\quad (-),$$

one finds

$$u_1^{211,100}=u_1^{21-1,100}=0,\quad u_1^{+,100}=u_1^{-,100} \tag{6.54}$$

so that

$$I_{211,100}=I_{21-1,100}=0,$$

$$I_{+,100}=\frac{u_1^{+,100}}{\pi(\Delta\omega_{+,100})^2};\quad I_{-,100}=\frac{u_1^{-,100}}{\pi(\Delta\omega_{-,100})^2}, \tag{6.55}$$

$$u_1^{+,100}=u_1^{-,100}=\tfrac{1}{2}|\mu_{+,100}^{0}|^2\langle 6e^2a_0/v\rho\hbar\rangle,$$

and

$$\left(\frac{6e^2a_0}{\rho v\hbar}\right)\equiv 2\pi n_e\int_0^\infty vW(v)dv\int_\rho^{\rho_m}\rho d\rho\left(\frac{6e^2a_0}{v\rho\hbar}\right). \tag{6.56}$$

The off-diagonal elements contribute twice as much as the diagonal elements to Eq. (6.55). We may therefore write Eq. (6.54) in the form

$$I_{+,100}=\frac{3(u_1^{+,100})_{\rm ad}}{\pi(\Delta\omega_{+,100})^2}, \tag{6.57a}$$

$$I_{-,100}=\frac{3(u_1^{-,100})_{\rm ad}}{\pi(\Delta\omega_{-,100})^2}, \tag{6.57b}$$

where $(u_1^{+,100})_{\rm ad}$ is given by Eq. (6.40) with only the diagonal term, $\mu_{+,100}^{0}(H_1)_{++}$ appearing in the sum. Finally, then,

$$\begin{aligned}(u_1^{+,100})_{\rm ad}&=(u_1^{-,100})\\&=\frac{|\mu_{+,100}^{0}|^2}{3}\frac{144a_0^2e^4}{\hbar^2}\frac{n_e}{\langle v\rangle}\ln\left(\frac{\rho_m}{\rho_c}\right).\end{aligned} \tag{6.58}$$

This result for $(u_1^{+,100})_{\rm ad}$ agrees with the corresponding one obtained from the adiabatic theory of part D of this section, Eq. (6.51) with $\Omega_2^{\epsilon\alpha}/A=2$ and definitions of (6.49), (6.45a), and (6.42). Thus a pure adiabatic treatment (part D) which ignores collision-induced transitions underestimates the broadening by a factor of 3, a conclusion which is important later when an attempt is made to introduce both ions and electrons. Such an attempt succeeds simply only in an adiabatic theory. But with the information now at hand one can estimate the contribution to $u_1^{\epsilon\alpha}$ from the off-diagonal elements (diabatic effects) by using the results of this section.

F. Simultaneous Broadening by Ions and Electrons in the Adiabatic Approximation

In this section both electrons and ions are taken into account in the adiabatic approximation to the theory. The basic formulas are Eqs. (6.27), (6.28), and (6.30). The u_1's are treated in the manner explained in part D. So far as the ions are concerned the averaging process indicated in Eq. (6.30) can be performed with the use of the Holtsmark distribution for the field F since the ions are to be treated in the statistical approximation. Thus, define $W(\Omega)$ to be the probability distribution for

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

the quantity $\Omega \equiv F/e$; Eq. (6.30) then becomes

$$I_{\epsilon\alpha}=\frac{|\mu_{\epsilon\alpha}{}^0|^2}{\pi}\int_0^\infty W(\Omega)d\Omega \times\left\{\frac{u_1{}^{\epsilon\alpha}}{(\Delta\omega_{\epsilon\alpha}{}^0-\Omega_2{}^{\epsilon\alpha}\Omega)^2+(u_1{}^{\epsilon\alpha})^2}\right\} \quad (6.59)$$

and, according to the adiabatic theory for electrons, is $u_2{}^{\epsilon\alpha}$ zero, and $u_1{}^{\epsilon\alpha}$ is independent of Ω. Using the Holtsmark distribution for $W(\Omega)$ and adding together a pair of lines that satisfy $\Omega_2{}^{\epsilon\alpha}=-\Omega_2{}^{\epsilon'\alpha'}$ [this simplifies the results and makes $I(\Delta\omega)$ symmetric] one gets after some mathematical manipulation (see Kolb)

$$I_{\epsilon\alpha}=\frac{2}{\pi}\frac{|\mu_{\epsilon\alpha}{}^0|^2}{(\Omega_2{}^{\epsilon\alpha})^2}\int_0^\infty \xi d\xi \exp[(-4.21\Omega_2{}^{\epsilon\alpha}n_i\xi^3-u_1{}^{\epsilon\alpha}\xi)/\Omega_2{}^{\epsilon\alpha}] \times\left[\Delta\omega_{\epsilon\alpha}{}^0\sin\left(\frac{\Delta\omega_{\epsilon\alpha}{}^0\xi}{\Omega_2{}^{\epsilon\alpha}}\right)+u_1{}^{\epsilon\alpha}\cos\left(\frac{\Delta\omega_{\epsilon\alpha}{}^0\xi}{\Omega_2{}^{\epsilon\alpha}}\right)\right], \quad (6.60)$$

where n_i is the number of ions per cubic centimeter. This equation can be expanded for large and small frequencies ($\Delta\omega_{\epsilon\alpha}{}^0$). We present here only the large frequency expansion, since the other is subject to too many invalidating uncertainties. For convenience we make the following changes in notation:

$$Z_{\epsilon\alpha}\equiv 4.52\Omega_2{}^{\epsilon\alpha}n_i^{\frac{2}{3}}/A, \quad A\equiv \tfrac{3}{2}e^2a_0/\hbar,$$

i.e., $Z_{\epsilon\alpha}$ is the Stark shift (in radians per second) resulting from the mean Holtsmark field strength, and

$$B\equiv\Delta\omega_{\epsilon\alpha}{}^0/Z_{\epsilon\alpha},$$

i.e., B is the shift in units of $Z_{\epsilon\alpha}$ while

$$R\equiv Z_{\epsilon\alpha}/u_1{}^{\epsilon\alpha},$$

i.e., R is a measure of the relative importance of ion and electron broadening. With these changes in notation, for large frequencies ($\Delta\omega_{\epsilon\alpha}{}^0$), Eq. (6.60) becomes

$$I_{\epsilon\alpha}(B)dB=|\mu_{\epsilon\alpha}{}^0|^2dB\frac{2}{\pi}\left\{\frac{1}{R(B^2+1/R^2)}+\sum_{n=2}^{\infty}\frac{(-1)^{n-1}}{(n-1)!} \times\frac{\Gamma[(3n+1)/2]}{B^{(3n-1)/2}}\frac{\cos[\{(3n-1)/2\}\tan^{-1}(BR)]}{[1+1/(BR)^2]^{(3n-1)/4}}\right\}. \quad (6.61)$$

Equation (6.61) reduces to the Holtsmark distribution for ions if we set $u_1{}^{\epsilon\alpha}=0$ ($R=\infty$), for in this limit

$$I_{\epsilon\alpha}(B)dB=|\mu_{\epsilon\alpha}{}^0|^2dB\frac{2}{\pi}\sum_{n=2}^{\infty}\frac{(-1)^{n-1}}{(n-1)!}\frac{\Gamma[(3n+1)/2]}{B^{(3n-1)/2}} \times\cos[\{(3n-1)/4\}\pi]. \quad (6.62)$$

This agrees with Eq. (3.11b) when the coefficients are evaluated. Equation (6.61) reduces to the results of the adiabatic electron theory if $Z_{\epsilon\alpha}=0$.

The electron effects are revealed by comparison of Eqs. (6.61) and (6.62). In addition to the correction factors in each term of the sum in Eq. (6.61), there is a term that depends only on the electrons. In the wings of the line this is dominant since it is of the order B^{-2} whereas the mixed electron ion effects are of the order $B^{-\frac{5}{2}}$. This feature is present in all theories which attempt the fusion of statistical and impact features: the intensity in the statistical theory for large B is proportional to $B^{-\frac{5}{2}}$ that in all impact theories B^{-2}.

Equation (6.61) is applicable to any two pairs of states (ϵ,α), (ϵ',α') for which $\Omega_2{}^{\epsilon\alpha}=\Omega^{2\epsilon'\alpha'}$ since it neglects collision-induced transitions (off-diagonal elements of C). Formally, Kolb does generalize Eq. (6.1) to include the off-diagonal elements. This leads to mathematical difficulties because the $u_1{}^{\epsilon\alpha}$ are then dependent on the ion field strength, which complicates the ion-averaging process. The dependence arises through the $C_{\alpha'\alpha}$ (where $\alpha'\neq\alpha$) (taken as zero in the adiabatic approximation). Under certain conditions, these can be neglected. If, for instance, the average ion field is large the degenerate states are split far enough apart so that the off-diagonal elements vanish. Under other conditions, the term in $C_{\alpha'\alpha}$ that causes the difficulty, namely $\exp(i\omega_{\alpha'\alpha}{}^0t)$ (where $\omega_{\alpha\alpha'}{}^0$ is the separation of two degenerate levels due to the ions) can be replaced by unity. This will be true if the collisions are fast enough, i.e., if the collision time is small compared to $(\omega_{\alpha'\alpha}{}^0)^{-1}$. In this latter case, one can employ the adiabatic theory of Sec. E and estimate the diabatic contribution to $u_1{}^{\epsilon\alpha}$ from a knowledge of the diabatic electron effects, using the procedure given in the treatment of the Lyman-α line. That is, one first determines $u_1{}^{\epsilon\alpha}$ (adiabatic and diabatic) by considering only electrons and then uses this $u_1{}^{\epsilon\alpha}$ in the formula for broadening by ions and electrons in the adiabatic approximation.

As an example of this procedure, Kolb considers the following situation. For $n_e=n_i=10^{16}$ cm^{-3}, $T=15\,000$ °K, and $\Omega_2{}^{\epsilon\alpha}/A=10$. While an analysis of this line to determine the diabatic effects has not been carried out, Kolb estimates that they are of the same order of magnitude as the Lyman-α line. He takes the contribution to the weak collision to be twice the adiabatic contribution Eq. (6.51):

$$(u_1{}^{\epsilon\alpha})_{\rho>\rho_c}\simeq -2\left[\frac{16}{3}\frac{n_e}{\langle v\rangle}(\Omega_2{}^{\epsilon\alpha})^2\ln\delta_m{}^{\epsilon\alpha}\right] \quad (6.63)$$

and for the close collisions

$$(u_1{}^{\epsilon\alpha})_{\rho<\rho_c}=\left[4\pi\frac{n_e}{\langle v\rangle}(\Omega_2{}^{\epsilon\alpha})^2\right] \quad (6.64)$$

assuming that

$$u_1{}^{\epsilon\alpha}=(u_1{}^{\epsilon\alpha})_{\rho<\rho_c}+(u_1{}^{\epsilon\alpha})_{\rho>\rho_c}.$$

The result is shown graphically in Fig. 8.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

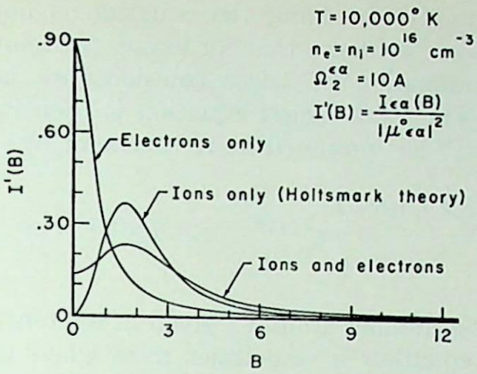

FIG. 8. Line contours produced by different agencies (after Kolb).

This result may be compared with that obtained from the classical theory. Lindholm's result [see Eq. (4.28)] is

$$(u_1^{\epsilon\alpha})_{\mathcal{L}} \equiv \omega_{\frac{1}{2}}/2 = \pi^3(\Omega_2^{\epsilon\alpha})^2(n_e/\langle v\rangle) \times[0.923 - \ln(\pi\Omega_2^{\epsilon\alpha}/\langle v\rangle\rho_m)\cdots].$$

We have replaced the cutoff r_0 by the Debye cutoff ρ_m and v by $\langle v\rangle$. The ratio is then

$$\frac{u_1^{\epsilon\alpha}}{(u_1^{\epsilon\alpha})_{\mathcal{L}}} \approx 0.345\left[\frac{\ln(\rho_m\langle v\rangle/\Omega_2^{\epsilon\alpha})+0.485}{\ln(\rho_m\langle v\rangle/\Omega_2^{\epsilon\alpha})-0.212}\right]. \quad (6.65)$$

For large $\ln(\rho_m\langle v\rangle/\Omega_2^{\epsilon\alpha})$, therefore,

$$u_1^{\epsilon\alpha} \approx 0.345\,(u_1^{\epsilon\alpha})_{\mathcal{L}}. \quad (6.66)$$

The quantity $\ln(\rho_m\langle v\rangle/\Omega)$ is in general large enough so that the difference between Eqs. (6.66) and (6.65) is within the uncertainties of Kolb's method.

For the condition which led to Eqs. (6.63) and (6.64)

$$\ln(\rho_m\langle v\rangle/\Omega_2^{\epsilon\alpha}) \approx 3.25.$$

Equation (6.65) then gives

$$u_1^{\epsilon\alpha} \approx 0.43\,(u_1^{\epsilon\alpha})_{\mathcal{L}}.$$

This is the line width of a single Stark component which is unobservable. The disparity between u_1 and $(u_1)_{\mathcal{L}}$, however, will remain no matter how the components are combined into a resultant contour. Because of the numerous approximations and inherent uncertainties involved in either of the classical path calculations it is difficult to say which formula is numerically preferable, even though Kolb's approach is the more circumspect and realistic one. Later we compare the result of the quantum-mechanical treatment with $(u_1)_{\mathcal{L}}$ (after compounding of Stark states) and find closer agreement.

VII. EXPERIMENTAL RESULTS AND CLASSICAL INTERPRETATIONS

A. Experimental Determination of Plasma Properties

Among the important physical parameters characterizing a plasma are the concentrations of various ions n_i, the electron concentration n_e and the temperature T. In a simple plasma, i.e., one containing but a single type of ion, $n_i = n_e$. The remarks of this section are confined to this case. In complex cases, Dalton's law of total pressure must be employed in addition to the equations discussed below,[46] but otherwise nothing fundamentally new emerges in the analysis of lines from complex plasmas.

A common temperature T exists for all constituents of a plasma if it is in thermal equilibrium. This is not necessarily true in the presence of agencies (discharge currents, ionizing radiations, shocks in rarefied media) which are not part of the thermal mechanism. In such instances it is customary to assign different temperatures to different components (neutral molecules, ions, electrons, photons) and to find ways of measuring each. The limitations of such an approach should, however, be apparent; for the external agencies just mentioned do not always produce a Maxwellian distribution of particle speeds,[47] and a temperature is definable only for a Maxwellian distribution. In a discharge plasma at low electron densities ($n_e < 10^{13}$ cm^{-3}) the temperature concept is known to break down, but it becomes meaningful once more at higher densities when long-range Coulomb forces among the ions and electrons begin to randomize the distribution toward its canonical form. This report does not deal with the pathologies of T, and we assume for the most part that a common T exists.

It has been standard practice to determine $n_i = n_e$ by measuring the intensity distribution of the Balmer lines and comparing it with the Holtsmark formula. Since the temperature does not enter in this procedure, simplicity strongly recommends it. Recent investigations by Edels and Craggs,[48] Lochte-Holtgreven and Nissen,[49] and by Olsen and Huxford[50] are based on it. The risks involved in this method are evident from our earlier theoretical considerations (and from numerous experimental findings of more recent date): reliance on the Holtsmark theory alone is permissible at low ion and electron densities ($n_e < 10^{16}$ cm^{-3}). At high densities, repulsion between perturbing ions produces a smaller intensity in the line wing (where measurements and theory are usually compared), but the electrons add to it. It is likely that a fortunate, rough cancellation between these opposing errors has sometimes led to correct values of n_i even when the method was not strictly valid.

Ion densities obtained by Edels and Craggs and by Lochte-Holtgreven and Nissen in hydrogen arcs were

[46] See, for instance, W. Lochte-Holtgreven, *Temperature, its Measurement and Control in Science and Industry* (Reinhold Publishing Corporation, New York, 1955), Vol. 2. Also Reports on Progress in Physics 21, 312, 1958.

of the order 10^{16} cm^{-3}, in a range where the simple method can hardly fail. Those reported by Olsen and Huxford are somewhat higher (condensed flash discharge) and very probably subject to some error. One should also mention that "fitting a Holtsmark contour" is not a wholly obvious matter. It involves the composition of many Stark-broadened component lines into a single distribution with appropriate weights. The weighting has not always been performed correctly; there are differences, for example, in Olsen and Huxford[50] and Craggs and Hopwood[51] (factor 2 for perpendicular Stark components).

When n_i has been determined, it is a relatively easy matter to find T from the Saha equation (see the following), the relative intensity of different Balmer lines and other known effects involving n_i and T.[46,49] However, since line broadening is strictly also a function of T (mainly through the electron effect), and since we are furthermore interested in *testing* line broadening theories, it behooves us to discuss briefly some available methods for determining n_i and T that are independent of the details of plasma broadening.

1. Saha-Eggert Equation (Mass-Action Law)

This is a relation correcting n_e and T as follows:

$$\frac{n_i n_e}{n_0}=\frac{2Z_i}{Z_0}\frac{(2\pi m_e kT)^{\frac{3}{2}}}{h^3}\exp\left\{-\frac{\chi-\Delta\chi}{kT}\right\}. \qquad (7.1)$$

Z_0 and Z_i are partition functions for neutral atoms and ions, n_0 and n_i their concentrations. For protons, Z_i has the classical form $(2\pi M_p kT)^{\frac{3}{2}}/h^3$; for neutral H atoms, however, Z_0 consists of two factors, the one just written (since $M_H \approx M_p$) and the sum of states $\sum_n g_n \exp(-E_n/kT)$ with weights $g_n=2n^2$ and E_n = hydrogen energy for principal quantum number n. This sum diverges because $E_n \propto n^{-2}$. Physically, however, this divergence is prevented by the drowning of levels discussed in Sec. V. A good practice, established on theoretical and experimental grounds, is to cut off the sum at $n=6$ or 7.

The quantity χ is the ionization potential for the ion, and $\Delta\chi$ is a correction resulting from the drowning of the high levels or, to put it another way, by the lowering of the ionization potential in the presence of ions. It has been computed by Unsöld, Weizel and Ecker, and others (see Sec. V).

Equation (7.1) holds in thermal equilibrium. Strictly speaking, this means that radiative processes as well as corpuscular collision processes, both those generating ions and destroying ions (recombination), must be balanced in detail.[52] If, for instance, radiation escapes partly from the medium, the equation is not exact. There is some evidence that for low n_e photoionization and recombination by triple collisions are not fully effective. The Saha-Eggert equation is then impaired, and Elwert[53] has proposed its replacement by

$$\frac{n_e}{n_0}=\frac{8.4\times10^5\,kT}{n\chi}\frac{}{g}e^{-\chi/kT}, \quad n_e<7\times10^{16}\text{ cm}^{-3}, \qquad (7.2)$$

where g is a number around 2 given in reference 53.

Saha's equation is sometimes used when the temperatures of different plasma components are different. It is then said to define an ionization temperature T_i. The physical meaning of this concept is far from clear; still it may be a useful parameter. But if the energy distribution of the electrons is not Maxwellian (e.g., discharges with $n_e \approx 10^{14}$ cm^{-3}) the Saha equation may be vastly in error. E. Dewan[54] has derived the analog of (7.1) for electron distribution functions given in references 47 and found departures from Eq. (7.1) by large factors.

2. Absolute Intensity of a Line

The temperature alone is involved in the formula for the absolute intensity of the Balmer lines (in emission):

$$I=\frac{2\pi e^2 h f n^2}{m_e\lambda^3}n_0 l\exp\left(-\frac{E_n-E_0}{kT}\right) \qquad (7.3)$$

(λ = wavelength of line, f = oscillator strength, quantum number, n and E_n refer to upper state of line, l is the thickness of the radiating layer, which must be small, i.e., optically thin). If l and n_0 can be determined with precision, this formula is the most direct and reliable means for determining T.

3. Relative Intensity of Different Lines

Two Balmer lines, one originating in the state of principal quantum number n', the other in state n, and of frequencies $\nu_{n'}$ and ν_n, have an intensity ratio

$$\frac{I_n}{I_{n'}}=\frac{n^2\nu_n A_n}{n'^2\nu_{n'}A_{n'}}\exp\left\{\frac{E_{n'}-E_n}{kT}\right\} \qquad (7.4)$$

if all excited states are in thermal equilibrium. A_n is the coefficient of spontaneous emission. Again, in the absence of external agencies, and at high electron-ion concentration even in their presence, this condition is satisfied. Recent measurements in a hydrogen arc discharge by Edels and Craggs,[55] who compared H_α, H_β, and H_γ, have revealed large departures from formula (7.4).

4. Intensity of the Balmer Continuum

The intensity of radiation at a wavelength λ below the Balmer continuum limit of 3646 A is given by the formula[56]

$$I_\lambda=\gamma\frac{16\pi^4 m_e e^{10}}{3^3 c^2 h^5 \lambda^2} n_0 l \exp\left\{\frac{E_1-E_2}{kT}-\frac{hc}{\lambda kT}\right\} \times\left[1+\sum_{n=3,4}\binom{2}{n}^3 \exp\left\{\frac{E_2-E_n}{kT}\right\} +\frac{4kT}{Rhc}\exp\left\{\frac{E_2-E_5}{kT}\right\}\right], \quad (7.5)$$

where n_0 is again the concentration of H atoms, l the layer thickness, E_n = energy of nth quantum state $=-Rhc/n^2$, and R = Rydberg constant. The last two terms in [ ] represent contributions of higher continua in the region of the Balmer continuum.

5. Temperature in Shocks

Shocks are an increasingly important agency for producing high temperatures of short duration, yet long enough to emit measurable spectra lines. Temperatures and ion densities obtainable in shocks surpass by far the limitation of most electrical discharges.[57] Formulas for the temperature in shocks may be derived from the Rankine-Hugoniot equations, are given in Turner's dissertation[57] and, in a more elaborate manner, in Courant and Friedrichs.[58]

Of the five methods thus far surveyed only the first presents means for determining n_e; the remainder are independent ways of finding T. The Saha equation, involves both n_e and T; hence it must always be coupled with one or more of the later formulas. Unfortunately, a determination of n_e from Eq. (7.1) is highly inaccurate because $\Delta\chi$ and T appear in an exponent; the error in T resulting from an uncertainty in a given value of n_e would be much less.

A higher degree of confirmation can be given to a Saha n_e if use is made of the Inglis-Teller formula (Sec. V) which involves n_i $(=n_e)$ and only n_i directly. Although it depends on line widths, details do not enter that equation, and the action of electrons affects it in a minor way. But of course it yields only an estimate.

B. Some Recent Experimental Results

The need for modifications of the statistical theory because of the impacts of electrons was recognized by Unsöld and Lochte-Holtgreven at Kiel where, in consequence, a systematic series of experiments were recently performed on the Balmer series by Jürgens,[56] Griem,[59] Dieter-Henkel,[60] and Bogen.[61] High-intensity carbon electrode arcs maintained in a water channel and supporting currents up to 200 amp were used as sources of radiation, the first six series members being observed for various values of temperature and electron density. Although their experiments were done independently, the sum total of work of the Kiel group exhibits a large measure of unity, justifying a discussion of their findings as a whole.

In these experiments, the perturbations arise from protons and electrons acting together in the discharge; these always occur in equal numbers so that $n_e=n_p$ where n_p is the density of protons per cubic centimeter.

In order to allow the application of a theory of broadening to given experimental contours, values of T and n_e must first be determined, for as we have seen in Sec. II, the validity of a particular broadening theory in general depends upon the values of these parameters. Several independent methods for determining the temperature were employed, such as: measurement of the relative intensities of the successive lines of the series emitted from optically thin portions of the discharge, measurement of the degree of inversion of the lines when emitted from optically thick portions of the discharge, and variation of the intensity of the series continuum. The temperatures calculated by these several methods were found (doubtless in part by good fortune) to agree within a few percent, the values ranging from about 5×10^3 to 1.4×10^4 °K. The determination of n_e was made by the single method of matching the observed contours to an intensity distribution. Two distributions were used, the first being the statistical distribution of Holtsmark and the second a distribution formed by smearing the statistical distribution over the Lindholm impact distribution.

The Holtsmark fitting is performed in the far wings of the line where the inequality, Eq. (4.27), holds. Large discrepancies between this distribution and the observed contours were found, especially in the cases of H_α and H_γ, both of which have undisplaced central components in their Stark patterns which contain large fractions of the total intensities of the lines (38% for H_α and 16% for H_γ). The H_β line, having no undisplaced component, lends itself best to a fit by the statistical distribution. An application of the conditions, Eq. (5.2) to the last resolved member of the series shows that the electrons may be neglected as statistically broadening particles at the temperatures calculated. Hence the perturber density determined by the statistical fit is interpreted as that of the protons only.

The dashed curves of Fig. 9 show the contours as found for the first three lines of the series along with their Holtmark wing fits; these curves were taken from

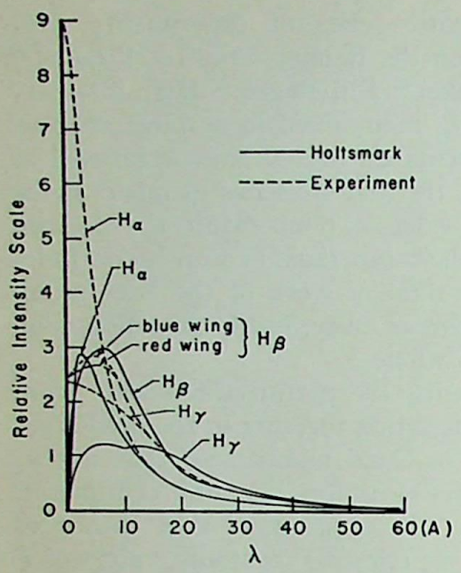

FIG. 9. Comparison of experimental with Holtsmark contours (after Jürgen).

Jürgens and correspond to $T=12\,300$ °K and $n_e=8.4\times10^{16}/\text{cm}^3$.

According to these findings, the experimental contours agree with the statistically calculated ones beyond 30 A, and the agreement occurs for a value of n_e identical with that obtained from the Saha equation. This was disquieting to theorists when the data appeared, for it seemed to show the old but unjustifiable belief in the unimportance of the electrons (at these wavelengths) to be correct. But the later work of P. Bogen[61] has changed this picture.

In his painstaking investigation, which includes a good discussion of errors, Bogen first measures the absolute intensity of the H_β line and uses formula (7.3) to find T. This requires knowledge of n_0, the number of hydrogen atoms, which for the water-stabilized arc employed in these experiments is not readily at hand. It is obtained from a previous study[62] of the properties of this arc, which resulted in the determination of n_0 as a function of T (with use of the Saha equation). Bogen then substitutes T in the Saha equation and obtains $n_e=2.1\times10^{16}$ cm^{-3} for the most fully documented example. When the intensity in the wing of the Balmer lines is plotted one obtains for each of the Balmer lines a graph such as Fig. 10. In the indicated wavelength range the experimental curve lies between two Holtsmark curves, one drawn for $n_e=2.2\times10^{16}$ cm^{-3}, the other for twice that value. For H_α, but not for the higher Balmer lines, the experimental curve approaches the upper Holtsmark curve at about 60 A, and the indication is that the higher Balmer lines likewise show this feature, but the approach takes place at higher wavelengths. Bogen concludes that for large λ the Holtsmark theory is correct for all lines, provided one lets ions and electrons have independent additive effects, i.e., one chooses $2n_e$ instead of n_e as the number of perturbers. The range of correctness coincides with that in which the binary statistical theory (see Sec. III A) is valid. Electron effects appear to be confined to the center of the Balmer lines, and they extend to greater distances from the line center in the higher series members.

We end this review of experimental results with a graphical summary of the shock tube work at Michigan. The latest data of this group may be found in the dissertation of Turner,[57] analyzed by Kolb,[22] from whose thesis Fig. 11 is taken. Again the experimental curve falls outside the Holtsmark distribution for the proper n_e at large distances from the line center. The dashed curve marked "ion and electron theory" represents Kolb's calculation (see Sec. VI), adapted in a suitable way to the Balmer lines, for which a complete calculation is still missing.

C. Classical Interpretations

The electrons must be included in an adequate theory. Their effect, according to all the foregoing developments, is most pronounced in the center of the lines. A simple way to incorporate it is to fold an impact distribution for the electrons into a statistical (Holtsmark) contour. This method, suggested in another connection by Margenau, Burkhardt, and doubtless others, was employed by Griem and Henkel in their data analyses. Griem adopts the use of the distribution:

$$I(\lambda)=\frac{\Delta}{\pi}\frac{I_0(\lambda)}{\lambda^2+\Delta^2}+\frac{\Delta}{\pi F_0}\int_{-\infty}^{+\infty}\frac{\bar{W}(x/F_0)dx}{(\Delta-x)^2+\Delta^2}. \quad (7.6)$$

Here 2Δ is the half-width computed for the electron impacts by the Lindholm theory; $\bar{W}(x/F_0)$ is the statistical distribution for a normal field strength F_0. This is taken from the work of Verwey and Schmaljohann (see Sec. III), which excludes the central undisplaced component of a Balmer line. Hence the central component, whose total intensity is I_0, must be added in via the first term of Eq. (7.1), which shows only an impact width. In Eq. (7.1), λ is measured from the normal position of the line. The bar over $\bar{W}$ is to indicate that a proper average over different Stark components has been taken. Much better representations of the data are obtained through the use of (7.6) as can be seen from the curves of Fig. 12 which are taken from the paper of Henkel.

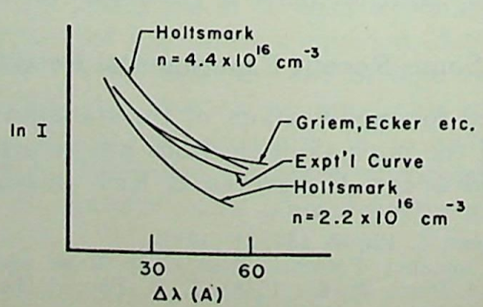

FIG. 10. Comparison of wing intensities (schematic, after Bogen).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

A plausibility argument in favor of smearing the distributions takes a form similar to the one used in earlier sections. When a perturbation of the radiator contains two components, one of which acts slowly and the other quickly, the action of the slow one is to produce discrete shifts in energy which may be considered to be constant over time intervals in which many broadening collisions involving the fast component occur. Hence, in our example, each discretely shifted frequency of the statistical theory, produced by the protons, is broadened by the many impacts of the electrons. The condition under which many electron collisions occur during a time in which the ions are essentially motionless is:

$$t_e \ll t_p, \tag{7.7}$$

where t_e is the time between successive electron collisions and t_p is the time during which a proton collision occurs. For classically describable particles we have the definitions,

$$t_e = 1/(n\pi d^2 v_e), \quad t_p = d/v_p, \tag{7.8}$$

where d is defined by Eq. (2.5); v_e and v_p are, respectively, the mean speeds of the electrons and the protons. The inequality (7.2) thus becomes:

$$[(6.90)^3 \pi T^{\frac{3}{2}}/n^{\frac{1}{2}}](m_p/m_e)^{\frac{1}{2}} \gg 1, \tag{7.9}$$

where m_p is the mass of the proton and m_e is the mass of the electrons. This inequality holds for many important applications of electron broadening, both stellar and terrestrial.

It was shown in Sec. II that the classical-path assumption of the impact theory is not necessarily valid for collisions producing phase shifts less than unity. Such phase shifts, however, contribute most of the shift and broadening, as calculated by that theory, for the first order Stark effect [see Eqs. (4.27) and (4.28) and Table V]. Since this is the case, there exists no *a priori* justification for employing the Lindholm distribution, as Griem does in his folding procedure; instead one should replace it with the results of a quantum mechanical calculation. For the quadratic Stark effect this is not the case because the large contributions to the broadening result from collisions falling within the critical radius as has been shown by Unsöld[18] and in Sec. IV of this article.

The peculiarity in the behavior of the first-order Stark effect is connected with the nonconvergence of the broadening when collision parameters out to infinity

TABLE VII. Densities for which $d=\rho_c$ for the first-order Stark effect in hydrogen.

	n^*
H_α	$6.2 \times 10^{18}/\text{cm}^3$
H_β	$1.6 \times 10^{18}/\text{cm}^3$
H_γ	$5.48 \times 10^{17}/\text{cm}^3$
H_δ	$2.52 \times 10^{17}/\text{cm}^3$

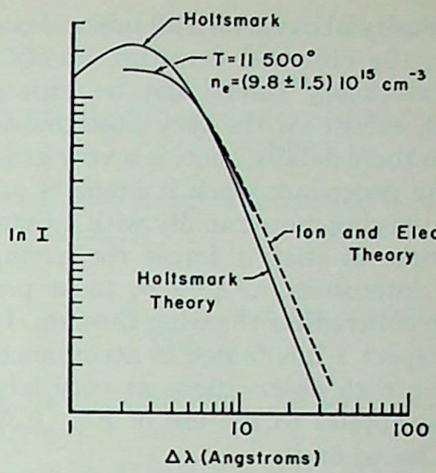

FIG. 11. Comparison of wing intensities (after Kolb).

are considered. The arbitrary cutoff in the collision parameter, taken usually at d or $n^{-\frac{1}{3}}$, introduces an uncertainty in the final broadening; but, more important even, the nonconvergence leads to the phenomenon of the most distant collisions producing the greatest amount of broadening. Griem, in establishing the applicability of the Lindholm distribution to his broadening results, states that only phase shifts greater than unity are important and points to the improbability of multiple impacts within ρ_c, in order to validate the single-impact theory. His arguments, therefore, ignore the long-range contributions to the broadening. In the cases where $d \leqslant \rho_c$, the Lindholm theory may indeed be used. At the temperature of the Kiel experiments $T \approx 10^4$ °K, and we find the values in Table VII

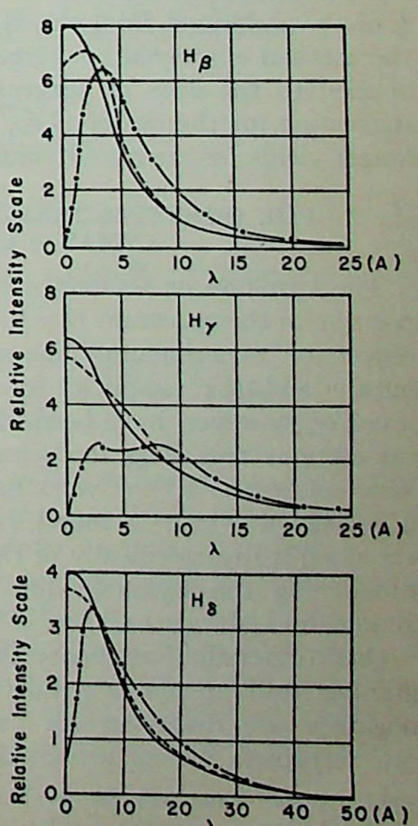

FIG. 12. Comparison of Holtsmark theory jor $F_0=100$ esu, and the folded distribution, with experiment for H_β, H_γ, and H_δ.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

for n^*, the density above which all impacts occur within ρ_c. Thus, for the observed densities, $n \approx 5 \times 10^{16}$ cm^{-3}, the Lindholm theory should not be expected to be strictly valid, except for the very close collisions.

Aside from these details, there is a very general defect of the folding procedure when it involves a statistical distribution varying more rapidly with λ than λ^{-2}, such as Holtsmark's, in that it forces the asymptotic dependence of intensities, as $\lambda \to \infty$, to be proportional to λ^{-2}, which contradicts the wing theorem. Hence, one should not expect a line folded in accordance with Eq. (7.1) to agree with observations at very large λ. This criticism also applies to the use of Eq. (6.30) and all applications based on it.

Ecker[30b] has discussed the desirability of including in the calculation of intensities both the electron effect and the modification of the statistical theory at large distances. He dealt with the latter in reference 30, where the parameter δ is introduced to effect the correction. In reference 30b he folds an impact distribution into a statistical one. But he does this for $\delta = \infty$ and, therefore, obtains results which do not go beyond those of Griem and are in essential agreement with them.

Another result obtained by the Kiel investigators demonstrates that electron collision effects increase at a more rapid rate than do the statistical effects as one proceeds to higher series members. This is in agreement with both the Lindholm theory and the quantum mechanical calculation. Difficulties in the inclusion of the electron effects are implied even in the early work of the Kiel group, as one may see from the following discrepancy. Henkel's fit with the folded distribution leads to values of the perturber density which are about $\frac{1}{3}$ of those derived from the Holtsmark wing fits, i.e., the method employed by Jürgens. When this result is applied to the data of Jürgens, which antedated the suggestion for the use of (7.6), the Saha[59] equation no longer yields his measured value of the temperature.

VIII. QUANTUM TREATMENT OF THE LYMAN-α LINE

The Lyman-α or resonance line of H, because of its position in the spectrum ($\lambda = 1216$ A), has not been the object of experimental line-width work. Its basic nature and the simplicity of the spectral terms it involves, however, have been inviting to theorists, and calculations regarding its behavior have been made. Much of Spitzer's[15a,19,63] work has reference to this line, a review of which is found in Breen's[64] article. An extended study specifically of the effects of electrons in broadening the Lyman-α line was made by Kivel, Bloom, and Margenau.[13]

Quantum radiation theory is applied from the beginning, and numerous details of little practical importance are discussed. In essence, however, three rather typical effects are distinguished. The first is called *universal* broadening. It results from a schematic calculation in which only two levels are included, the lower and the upper states of the line. In the case of L_α, the upper state is actually degenerate, but this degeneracy is not taken into consideration at this stage of the analysis. The results are therefore not specific to the line in question and have a very general meaning. They ignore the first-order Stark effect by not including linear combinations of the degenerate states; and they ignore the second-order Stark effect by neglecting higher energy levels whose virtual excitation normally accounts for the distortion of the radiating atom. What the universal effect describes, then, is broadening by electrons which are scattered nearly elastically, as is apparent in the following.

Polarization of the radiating atom is introduced by properly combining the degenerate states of the upper level. The four correct combinations are known from the theory of the linear Stark effect; they are

$$\psi_+ = \frac{1}{\sqrt{2}}(\psi_{200} + \psi_{210}); \quad \psi_- = \frac{1}{\sqrt{2}}(\psi_{200} - \psi_{210});$$

$$\psi_{21-1}; \quad \psi_{21+1}.$$

The subscripts on ψ denote, in spherical coordinates, the quantum numbers nlm. The first and second of these correspond to different energies $[(-e^2/8a_0) \pm 3ea_0F]$ whereas the last two belong in first approximation to the unchanged energy $-e^2/8a_0$. Moreover, the states ψ_+ and ψ_- have permanent dipole moments in the field F. Transitions between them involve, therefore, spatial *reorientations* of the atomic dipoles occurring as a result of the perturbing electrons. The effect of ψ_{21-1} and ψ_{211} is more subtle; it represents the *induction* of a dipole moment by the passing electron. The calculation which includes only ψ_+ and ψ_- is easy because it does not lead to divergent matrix elements. Its results on the line width were termed "polarization broadening by reorientation." The inclusion of ψ_{21+1} and ψ_{21+1} produces divergences which must be dealt with more carefully. It results in much larger effects, here called "polarization broadening by induction."

Finally, there is an effect connected with matrix elements of the electron perturbation between the states $2p$ and $1s$. These obviously represent quenching by electron collisions, a problem for which the theory had already been given by Wentzel.[65]

Polarization and quenching are strongly dependent on the nature of the quantum levels entering the calculation. The results computed are, therefore, not capable of immediate generalization to other cases and are here only cited as numerical examples. The universal effect, however, presents certain features of wider interest, even though it is small in the case of the Lyman-α line.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

The lengthy calculations in reference 13 concerning the universal effect lead to the same result as a much simpler picture,[17] which we use here. While this analysis standing by itself is perhaps not convincing, its plausibility is fairly high. Instead of considering atom, radiation field, and electron as the quantum system, we concentrate attention on the electron alone and investigate the change in its motion as it meets the radiating atom. If it loses an energy ΔE while it passes the atom, one may say that the atom gains ΔE and therefore emits a frequency shifted to the blue by $\omega_{if}=\hbar^{-1}\Delta E$. What this picture does not suggest is the potential exerted by the radiating atom upon the electron as it moves near it, for the atom has a finite probability of being in the upper as well as the lower state during the emission of radiation.

Here our earlier reflections are helpful. All through Sec. I it was evident that the perturbation responsible for line widths is ϵ, the difference between the upper and the lower energy levels as a function of the position of the perturbing particle. This is the quantity that alters the phase of the radiation in the impact theories and causes the shifts in the statistical theory. Reference 13 bears out the expectation that ϵ, in the form proper for a Coulomb interaction, should be used as the perturbation in the present problem. If the Coulomb interactions between the atomic electron at $\mathbf{r}_R$ and the perturbing electron at $\mathbf{r}$ are denoted by $C(\mathbf{r}_R,\mathbf{r})$, and $C_{ii}(r)$ is the diagonal element of $C(\mathbf{r}_R,\mathbf{r})$ with respect to the ith state of the atom, then

$$\epsilon(r)=C_{22}-C_{11}, \tag{8.1}$$

provided 2 is the upper and 1 the lower state of the line.

In accordance with the usual procedure in (time-dependent) perturbation theory it is now supposed that the electron, before the interaction, has an anergy E_i and its state is represented by a probability amplitude a_i, whereas afterward these quantities are changed to E_f and a_f. We take the states to be those of a free electron: $E_s=(\hbar^2/2m)k_s^2$, $\psi_n\propto\exp(i\mathbf{k}_n\cdot\mathbf{r})$. The amplitude a_f is then a function of t as well as of ω_{if}, and the intensity of the spectral line at a frequency ω_{if} beyond its normal frequency is given by

$$I(\omega_{if})\propto\lim_{t\to\infty}|a_f(\omega_{if})|^2. \tag{8.2}$$

Strictly, the limit $t\to\infty$ is meaningless because the radiative process lasts only for a finite time which is the reciprocal of the natural line width in cycles per second. This natural width is being neglected in the passage to an infinite limit.

The equations for the amplitudes are

$$i\hbar\dot{a}_i=\textstyle\sum_f a_f\epsilon_{fi}e^{-i\omega_{fi}t}, \tag{8.3}$$

$$i\hbar\dot{a}_f=a_i\epsilon_{if}e^{-i\omega_{if}t},$$
$$\omega_{if}\equiv\hbar^{-1}(E_i-E_f). \tag{8.4}$$

If we put $a_i=\exp(-\gamma_u t)$, integrate (8.4) and substitute in (8.3) we find

$$\gamma_u=\sum_f\frac{|\epsilon_{if}|^2}{\hbar^2}\frac{e^{i\omega_{if}t+\gamma_u t}-1}{i\omega_{if}+\gamma_u}. \tag{8.5}$$

The sum over final states is converted to an integral in a well-known manner:

$$\sum_f\to\int\frac{V}{(2\pi)^3}\cdot 2\pi k_f^2dk_f\sin\theta d\theta,$$

where θ is the angle between the wave-number vectors of the electron, $\mathbf{k}_i$ and f_f, and V is the volume per electron. If ω_n is written for $\hbar k_n^2/2m$, the integration over ω_f in (8.5) can be carried out according to the formula[66]

$$\int f(\omega_f)\frac{e^{i(\omega_i-\omega_f)t+\gamma_u t}-1}{i(\omega_i-\omega_f)+\gamma_u}d\omega_f\doteq\pi f(\omega_i),$$

and (8.5) results in

$$\gamma_u=\frac{V}{(2\pi)^2}\frac{m\pi k_i}{\hbar^3}\int|\epsilon_{if}|^2\sin\theta d\theta, \tag{8.6}$$

with the understanding that the remaining integrand is evaluated at $k_f\cong k_i$. This shows that the scattering which leads to γ_u is essentially elastic.

Now ϵ_{if} is easily computed; it is expressible in terms of other atomic integrals frequently encountered in scattering theory, namely,

$$F_{ss}(\kappa)\equiv\int\exp(i\boldsymbol{\kappa}\cdot\mathbf{r}_R)|\psi_s(\mathbf{r}_R)|^2d\mathbf{r}_R.$$

Thus

$$\epsilon_{if}=\frac{4\pi e^2}{V\kappa^2}(F_{22}-F_{11})$$

and

$$\kappa^2=k_i^2+k_f^2-2k_ik_f\cos\theta. \tag{8.7}$$

From this last relation $\sin\theta d\theta$ is computed, and Eq. (8.6) then gives

$$\gamma_u=\frac{2\pi e^4}{V}\frac{a_0^2m}{\hbar^2k_i}\int_0^{x'}\left(\frac{F_{22}-F_{11}}{x}\right)dx. \tag{8.8}$$

The variable x here stands for κ^2a_0 and a_0 is the first Bohr radius; F_{11} and F_{22} refer, of course, to the $1s$ and to the weighted mean of the $2p$ states of hydrogen. The upper limit, $x'=4k_i^2a_0^2$, represents the maximum value permitted by (8.7) when $k_i=k_f$.

Let us call the remaining integral in (8.8) $2\pi^2Y$; it is a function of the initial energy of the perturbing electron through x'. In Fig. 13 it is plotted for the L_α line, E_i being in units equal to the ground-state energy

[66] W. Heitler, *Quantum Theory of Radiation* (Oxford University Press, 1936), first edition, p. 112.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

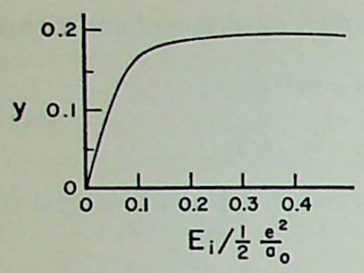

FIG. 13. Graph of the efficiency factor Y *vs* electron energy. See Eq. (8.9).

of hydrogen. If now we replace V in Eq. (8.8) by n^{-1} and $\hbar k_i$ by mv_i, that equation reduces to

$$\gamma_u = nv_i\pi(h/mv_i)^2 Y(v_i). \tag{8.9}$$

From Eq. (8.4)

$$-iha_f = \epsilon_{if}\frac{e^{-\gamma_u t - i\omega_{if}t}-1}{\gamma_u + i\omega_{if}}$$

because $a_i = e^{-\gamma_u t}$. Hence, (8.2) yields a dispersion curve of half-width $2\gamma_u$; from (8.9), therefore

$$\omega_{\frac{1}{2}}(u) = 2n[\pi(h/mv_i)^2]Y(v_i)\cdot v_i. \tag{8.10}$$

A comparison of this result with Lorentz' formula, (1.3), is interesting, for both are of the same form. Evidently the collision cross section for this type of electronic broadening is $\pi\lambda^2$ times an efficiency factor $Y(v_i)$, λ being the DeBroglie wavelength. The rise of $Y(v_i)$ from small values at small v_i illustrates again that a perturbing electron, if it is to produce effects other than shifts described by a static theory, must have sufficient velocity. The development here sketched, and also the work in reference 13, relies upon the Born approximation. When the energy of the impinging electrons is of the order of magnitude of 1 volt, as in the examples under study, this approximation may be greatly in error and the numerical results (e.g., Fig. 13 and Table VIII) may be inaccurate. When good experimental data are at hand, recalculation with better wave functions is desirable.

Meyerott and Margenau[67] computed the analog of Eq. (8.10) with the use of Lindholm's impact theory, basing the work on (4.16). But instead of using a schematic potential of the form (4.17) they employed the potentials ϵ_{2p} and ϵ_{1s} which the electron actually experiences in its approach to the hydrogen atom. The result, plotted in Fig. 14, shows moderate agreement with Eq. (8.10).

TABLE VIII. Broadening of L_α by *electron impacts* at an electron concentration $n=10^{14}$ cm^{-3}, mean energy $(1/25)(e^2/2a_0)$ ($\approx\frac{1}{2}$ ev). The quantity $\omega_{\frac{1}{2}}{}^0$ is the natural line width, 3.12×10^8 sec^{-1}.

Effect, i	$\omega_{1/2}{}^{(i)}/\omega_{1/2}{}^0$
"Universal" broadening	0.13
Polarization by	
reorientation	0.027
induction	2.7
Quenching	0.0013
(Stark broadening by ions	80)

In several publications[68] Sobel'man has shown that Eqs. (8.8) and (8.10) can also be derived in a simple way from scattering theory. His method is quite similar to that employed in reference 67, and he gives useful criteria for the applicability of the scattering approach to line-width problems.

We now turn to the polarization effects, in which electrons cause transitions between the initially degenerate states. Here, the calculation is troubled by the occurrence of spurious divergences in the matrix elements, divergences which can only be avoided by the choice of a cutoff radius like the d encountered in Sec. II. The uncertainties introduced by this somewhat arbitrary procedure are not serious, however. Polarization brings the greatest contribution to the line width so far as the effect of the electrons is concerned.

Kolb, on applying his classical-path theory to the line, has made a careful comparison between his results and those of reference 13. While he reaches numerically different conclusions (resulting from omission of one matrix element in Kivel *et al.*,[13] and also from the fact that Kolb averages the Stark components of L_α with proper weight factors whereas Kivel *et al.* do not average), he is able to show that even the polarization effects can be calculated for the conditions under study with the use of classical-path theory instead of the completely quantum mechanical theory here summarized. The only effect not appearing in Kolb's work is the one called polarization by reorientation, and this is seen to be very small. In Sec. IX it appears that a similar conclusion holds for the Balmer lines—a fortunate fact likely to obviate the need for further detailed calculations.

Finally, there is the width caused by quenching. This, for L_α, turns out to be negligible. In illustration of orders of magnitude the various results are collected in Table VIII, where all quantities refer to a special situation that is approximately realized in the photosphere of the sun. The last line in the table represents the Holtsmark width produced by the ions which in this instance quite evidently outweighs all electron effects.

In judging these results and in appraising the role of the electrons at higher charge densities and for other lines, two facts need to be borne in mind. First, electron effects increase with n, ion effects only with $n^{\frac{1}{4}}$ (see Sec. III). Secondly, lines involving states of higher excitation than L_α offer larger targets to the impinging electrons, and this enhances their sensitivity to broadening impacts. The enhancement is, in fact, greater than the accompanying increase in static polarizability which accounts for the Holtsmark width. While this is not apparent from the present discussion, it manifests itself

[67] R. E. Meyerott and H. Margenau, Phys. Rev. **99**, 1851 (1955).

[68] I. Sobel'man, Optika i Spektroskopiya **1**, 617 (1956); Fortschr. Physik **5**, 175 (1957).

in our treatment of the Balmer lines in the following section, where the electrons begin to play a role that is no longer subordinate to that of the ions at attainable concentrations. There the work is limited to the effect which was here found to be predominant, namely polarization. In the terminology of Sec. IV, the adiabatic hypothesis is abandoned and full consideration is given to the degenerate states that go into the formation of a broadened line.

IX. QUANTUM THEORY OF THE BALMER LINES

An entirely quantum-mechanical treatment of the broadening of the Balmer lines *due to electrons* has been given by Landwehr.[23] A system composed of the radiator (i.e., an atom or molecule), a number N of perturbing electrons, and the quantized radiation field all confined to a volume V, is described by the Schrödinger equation

$$H\Psi = i\hbar\dot{\Psi}. \tag{9.1}$$

The Hamiltonian H is decomposed into an unperturbed part H^0 representing the total energy of the isolated components of the system, and a part H' which accounts for their mutual interaction. We write

$$H^0 = H_R{}^0 + H_f{}^0 + \sum_{j=1}^{N} H_{pj}{}^0, \tag{9.2}$$

where $H_R{}^0$, $H_{pj}{}^0$, and $H_f{}^0$ are, respectively, the unperturbed Hamiltonians of the radiator, the jth perturbing electron and the radiation field. The perturbation

$$H' = J_{Rf} + \sum_{j=1}^{N} C_{Rj}, \tag{9.3}$$

where J_{Rf} is the interaction between the radiation field and the radiator, and C_{Rj} the Coulomb interaction between the jth electron and the radiator. The Coulomb interactions between the perturbing electrons has been neglected.

Landwehr's method of calculation is similar to that of Weisskoff and Wigner[69] for the problem of the natural line width. It starts with an initial condition in which an excited atom but no photons are present and then derives the probability of finding a photon of a given frequency after a time long enough so that the atom has certainly radiated. At zero time the perturbations are "turned on" suddenly. We then have at $t=0$:

$$\psi(0) = \psi_{n_0}{}^R \psi_0{}^f \psi_{\lambda_0}{}^p,$$

where $\psi_{n_0}{}^R$ is the n_0th eigenstate of $H_R{}^0$, $\psi_0{}^f$ the null state of $H_f{}^0$, and $\psi_{\lambda_0}{}^p$ the λ_0th eigenstate of $\sum H_{pj}{}^0$. The function $\psi_{\lambda_0}{}^p$ is taken to be a product of plane waves. The momentum distribution of the N electrons is assumed to be the equilibrium distribution of the particles at the temperature T (i.e., the Boltzmann distribution).

The solution of (9.1), corresponding to the initial conditions given above, can be expanded over the eigenfunctions of H^0 to give

$$\Psi(t) = \sum_{n\lambda\nu} a_{n\lambda\nu}(t)\psi_n{}^R\psi_\lambda{}^p\psi_\nu{}^f \times \exp\left[-\frac{i}{\hbar}(E_m{}^R + E_\lambda{}^p + E_\nu{}^f)t\right], \tag{9.4}$$

with $a^{(0)}_{n_0,\lambda_0,0} = 1$. The determination of the coefficients a is extremely unwieldy; hence, it is assumed that a satisfactory approximation can be obtained by neglecting all matrix elements of H' that do not involve the initial state. This means that only the initial state can radiate a photon and all collision-induced transitions are from and into the initial state. With this assumption, the equations for the amplitudes become

$$\begin{aligned}
\dot{a}_{n_0,\lambda_0,0}(t) = &-\frac{i}{\hbar}\left\{\sum_{n\lambda}\left(n_0\lambda_0\left|\sum_{j=1}^{N} C_{Rj}\right|n\lambda\right)a_{n,\lambda,0}(t)\right. \\
&\times\exp\left[-\frac{i}{\hbar}(E_n{}^R + E_\lambda{}^p - E_{n_0}{}^R - E_{\lambda_0}{}^p)t\right] \\
&+\sum_{n'\nu}(n_0,0|J_{Rf}|n'\nu)a_{n',\lambda_0,\nu}(t) \\
&\left.\times\exp\left[-\frac{i}{\hbar}(E_{n'}{}^R + E_\nu{}^f - E_{n_0}{}^R)t\right]\right\}, \\
\dot{a}_{n,\lambda,0}(t) = &-\frac{i}{\hbar}\left(n\lambda\left|\sum_{j=1}^{N} C_{Rj}\right|n_0\lambda_0\right)a_{n_0,\lambda_0,0}(t) \\
&\times\exp\left[-\frac{i}{\hbar}(E_{n_0}{}^R + E_{\lambda_0}{}^p - E_n{}^R - E_\lambda{}^p)t\right], \\
\dot{a}_{n,\lambda_0,\nu}(t) = &-\frac{i}{\hbar}(n'\nu|J_{Rf}|n_0 0)a_{n_0,\lambda_0,0}(t) \\
&\times\exp\left[-\frac{i}{\hbar}(E_{n_0}{}^R - E_{n'}{}^R - E_\nu{}^f)t\right].
\end{aligned} \tag{9.5}$$

The approximations have not interfered with the correct normalization, as the solutions of Eq. (9.5) retain the property

$$\sum_{n\lambda\nu} |a_{n\lambda\nu}(t)|^2 = 1.$$

For J_{Rf} we take the single-photon operator

$$J_{Rf} = -(e/m)\mathbf{p}_R \cdot \mathbf{A}_f,$$

where $\mathbf{p}_R$ is the momentum of the radiator's atomic electron and $\mathbf{A}_f$ is the vector potential of the field. The Coulomb interaction, C_{Rf}, is cut off at the distance d

[69] V. Weisskopf and E. Wigner, Z. Physik **63**, 54 (1930).

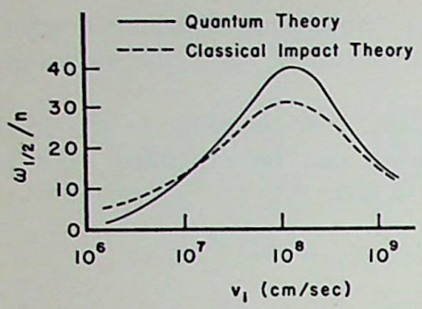

FIG. 14. "Universal" broadening. Graph of half-width *vs* electron velocities.

from the center of the radiator and given by

$$C_{Rj}=\begin{cases}-\dfrac{e^2}{r_j}+\dfrac{e^2}{|\mathbf{r}_j-\mathbf{r}_R|} & \text{for } 0\leqslant r_j\leqslant d\\ 0 & \text{for } r_j<d.\end{cases}$$

It develops that the solution of (9.5) for the initial state amplitude, is of the decaying exponential form when the following conditions hold:

$$\frac{3}{2}\frac{kT}{\hbar}\gg\Gamma_C+\Gamma_J,\quad \omega'\gg\Gamma_C+\Gamma_J.$$

Here ω' is again the frequency of the undisplaced line and $\Gamma_C+\Gamma_J$ is the total decay constant of the initial state, a sum of the contribution from electron scattering Γ_C and from spontaneous emission Γ_J. The inequalities above are both satisfied over wide ranges of interest; the case of electron broadening of the Balmer lines will be analyzed with respect to them below.

There results, for the distribution of amplitudes corresponding to frequency ω due to transitions from an initial state $(n_0,\lambda_0,0)$ to a final state (n',λ_0,ω), the simple formula

$$|a_{n'\lambda_0\omega}(\infty)|^2=\frac{(\Gamma_C+\Gamma_J)/\pi}{(\omega-\omega')^2+(\Gamma_C+\Gamma_J)^2}. \qquad (9.6)$$

Here $\Gamma_J=\sum_{n''}\Gamma^J_{n_0,n''}$ is the total radiative decay constant of the upper state, the sum being taken over all states into which the atom can radiate; $\Gamma_C=\sum_{n'''}\Gamma^C_{n_0,n'''}$ is the total collisional decay constant of the upper state, and the sum is over all states to which the atom can pass by collisional transitions. The Γ_C depends on the transition matrix elements,

$$\Gamma_C\propto F(\kappa)\sum_{n'''}|[n_0|1-\exp(i\boldsymbol{\kappa}\cdot\mathbf{r}_R)|n'']|^2,$$

where $F(\kappa)$ is a function of κ, the wave-number difference between the initial and final states of the colliding electron ($\boldsymbol{\kappa}=\boldsymbol{\kappa}_i-\boldsymbol{\kappa}_f$), and r_R is the coordinate of the atomic electron.

When degeneracy exists in the states of the radiator, the largest contribution to Γ_C comes from matrix elements of the states that are degenerate with the initial state. In addition, $F(\kappa)$ is highly weighted for values of κ which correspond to elastic scattering. The evaluation of Γ_C is, therefore, restricted to those states that are degenerate with the initial state. These matrix elements may be summed approximately in a convenient manner by using known sum rules.

The method leads to a spectral contour associated with a particular radiative transition between given initial and final states. In order to form a single spectral line, such as a Balmer line of hydrogen, it is necessary to combine the results obtained for each transition from one of the initial degenerate states with one of the final degenerate states. In this procedure each of the initial states is assumed to be equally populated and each transition is weighted by the relative transition probabilities per unit time in the dipole approximation. The line formed in this manner is symmetric about ω' but is not of strict resonance shape, being lower in the line core and higher in the wings.

The diagonal matrix elements of H' have been neglected in Eq. (9.6). These represent shifts in the individual line components but are presumably small because of the uniformity of the perturber's charge distribution. These neglected matrix elements, of course, are responsible for the line width and shifts in a purely adiabatic theory; however, in the extreme diabatic case (collision-induced transitions) they contribute only to the shift.

Landwehr has applied this theory to the first three Balmer lines. The half-width Γ_C arising from collision broadening of the atomic state $(n_0l_0m_0)$ is expressible in the form

$$\Gamma^C_{n_0l_0m_0}=n_0^2\left(\frac{2\pi m}{kT}\right)^{\frac{1}{2}}e^4n_ea_0^2\left\{A-B\ln\left(\frac{\hbar^2}{n_e^{\frac{1}{3}}2mkTn_0a_0}\right)+C\mathfrak{E}(\hbar^2/2mkTn_0^2a_0^2)\right\}, \qquad (9.7)$$

where A, B, and C are constants dependent on $(n_0l_0m_0)$ and $\mathfrak{E}(x)$ is the exponential integral of x.

Table IX, calculated for $n_e=5\times10^{16}$ cm^{-3} and $T=10^4$ °K, lists the ratio $\Gamma^C_{n_0l_0m_0}/\Gamma^C_{n_022}$ for the first three Balmer lines.

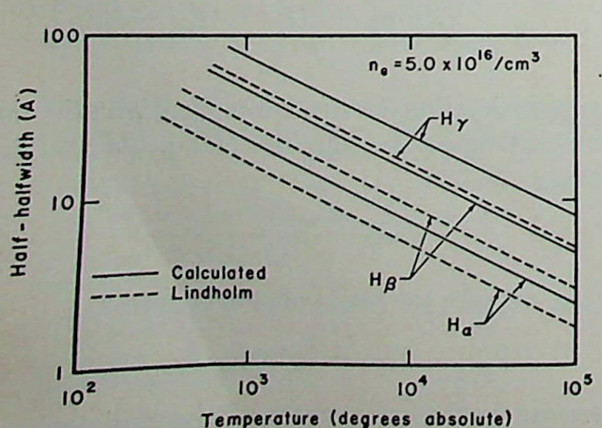

FIG. 15. Broadening of H_α, H_β, and H_γ as calculated by Landwehr, compared with classical impact theory.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

The form of Eq. (9.7) is strikingly similar to Eq. (4.28) for the impact half-width. Indeed when comparison is made of the results of the two theories we find exactly the same variation with temperature and electron density, as shown in Fig. 15. The dotted line is an application of the Lindholm theory, as adapted to the Balmer lines by Griem.[59] Griem treats the normally degenerate states in a given excited level as one state using an average splitting factor for this composite state. The quantum mechanical values of the half-width of the lines exceed those of the classical impact theory, by hardly more than the possible error introduced by Landwehr's use of sum rules in the evaluation of matrix elements. Thus the two theories yield about the same results, the major difference being that the Lindholm theory produces a resonance contour and the quantum mechanical theory a less peaked distribution.

The form of the variation of the collision damping constant with T and n_e

$$\Gamma^C \propto n_e T^{-\frac{1}{2}}$$

is a quite general result and has been found also by Rudkjobing[70] in a quantum mechanical calculation of a different sort.

TABLE IX. $\Gamma^C_{n_0 l_0 m_0}/\Gamma^C_{n_0 22}$ for $n_e = 5\times10^{16}$ cm^{-3} and $T = 10^4$ °K.

		(l_0, m_0)								
		(2,2)	(2, −2)	(2,1)	(2, −1)	(2,0)	(1,1)	(1, −1)	(1,0)	(0,0)
n_0	3	1	1	1.7	1.7	3.4	1.9	1.9	5.5	3.6
	4	1	1	2.8	2.8	2.9	1.3	1.3	4.7	2.8
	5	1	1	3.0	3.0	3.7	1.5	1.5	4.1	2.4

Figure 16 shows the complete quantum contour of H_β taken at $n_e = 5\times10^{16}$ cm^{-3} and $T = 1.25\times10^4$ °K as compared with a resonance curve (as predicted by Lindholm theory) of the same half-width and total integrated intensity. The solid curve in this figure results from a superposition of curves based on Eq. (9.6) for the different degenerate upper state.

Figure 17 compares the values of the half-width of H_β produced by electrons with that produced by ions (Holtsmark theory) where the average broadening is given by[59]

$$\Gamma_H \approx (3\hbar/\pi m)7.8n^{\frac{2}{3}}.$$

For stellar applications at $n \leqslant 10^{15}$ cm^{-3}, $T > 5\times10^3$ °K the electrons do not contribute much broadening of the line and may be omitted from consideration. In some interesting terrestrial applications, such as those discussed in Sec. VII B, the electrons do contribute large effects to the line. Electron broadening becomes inappreciable for extremely large values of the temperature if the number density of electrons is held fixed.

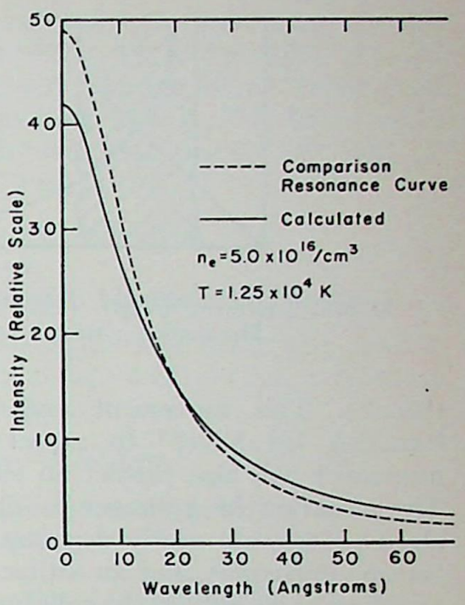

FIG. 16. Comparison of line shapes. Landwehr calculation against resonance curve.

X. SHIFTS PRODUCED BY ELECTRON COLLISIONS**

Argon spectra from high-temperature plasmas produced in shock tubes by Petschek, Rose, Glick, Kane, and Kantrowitz at Cornell proved surprising at first because the lines were not at their expected wavelengths. It seemed that the shifts were greater than could be accounted for by the usual Holtzmark theory of static ion fields and the consequent Stark shifts.†† Hence the results were attributed to line shifts induced by the free electrons in the plasma. Baranger[71] made a quantitative calculation based on the theory of Lindholm (see Sec. IV) which showed that this interpretation was reasonable.

At the same time the group at Yale[13] had been working out the details of the quantum mechanical theory of electron effects. Their predictions of hydrogen line broadening have been shown by Meyerott and Margenau[67] to agree with semiclassical broadening

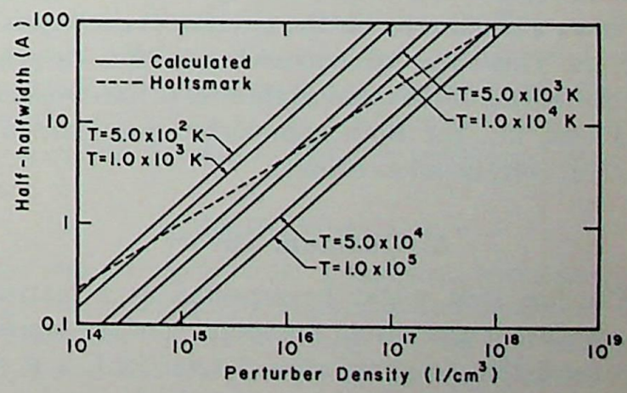

FIG. 17. Broadening of H_β, as calculated quantum mechanically, compared with Holtsmark theory.

** We are greatly indebted to Dr. B. Kivel for a draft of this section.

†† This point has not been entirely clarified; for the asymmetry of the statistical background can introduce a shift.

[71] M. Baranger, Phys. Rev. 91, 436 (1953).

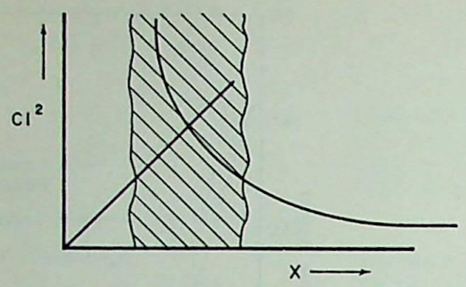

FIG. 18. Matrix element $|C(2p0 \rightarrow 2s0)|^2$ as a function of $x \equiv a_0^2K^2$. The shaded portion is uncertain.

theories. This agreement and the calculation by Baranger led Kivel[72] to expect that the quantum mechanics will also predict an electron-induced shift. The situation in hydrogen is obscured because the atomic levels are nearly degenerate, distant collisions become important, and an artifact such as the Debye shielding to cut off distant collisions must be employed in the calculations. On the other hand, argon presents the difficulty of unknown matrix elements. Helium, having hydrogenlike atomic wave functions and nondegenerate eigenvalues is free of these two problems. The experiment in pure helium, however, is not easy because for elements of low molecular weight it is difficult to heat gas to 20 000 °K and obtain the high free electron densities (10^{17}/cm^3) required. Nevertheless, Seay and Seely[73] of Los Alamos have largely succeeded in carrying it out by using a high explosive driver for their shock tube. The preliminary results are in agreement with the theory when an algebraic error in reference 72 is corrected.

An interesting aspect of this work is that the Born approximation used in the theory gives a reasonable result. Though perhaps somewhat surprising, this reflects the fact that the approximation requires only that the energy of the electron be large compared to the atomic energy separation, and not the atomic binding energies. Also, while the Born approximation fails to some extent for slow electron scattering, in our problem a small error in the electron trajectory is not serious. This same circumstance accounts in general for the success of the classical theories in line-broadening problems, i.e., the Born approximation is close to the classical correspondence limit.

A. Quantum Theory

The line shift might be expected as a matter of course since it arises from the coupling of two states by a perturbation (electron-atom interaction), and such perturbations generally cause coupled states to separate in energy. To deal with this shift quantitatively, we apply a simple correction to the theory of the line width in Sec. VIII where we used the approximation

$$\int f(\omega_f)\frac{e^{i(\omega_i-\omega_f)t+\gamma t}-1}{i(\omega_i-\omega_f)+\gamma}d\omega_f \doteq \pi f(\omega_i). \qquad (10.1)$$

In this formula $f(\omega_f)$ is the collision matrix element integrated over the scattering angle; it depends on $\omega_f \equiv (h/2m)k_f^2$ through the quantity κ, defined in (8.7), which appears in ϵ_{if} and therefore in $f(\omega_f)$. As an example, we reproduce the sketch of $|C(2p0 \rightarrow 2s0)|^2$, which is proportional to $f(\omega_f)$ as a function of the momentum transfer $a_0^2\kappa^2 \equiv x$ given in reference 13 (see Fig. 18). The region of interest in helium is that of large momentum transfers, since the atomic states are not degenerate. Here the close collisions matter, the Debye cutoff does not enter, and the $|C|^2$ dependence on x is known. For hydrogen, however, where the energy levels are close together and the distant collisions become important, the problem is more complicated and is not worked out at this time.

The physical meaning of the decrease in the matrix element with x is that the electron prefers to minimize its momentum change. Consequently, if the electron causes an atomic transition which requires energy (excites the atom) some of this energy will come from the photon (red shift) since the electron is stingy with its own energy change. Similarly for de-exciting collisions the photon will gain energy (blue shift). This is in agreement with simple expectation based on first order perturbation theory where coupled levels repel each other. Figure 19 shows this schematically: the perturbation C changes the optical transitions J in the indicated manner.

Now we return to Eq. (10.1). In view of the slow variation of $f(\omega)$ with ω, Eq. (10.1) is not strictly valid. A more careful evaluation yields an extra, imaginary term on the right, and this term gives rise to a shift, δ_i, of the line.

Quantitatively,[72] the shift (assumed small compared to energy separation; hence the formula given is not valid for hydrogen) is a sum over all coupled states

$$\hbar\delta_i = (hnv_\lambda\sigma_\lambda/3)\sum_{n\neq i}(\omega_{ni}/|\omega_{ni}|)(|\mathbf{r}_{ni}|/a_0)^2, \qquad (10.2)$$

where n=electron density, v_λ=electron velocity, $\sigma_\lambda = \pi(\hbar/mv_\lambda)^2$, $|r_{ni}|^2 = |x_{ni}|^2 + |y_{ni}|^2 + |z_{ni}|^2$, ψ_n=free atom function for eigenvalue E_n with space vector $\mathbf{r}$, and $\hbar\omega_{ni} = E_n - E_i$.

The error in Bethe[74] was the use of $|z_{ni}|^2$ instead of the correct $|\mathbf{r}_{ni}|^2$, as given above. It is interesting that the shift does not depend on the magnitude of the energy separation if the electron has enough energy to excite the transition. For a Maxwell-Boltzmann dis-

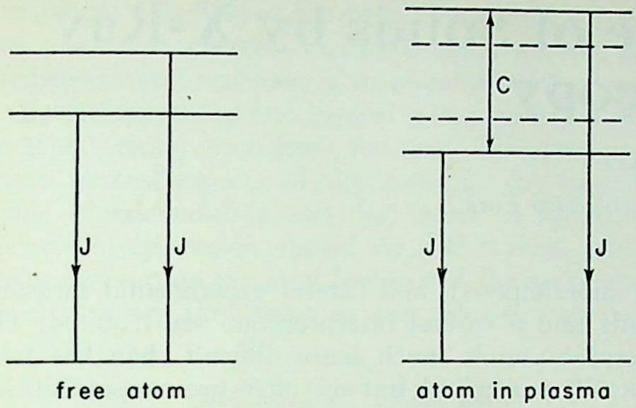

FIG. 19. Energy levels in a plasma.

tribution of velocities we find (δ is in units of sec^{-1}):

$$h\delta_i = 4.55\times10^{-8} hn\left(\frac{e^2}{2a_0kT}\right)^{\frac{1}{2}}\left\{\sum_{E_n>E_i}\left|\frac{\mathbf{r}_{ni}}{a_0}\right|^2 \times\exp(-\hbar\omega_{ni}/kT)-\sum_{E_n<E_i}\left|\frac{\mathbf{r}_{ni}}{a_0}\right|^2\right\}. \quad (10.3)$$

This assumes the Born approximation even for the zero energy electrons.

B. Application to Helium

As a sample application we consider the He line $4s \rightarrow 2p$ at $\lambda = 4713$ A. This is one of the lines studied by Seay and Seely at Los Alamos and has a measured shift to the red estimated to be 25 A when the electron density is $n = 4\times10^{17}/\text{cm}^3$ and the temperature is $T = 20\,000$ °K. This shift is far too large to be accounted for by ions, which produce only a few angstroms. On the other hand, Eq. (10.3) predicts a line shift of about 35 A, as shown below. Considering that the measurement is preliminary and that the calculation uses the Born approximation, this seems to establish the electron effect.

To evaluate Eq. (10.3) we note that the sum over the magnetic quantum number removes the angular dependence[74]; i.e.,

$$\sum_{m'}|\mathbf{r}_{nlm}{}^{n'l+1\,m'}|^2=\frac{l+1}{2l+1}(R_{nl}{}^{n'l+1})^2$$

and

$$\sum_{m'}|\mathbf{r}_{nlm}{}^{n'l-1m'}|^2=\frac{l}{2l+1}(R_{nl}{}^{n'l-1})^2.$$

The radial integrals R are tabulated for hydrogenic wave functions in the quantum mechanical literature.

For the $4s \rightarrow 2p$ transition the most important term in the curly brace is the $4s \rightarrow 4p$ term for which $(R_{4s}{}^{4p})^2 = 540$, $(l+1)/(2l+1) = 1$ and the exponential in Eq. (10.3) is 0.9360, so that there is a contribution of $+505$ (to the red); similarly the transition $4s \rightarrow 5p$ contributes $+56$; $4s \rightarrow 6p$, $+8.4$, $2p \rightarrow 3d$, -4 (to blue); and $2p \rightarrow 2s$, $+9$. The net of all terms with principal quantum number $\leqslant 8$ is 573. The corresponding wavelength shift for $n = 4\times10^{17}$ and $T = 20\,000$ °K ($kT = 1.72$ ev) is

$$\Delta\lambda = \lambda^2\delta/2\pi c = 35 \text{ A}.$$

C. Comparison with Lindholm's Theory

It is interesting to compare this result with that of Lindholm's theory. From Eq. (4.22) we find for the line shift according to Lindholm:

$$u_2 = 9.8\Omega_4{}^{\frac{1}{3}}v^{\frac{1}{3}}n.$$

Considering only the main contributions of $4s-4p$ to the polarization, one finds

$$u_2=\pi^2 nva_0{}^2\left[\frac{|z_{4s,4p}|^2}{a_0{}^2}\frac{e^2/a_0}{hc\Delta\nu}\frac{\alpha c}{v}\right]^{\frac{3}{2}}. \quad (10.4)$$

Since $\alpha = 1/137$, $|z_{4s,4p}|^2 = 180a_0{}^2$, $\Delta\nu_{4s,4p} = 919$ cm^{-1} the line shift for the same values of n and T as in B is about 24 A. We have written (10.4) so that it can be compared with the quantum result, Eq. (10.3), which reads, with retention of the same matrix element,

$$\delta=\pi nva_0{}^2\left[2\frac{|z_{4s,4p}|^2}{a_0{}^2}\left(\frac{\alpha c}{v}\right)^2\right]. \quad (10.5)$$

This gives a shift of 28 A.

Lindholm's theory assumes that the perturber can be localized sufficiently long so that it is reasonable to consider a polarized atom. This is in contrast with our calculation, which assumes the particles to be moving so quickly that the atom is at all times essentially free. Also our treatment which uses the Born approximation is restricted to perturbers with kinetic energy large compared to the atomic energy level separations (e.g., $\Delta\nu_{4s,4p}$).

These two extreme assumptions predict similar effects, since the physical situations being considered lie between their separate provinces. Their agreement makes the magnitude of the result more secure, especially since they are reasonably close to the experimental value.

ACKNOWLEDGMENT

This paper evolved from a technical memorandum written two years ago by Margenau and Landwehr. To Dr. Landwehr we are indebted for the first draft of Secs. II and IX. Dr. Kivel's contribution (see Sec. X) is gratefully acknowledged. After this article had been written, a manuscript and a research memorandum by M. Baranger were received. Unfortunately, their contents, though of great relevance to the problems here discussed, could not be included in this survey.

I. INTRODUCTION

X-RAY spectroscopy provides the most precise and reliable information about the general electronic structure of atoms. This method is likewise powerful in elucidating certain features of the general electronic structure of solids. Metals, semiconductors, and insulators may all be studied alike.

In principle, x-ray emission spectra give a more or less direct view of the outer occupied electronic levels or, rather, of the corresponding energy states of the solid, e.g., the valence band of states; and absorption spectra provide a similar view of the states corresponding to the unoccupied levels. With a combination of emission and absorption spectra, one hopes to see the forbidden energy gap characterizing nonmetals, and to see the Fermi energy for metals. However, what one actually sees is often dominated by the local discrete states set up as a consequence of the inner electron vacancy. The most difficult feature of this x-ray method is that the unperturbed or normal solid-state band spectra and the local discrete state spectra are superimposed, and careful experimental measurements and a careful interpretation are required. The interpretation is much more difficult than has been generally recognized, but also offers greater possibilities.

Another feature of the method is that, in interpreting emission or absorption spectra, due account must be taken of the relative transition probabilities. These probabilities involve the wave-function characters (symmetries) of the initial and final states, in accord with the well-known selection rules. Although it is commonly supposed that the admixture of the various wave-function symmetries is rather great in the valence and conduction bands of solids, it is still not complete. However, with a combination of spectra characterized by two or more different high-energy states, for example with the $K(1s)$ and the $L_{III}(2p)$ spectra, we can determine (again in principle since the interpretation is very difficult) the energy positions, widths, and shapes of the energy levels or bands, and the degree of occupancy of the corresponding outer electronic levels or bands, of any amenable solid.

For the investigation of its x-ray emission spectra the solid specimen is prepared as an anode of the x-ray tube, or as a secondary radiator for fluorescence radiation. For absorption spectral measurements it is prepared as a thin x-ray absorber. All the elements in the periodic table (except hydrogen and helium) can be studied by this method, although for many of them the variety of practical high-energy states is restricted.

Wavelengths employed in this work range from about 0.5 A (~25 000 ev) to about 800 A (~15 ev). There is thus brought into play a wide variety of both old and new experimental techniques, techniques involving the radiation source, diffraction of the beam for monochromatization, dispersion and resolving power, and devices for precise measurement of the x-ray relative intensity.

It is to be understood that this brief review is not intended to be exhaustive; it is intended to introduce and to orient the fundamental aspects of the subject in its present state of development for those physicists, chemists, metallurgists, etc., who have not had time to keep up with it. Other reviews of the subject have recently appeared[1–6] emphasizing the historical de-

velopment and most of the experimental techniques, so we place our greatest emphasis upon current (and perhaps future) problems of interpretation.

Before launching into typical x-ray spectra and the interpretational problems, we first (a) mention the more general aspects of the method, (b) emphasize some experimental factors that must be appreciated before interpretation should be undertaken, and (c) point out certain essential features of the x-ray energy level diagram that have so far received inadequate attention.

II. GENERAL ASPECTS

Advantages and Disadvantages

As compared with other methods for studying the electronic structure of solids, the x-ray spectroscopic method has five significant general advantages:

(1) All types of solids can be studied (metals, semiconductors, insulators, pure elements, compounds, alloy systems, etc.).

(2) Details of the structure are obtained by the use of a relatively narrow high-energy state as a scanning probe.

(3) A wide energy range of the structure is covered giving widths, shapes, and energy positions of many states and bands of states.

(4) The degree of admixture or hybridization of wave-function symmetries is revealed by the use of two different types of inner electron vacancies.

(5) The spectra are relatively insensitive to the chemical impurities, surface states, or other types of lattice defects (except the defect due to the inner electron vacancy itself) which are so troublesome in most solid-state work.[7,8] Two important general disadvantages of the method are (a) the theoretical and experimental techniques for quantitative work are rather exacting, and (b) the problems of separating the two superimposed types of spectra, *viz.*, the unperturbed solid-state band spectra and the local discrete state spectra, have not been generally solved.

The theoretical aspect deserving special mention is the atrocious many-electron nature of x-ray transitions. Numerous simplifying approximations must be adopted for reasons of expediency and the final effects of these approximations remain unknown. Comment must also be made on the very short times involved in x-ray transitions,[9] of the order of 10^{-12} to 10^{-16} sec, making it important in most instances to take time-dependencies into account in the theoretical descriptions of the pertinent states and transitions. On the experimental side, the measurements must be made with the best techniques and with the highest accuracy in order to allow the necessary corrections to be applied with reasonable conviction. These corrections are listed later. Many spectra have been recorded in the literature for which the appropriate corrections are very large and have not been made.

With regard to the second disadvantage, studies of the local discrete states themselves (which we shall call "excitation" states[10]) provide valuable information about the perturbation due to the inner vacancy; such a perturbation becomes an additional tool in solid-state analysis. The excitation states are most easily recognized in absorption spectra with semiconductors and with insulators, although they are probably present also in some emission spectra. They are very much akin to those commercially-important states (in optical fluorescence) associated with an impurity atom.[11]

[7] Since the inner electron vacancy (the essential vacancy for an x-ray transition) involves a relatively high energy, its production is not much affected by the low energies that characterize the bonds in the crystal lattice. It is most improbable that an appreciable fraction of the observed x-ray transitions takes place in the immediate neighborhood of a chemical impurity or other lattice defect (exclusive of the defect due to the inner vacancy itself) unless these defects are present in an *unusually* high concentration.

[8] Another type of impurity, however, is a serious problem. This is the matter of being sure that the material under study is really of the crystalline form desired and is really free of volume and surface contaminants. In emission from an x-ray tube anode, only the first hundred or thousand angstroms of material is sampled, a sampling depth that depends upon the material, geometry and voltage of the anode. The effective temperature of the emitting volume of the anode is difficult to know or to control, especially with a nonmetallic anode, and some physical or chemical change may be unwittingly induced. A thin layer of oxide or sulfide, or a time-dependent layer of tungsten or of a carbonaceous deposit on the anode surface, is often a trial. In x-ray emission in fluorescence, the sampling depth is somewhat greater, the temperature is much easier to know and to control, and generally the physical and chemical state is much better known.

[9] An initial x-ray state may decay either radiatively or nonradiatively. If it decays nonradiatively, an Auger electron, rather than an x-ray photon, is emitted. The probability for radiative decay is called the fluorescence yield (it should be called the "radiative" yield). Values and discussion of this yield are given by Broyles, Thomas, and Haynes, Phys. Rev. 89, 715 (1953); E. H. S. Burhop, *The Auger Effect* (Cambridge University Press, London, 1952). For any state of energy less than about 15 kev, the Auger process is the more probable one and, hence, dominates the state lifetime; and for states of even smaller energy, the radiative probability becomes rapidly less, being less than 0.1 for states of energy less than about 4 kev.

[10] The term "exciton" is commonly used in reference to one type of excitation states in absorption spectra, especially in ultraviolet absorption. "Exciton" is a theoretical term that refers specifically to a coupled electron and positive hole that, as originally proposed by Frenkel, travel as a unit more or less freely around in the lattice. This term has acquired so much of the aura of the theoretical one-electron model that its use is apt to be misleading in practice, especially in the interpretation of x-ray spectra. Further comments on the one-electron model are made later.

[11] The "impurity atom" in the present case is commonly spoken of as one of atomic number $Z+1$ in a lattice site normally containing an atom of atomic number Z. Actually it is somewhere

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Excitation states are discussed further in connection with the energy level diagrams.

Two Energy Regions

Requiring high resolving power (an energy resolution of about 0.1 ev) and accurate measurements of relative intensity (of the order of one percent), this spectroscopic method divides experimentally into two energy regions, with a strong tendency for a corresponding dichotomy of the subject as it appears in the literature.

The division is essentially according to the type of monochromator: For the region roughly 0.5 to 18 A, reasonably perfect crystals (calcite, quartz, mica, etc.) are used either on a two-crystal spectrometer (sometimes called a double crystal spectrometer) or on a focusing instrument in which a single crystal is carefully bent to focus the diffracted beam. For the region roughly 15 to 800 A, ruled concave gratings are used at grazing incidence in a Rowland mount. Vacuum instruments, or instruments whose x-ray path (including any transmission windows) is otherwise made easily penetrable, are employed for wavelengths greater than about 2.8 A.

Another difference between the two regions has to do with the method of measuring the x-ray relative intensity: The precise and reliable photon-counting techniques, especially with the proportional counter,[12] are used most advantageously in the 0.5 to 18 A range. The less accurate photographic techniques are used in the longer wavelength range. However, much work in the former range, especially pioneering work, has been photographic, and some success has been achieved with photon counters in emission work in the latter range. In either range, the photographic method is far better suited for quick surveys of wide spectral regions since only a single exposure is required. It is well known, of course, that the photographic method is well adapted to precise determinations of wavelengths of *well-resolved symmetrical* lines in either range, but a difficult and often impractical procedure must be set up for each exposure in order to translate the photographic blackening to a reliable intensity (or absorption) scale. This fact seriously hampers accurate photographic studies of such spectral properties as widths, shapes and relative intensities. Indeed, reports of such properties, if a reliable scale has not been established, are of very little or no quantitative value.

A third difference between the two regions is in the type of radiation used in absorption work. Continuous x-radiation from a conventional type x-ray tube is evidently too feeble to be practical at the longer wavelengths. Work to date, with one exception, has been done with optical spark lines. An excellent source of continuous radiation is now available from high-energy centripetally accelerated electrons in the orbit in a synchrotron.[13,14] This type of orbit radiation may soon replace the radiation from conventional x-ray tubes in x-ray spectroscopy in *both* wavelength regions, the beam being used directly in absorption work and being used to produce by fluorescence the characteristic emission spectra of any material placed in the beam.

Incidentally, the availability of the continuous radiation from the synchrotron "x-ray tube" will no doubt further stimulate the development of photon or electrical counters for the long wavelength region since this type of measurement system now becomes useful in absorption work as well as in emission. Because of the short pulses of radiation from the synchrotron, such counters will probably have to be arranged to measure an average number of photons per second by means of some integrating device.

III. RESOLVING POWER AND CORRECTIONS

In either energy region, two kinds of resolving power are involved: first, that due to the so-called "spectral window" of the instrument,[15] and, second, that due to the effective width and shape of the high-energy state in the x-ray transition. The central region of the spectral window, in the case of the two-crystal spectrometer, is determined essentially by the lattice type and degree of perfection of the monochromator crystals.[16] The tail regions of the window are usually

between Z and $Z+1$, depending upon the particular inner vacancy, because the screening of an inner electron on an outer electron is less than unity.

[12] The proportional counter, if designed to have a very stable and narrow pulse-height distribution, may be used with a single-channel discriminator to reduce the background intensity and also the intensity of any higher order spectra.

[13] D. H. Tomboulian and P. L. Hartman, Phys. Rev. **102**, 1423 (1956); D. H. Tomboulian and D. Bedo, J. Appl. Phys. **29**, 804 (1958).

[14] L. G. Parratt, Rev. Sci. Instr. **30**, 297(L) (1959).

[15] "Spectral window" refers to the effective *over-all* spectral response of the instrument. If the beam incident upon the spectrometer has a flat spectrum, the spectral window may be interpreted as the function which gives the probability that a photon of energy $h\nu$ will be counted when the spectrometer is set at energy $h\nu_s$. For example, the spectral window of a two-crystal spectrometer includes the effects of (a) the geometry of the horizontal and vertical collimating slits, (b) fluorescent radiation and the diffuse or Compton or other spurious scattering (especially from the second crystal), (c) any higher order spectra, (d) any frequency-dependent attenuation of intensity in the x-ray path in the spectrometer, (e) the relative wavelength sensitivity of the intensity-measurement system, as well as (f) the diffraction pattern of the two crystals in the $(n_A, \pm n_B)$ position of operation. The true spectrum is distorted by the spectral window by an amount that depends upon the window's width *and shape*—the somewhat remote tails of the window's shape cannot be ignored.

The dispersion of the instrument, *viz.*, the spread of an x unit or of an ev in Bragg angular measure or in linear measure along a photographic plate, should not be confused with resolving power, although with some types of instruments dispersion and resolving power are closely related.

[16] Calcite crystals are the traditional favorites, but recently quartz crystals have been shown to have higher resolving power and comparable percent reflection. [Adell, Brogren, and Haeggblom, Arkiv Fysik **7**, 197 (1954)]. Practical attainment of the higher resolving power requires skillful operation of a well-designed instrument. For example, with the two-crystal spectrometer with good quartz crystals, angular increments as small as 0.1 sec of arc must be measured accurately and the axes of the two crystals must be maintained parallel to within a few seconds of arc for *all* angular settings including both the parallel and the antiparallel positions of the instrument.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

determined by a combination of the so-called thermal diffuse scattering and the slit geometry. In the grating spectrograph, the window is usually dominated by the width of the slit. In the case of the focusing bent-crystal instrument, the window is due to some combination of the crystal, slit, scattering, and focusing imperfections.

In the 0.5 to 18 A range, the over-all effective resolving power is usually determined, not by the spectral window, but by the width of the high-energy state. This state width in the 0.5 to 18 A range is of the order of 0.2 to 8 ev at half-maximum, depending upon the particular state and atomic number. On the other hand, in the 40 to 800 A range, the slit is usually the more important; and it is of the order of 0.01 to 0.5 ev wide. In the longer wavelength range, the "smearing" due to the over-all resolving power is often negligibly small, but this is never so in the 0.5 to 18 A range.

The rather large width of the high-energy state in the shorter wavelength range has been considered by many investigators to be a serious disadvantage, often over-compensating for (a) the ease and efficiency of producing the x-rays, (b) the convenience of the more penetrating x-rays, and (c) the precise measuring techniques of the photon counters. Recently, however, methods have been developed[17] for correcting the observed spectra for both kinds of resolving power if (a) the experimental curves are very accurately recorded, and (b) if the width and shape of both the spectral window and the high-energy state are accurately known. With the two-crystal spectrometer the window shape (exclusive of the remote tails) is usually intermediate between Gaussian and Lorentzian; with the ruled grating it is usually more nearly Gaussian. The shape of the high-energy state is commonly taken to be Lorentzian, as due to lifetime, but it also contains a Gaussian component due to lattice vibrations and often a width due to unresolved multiplet states as well.

Corrections to Observed Spectra

In general, several different corrections must be made to the directly observed spectra in order to obtain a reasonably reliable view of the energy level structure of the solid. The most important corrections in the 0.5 to 18 A range are commonly those for resolving power, both for the spectral window and for the high-energy state. In the 15 to 800 A range, often the conversion from photographic blackening to x-ray intensity is the most important correction. In either range, other corrections are also involved. Briefly, the effects for which corrections must be made, and in the order of procedure for making them, are (a) nonlinearity of the intensity scale, (b) instrumental resolving power (spectral window), (c) self-absorption by the material emitting the x-rays, both of the emission line or lines and of the ubiquitous continuous radiation, (d) background under the particular emission contour being studied, (e) satellites (or other "spurious" lines) in emission, and (f) width and shape of the high-energy state either in emission or in absorption. It is presumed that the material emitting or absorbing the x-rays is clean and of known physical and chemical state. In case of mixed materials, correction for the foreign material must also be included in (c), (d), and (e).

The relative importance of each of these six corrections, as well as the details of the correction procedures, depends upon the particular spectrometer or spectrograph used and upon the particular spectra under study. Unfortunately, even a reasonably adequate discussion of these corrections has not been attempted in most of the published work in this subject to date, and this fact has greatly impeded progress in interpretations.

It is significant that now it is possible, in either wavelength range, albeit difficult in some instances, to obtain "experimental" curves in which essentially the product $N_a(E)T(E)$ is plotted *vs* the energy E. In this product, $N_a(E)$ is the density of those states, including the excitation states, having the appropriate wave-function symmetry for the particular transition according to the radiative selection rules, and $T(E)$ is the transition probability. [Logically, $T(E)$ includes the effects of wave-function symmetry, but it is customary, because of the use of the energy level diagram, to place the subscript s or p, etc., on $N(E)$.] If one desires a view of the normal energy band structure of the solid, $N(E)$, unperturbed by the inner electron vacancy and regardless of the wave-function symmetries of the states, corrections for two additional effects must be made: (g) excitation spectra and (h) variations in the transition probabilities, with due regard for wave-function symmetries,[18] for the pertinent transitions

[17] J. O. Porteus and L. G. Parratt (to be published). Preliminary reports appear in Bull. Am. Phys. Soc., Ser. II, 2, 55 (1957); *ibid.* 3, 263 (1958).

[18] For a free atom, the transition probability is proportional to $\nu|M_{i,f}|^2$ in emission and to $1/\nu|M_{i,f}|^2$ in absorption, where $M_{i,f}=\int\Psi_f^*(\partial/\partial x)\Psi_i d\tau$, ν is the radiation frequency, Ψ_i and Ψ_f are the wave functions of the initial and final states, and the integration is over all space. For a solid, a similar expression applies but now the wave functions, especially for a state which contains an outer vacancy (e.g., the final state in emission) or an extra outer electron (e.g., the final state in absorption), are not at all well known, and, in particular, they cannot be assumed to have one-electron properties or even a convenient symmetry for purposes of integration.

As a part of the wave function of the final state in an absorption transition, the wave function of the ejected electron, if it is ejected completely free of the positive hole it leaves behind, is commonly assumed to be that of a plane wave in the lattice. If this assumption is valid, then in the transition probability, the linear momentum of this plane wave electron must be expressed as an angular momentum about the atom from which the electron is ejected.

In emission, the transition probability is proportional to ν, and, hence, the emitted intensity is proportional to ν^2. Some authors have partially corrected for the transition probabilities by dividing the observed intensity by ν^2 (the division by ν^3 by a few authors is evidently in error).[2] By the same argument, the

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

from (or to) each and all states in the bands. With these eight corrections (a) through (h), one would obtain the density of states curve $N(E)$ *vs* E. But we do not yet know how to make corrections (g) and (h) satisfactorily. For example, each solid-state energy level or band contains an admixture of several different symmetries, and correction (h) presumes knowledge of this admixture. At present the most reliable method of obtaining this knowledge is from experimental x-ray spectroscopy with two or more high-energy states of different symmetries. However, in many respects, the degree of admixture is as interesting as the fully corrected $N(E)$ *vs* E curve itself.

Before discussing a few typical experimental spectral curves, let us prepare generally for some of the problems of interpretation. We devote considerable time to the qualitative details of the energy level diagram since it is here that confusion is most apt to arise.

IV. ENERGY LEVEL DIAGRAM

Terminology

At least to the uninitiated there seems always to be confusion among the terms "state," "energy level," "energy level diagram," "energy band," "electronic shell," "orbital," "ordinary x-ray state," "x-ray satellite state," "ionization state," "excitation state," and "electronic level." Let us first try to clarify these terms. This is a major step in the understanding of an energy level diagram.

"State" refers to an assemblage of particles in a particular configuration in a system. The system may be a gaseous atom, a polyatomic molecule, or a localized part of a large piece of liquid or solid material. In a liquid or solid, the degree of localization is determined by the lifetime of the state in question and by the Franck-Condon principle. The energy of a state is also called the energy level in implicit or explicit reference to an energy level diagram. Such a diagram is discussed in detail later. An energy band in a solid (or in a liquid or in a polyatomic molecule) refers to a band of energy levels extremely closely spaced.

Those electrons that are described by the same wave-function characteristics (except for the direction of electron spin) are said to make up, or to be in, one "electronic shell" or "orbital." For example, the $2p_{\frac{1}{2}}$ electrons (called L_{II} or sometimes L_2 electrons) comprise one electronic shell or orbital (called the L_{II} or L_2); so do the $3d_{\frac{1}{2}}$ electrons (called M_{IV} or M_4); etc. The term shell or shells is used especially for the appropriate group or groups of electrons or orbitals in a monatomic gaseous atom and for the inner electrons in a polyatomic molecule, a liquid or a solid, but not very often in reference to the outer electrons in a nonmonatomic system.

It follows that each state of a many-electron assemblage—a gas, liquid, or solid—refers to a configuration of *many* constituent electronic orbitals. It also follows that only an electronic shell or orbital (but *not* a state or band of states or an energy level) can be said to be occupied or unoccupied, i.e., by one or more electrons.

An ordinary x-ray state always refers to an electron configuration in the system in which there is one and only one inner electron vacancy. For this reckoning, any bound electron in the system, except a valence electron,[19] is an inner electron. This definition of an ordinary x-ray state unfortunately excludes the state corresponding to a vacancy in the valence orbitals. In spite of this exclusion, the valence state is, for obvious reasons, always included in the x-ray energy level diagram of ordinary levels.

Two or more inner vacancies correspond to a second- or higher x-ray state, sometimes called an x-ray satellite state.[20] Higher order or satellite states are usually emphasized only in the emission of satellite lines, but they are also of direct interest in absorption spectra.

Any ordinary x-ray state may be an ionization state or it may be one of various types of excitation states. It is an ionization state if the ejected electron is completely free from the Coulomb field of the atom (or ion) in question, and if there is no abnormal configuration of the valence electrons. If the inner electron is ejected from its shell but is not completely free, it remains bound in an orbital outside of the occupied valence orbitals. In this event the system is in one type of excitation state. Excitation states are discussed in detail later.

In this terminology, we refer to the type of many-electron assemblages actually encountered in the interpretation of any and all x-ray spectra. Insofar as the gross features of the *inner* part of the atom are concerned, an x-ray state may be thought of as a "one-electron vacancy state." One of the theorems in atomic spectroscopy says that a one-vacancy system behaves in many respects like a hydrogenic or one-electron system. In hydrogen, it suffices to treat the energy of the system as being the same as the energy of the one electron, and no distinction is made between the electron energy and the system energy. Because of the difficulty of theoretical calculations of a many-electron

observed absorption spectra (properly plotted as absorption coefficients) should be multiplied by ν. These partial corrections are of little importance in the short wavelength range but often change considerably the general shape of either emission or absorption curves in the long wavelength range.

[19] We use the term "valence electron" to refer to any electron in the *outermost* band of electronic orbitals that is normally partially or fully occupied. In this use, we do not separately distinguish a conduction electron in a metal, nor heed the special role of certain valence electrons in the physical or chemical bond in molecules or solids.

[20] This is the conventional definition of an x-ray satellite state, but the exclusion of a valence vacancy as the second vacancy does not mean that the energy of the state is not affected thereby. In fact, if the second vacancy is in what we later call an excitation valence orbital, especially if it has s-type symmetry, it produces a very significant change in the energy of an inner-vacancy state. We shall later refer to such an altered state as one type of x-ray excitation state.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

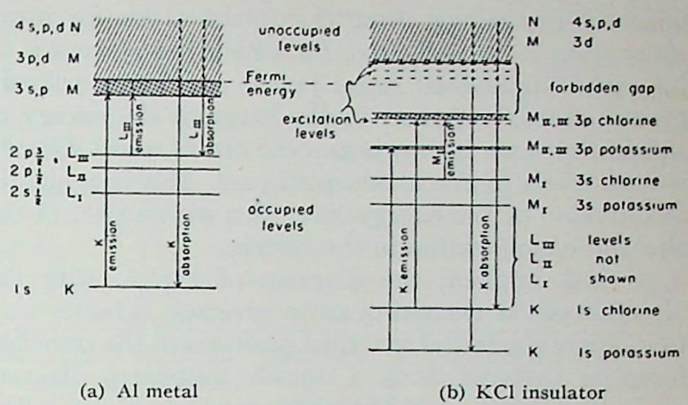
system, the theory of the one-electron approximation is used as the basis of the theory for the many-electron atoms and for the solid state. It is common in solid-state lore to refer to a change in a single electronic level as being simply the change in the energy of the system. This, of course, would be valid if, as *the* electron shifts in its momentum or energy position, there is no shift of any other electron in the system. Actually, in most physical phenomena when examined in some detail, including x-ray spectra, the interaction between electrons is so great as to invalidate this one-electron approximation.

The symbol terminology of the one-electron model, *viz.*, *s*, *p*, *d*, etc. (lower-case letters) to indicate electrons, electronic orbitals, bands of orbitals, states, energy levels, and energy bands, is usually retained in x-ray spectroscopy in spite of the intrinsic many-electron nature of the problems.[21] These one-electron symbols are retained with the implicit understandings that (1) they refer to the *principal* jumping electron in the x-ray transition, (2) they do not indicate an absence of interaction between this principal electron and other electrons in the system, and (3) in applying the radiative selection rules to determine the allowed transitions, the assumption or approximation is made that the change in the angular momentum of the entire system is given by the angular momentum change of just the principal jumping electron, i.e., that no other electron changes its angular momentum. It must be realized that retention of the one-electron symbols carries along a tendency to confuse the many-electron system energy levels with the one-electron system energy levels; *every effort must be made to avoid this confusion*.

"One-Electron-Jump" Diagram

Figure 1 presents a rough sketch of a conventional so-called energy level diagram (a) for a metal and (b) for an insulator. Although this type of diagram contains some confusion and is inherently inadequate, as implied generally above and as pointed out specifically below, it is the one that has been most used in this subject to date and therefore deserves discussion.

By definition, each level in the diagram is supposed to denote the energy of the entire system when one electron is missing from the particular electronic shell or orbital specified in the energy level terminology. It is supposedly a diagram of x-ray ionization states. A few so-called excitation levels are sketched in for the case of the insulator although, as we shall see, inclusion of these states in this type of diagram is somewhat abortive. The principal feature intended, of course, is that the transition arrow give the energy of the photon



(a) Al metal (b) KCl insulator

FIG. 1. Conventional x-ray "energy level" diagram (arbitrary scale) for each of two solids. This type of diagram was devised for a combination of a one-electron-vacancy model and a one-electron model; it is incomplete and misleading (see text).

emitted or absorbed. With a linear energy scale, this energy is interpreted as being the length of the arrow; however, for convenience in x-ray spectroscopy where a wide range of energies is involved, a logarithmic scale is usually used.

The confusion in this diagram appears in both atomic and solid-state work, but it is in solid-state work that it becomes especially serious.[22] We shall presently propose another type of diagram, one that is more complex but that, we believe, has the necessary features to avoid the pitfalls of misinterpretation inherent in the diagram of Fig. 1.

One type of confusion is the following. The lower part of the "occupied" region of the diagram is just an inversion[23] of the diagram conventionally used as a satisfactory approximation in interpreting the gross features of x-ray spectroscopy of the "inner" or high-energy levels. But, in the "occupied" and "unoccupied" regions near the valence and conduction bands, we have deviated from the one-vacancy system and have drawn in the normal or unperturbed solid-state bands in which the effect of the vacancy is ignored. In fact, we usually treat the upper or solid-state part of the diagram as a one-electron system instead of as a one-vacancy system. This composite leads to difficulties when transitions between the lower and upper parts are considered. One difficulty becomes readily apparent

[21] Upper case letters are often used in referring to theoretical x-ray satellite states corresponding to multiple inner vacancies. In this case the electron configuration is presumed to be completely known and to behave as a monatomic many-electron system.

[22] It may be argued that, in a general sense, any diagram is merely a shorthand aid to memory, and if someone finds a particular scheme useful as a memory aid, it cannot be properly called inadequate or inconsistent for him. But diagrams somehow have a penchant for becoming pedagogical and interpretational aids as well as memory aids, and a poor diagram is often definitely harmful.

[23] All the bound stationary states of a hydrogenic or one-electron system are of negative energy, and all unbound or continuum states are positive. In the case of a one-vacancy system, the bound states are properly reckoned as positive. Accordingly, several years ago, before "solid-state spectroscopy," the x-ray diagram was drawn with the *K* state at the top instead of at the bottom. The arrangement with the *K* state at the top is conceptually better for "atomic" x-rays but it does not allow conveniently for the continuum of states. The inverted arrangement of Fig. 1 has been used in deference to the convention in solid state work.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

when it is realized that the initial state for x-ray absorption is actually one for which the system is in its normal unexcited state, i.e., in its "single-valued" ground state,[24] whereas in the diagram the energy of this initial state is drawn as some one of *many different* energy levels in the unoccupied part. This is evidently a confusion of the energy level idea with a part of the electron configuration in the system.

As just implied, the diagram of Fig. 1, with the direction of the transition arrow reversed, is better used to indicate the initial and final positions of the principal jumping electron. Such a one-electron-jump diagram *could* purport to give the energy values of the initial and final states on the argument that each electron configuration, when completely specified, corresponds to a definite energy of the system. The difficulty in this use of the diagram is that there are generally many different electron configurations associated with each inner vacancy, and there may be several different electrons jumping in each transition. For example, it is clear that an excitation energy level exists only because of, and during the lifetime of, the inner electron vacancy. Consequently, when an electron jumps from any occupied orbital to fill the inner vacancy, the excitation level ceases to exist (or changes to a different excitation level), and any electron in the excitation orbital must also jump to some new orbital. In the special event that the inner vacancy is filled by the excitation electron, i.e., by the electron in the excitation orbital, the final vacancy is in no sense in the excitation energy level as this level appears in the diagram. Energy-wise, where did the electron jump from? No transition arrow can be drawn in the conventional diagram to indicate this jump.

X-Ray Excitation States: BEE and VEC Types

A proper x-ray energy level diagram should have a single energy level corresponding to the ground state (which is conveniently called zero energy) as the initial state for each and every x-ray absorption transition; and the final state, being one in which the ejected electron is in any one of many otherwise unoccupied outer electronic orbitals or in the continuum, should be represented as one of *many* high-energy levels. For example, for K absorption, the diagram should show the variety of final-state energies as a type of splitting of the conventional K state, including the continuum of K levels as well as the several discrete K levels. Any one of these many K levels may be the terminus of the head of the arrow representing a K-absorption transition. Similarly, each one of the other conventional x-ray energy levels (L_I, L_{II}, L_{III}, M_I, M_{II}, etc.) should be split into several discrete levels and a continuum. An x-ray state in which the ejected electron resides in one of the bound orbitals is one type of excitation state. To the many possible states of this sort, we assign the descriptive name "bound-ejected-electron" (BEE) excitation states.

Bound-ejected-electron excitation states are commonly produced in x-ray and ultraviolet absorption but are believed to be only rarely produced by bombardment with cathode electrons in an x-ray tube anode. Such states probably dominate the irregular structure observed near the absorption edges, e.g., see Fig. 2 for a curve for a monatomic gas,[25] Fig. 3 for a polyatomic gas, and Fig. 4 for a solid. But, especially in solids, other types of excitation states may also be involved. Since 1920, any observed structure near the "main" absorption edge has been known as Kossel structure.[1,26]

Another type of excitation state was implied earlier, *viz.*, a state in which the system has some abnormal

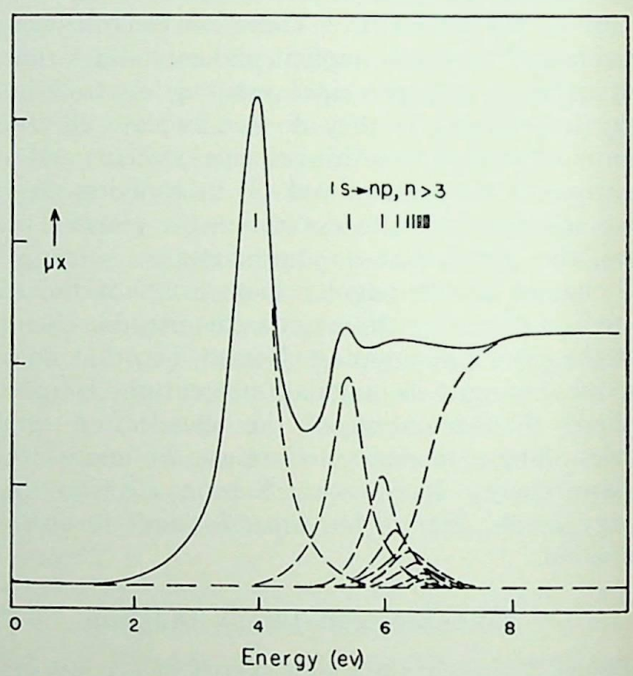


FIG. 2. K-absorption spectra (uncorrected) for gaseous argon [L. G. Parratt, Phys. Rev. **56**, 295 (1939)]. The structure is dominated by bound-ejected-electron excitation states; the "main" absorption edge occurs at the series limit of these states.

configuration of the valence electrons. For many materials, it is highly probable that only the so-called normal configuration of valence electrons is significantly involved. But for some materials, e.g., solids having s-type valence electrons and perhaps an incomplete inner shell (transition metals), the "abnormal" con-

[24] The energy of this ground state is conveniently taken as the zero energy for all kinds of systems—gases, liquids, or solids.

[25] The correction for instrumental resolving power as reported by L. G. Parratt [Phys. Rev. **56**, 295 (1939)] is not quite right as judged by the results of the new correction procedure. The curve in Fig. 2 is not corrected for resolving power.

J. A. Soules and C. H. Shaw [Phys. Rev. **43**, 470 (1959)] also report this absorption spectrum but they evidently have an inadvertent "thickness effect" in their curve. Indeed, many or most of the x-ray absorption curves reported in the literature suffer from this effect. For a discussion of the thickness effect, see Parratt, Hempstead, and Jossem [Phys. Rev. **105**, 1228 (1957)].

figurations are believed to be important. Let us look at the valence electrons more closely.

As the inner vacancy is being produced, a change occurs in the Coulomb field in which all the electrons of the system find themselves. No doubt, the final configuration of all the electrons would be essentially unique (i.e., only the normal configuration) for a given inner vacancy *if* the inner vacancy were formed very slowly and if the electrons were granted a long time in which to readjust to the altered field. But such deliberation is not allowed. The change in the Hamiltonian of the system occurs in less than about 10^{-18} sec, and in consequence of this change all the electrons are forced to change their wave functions. They do so as rapidly

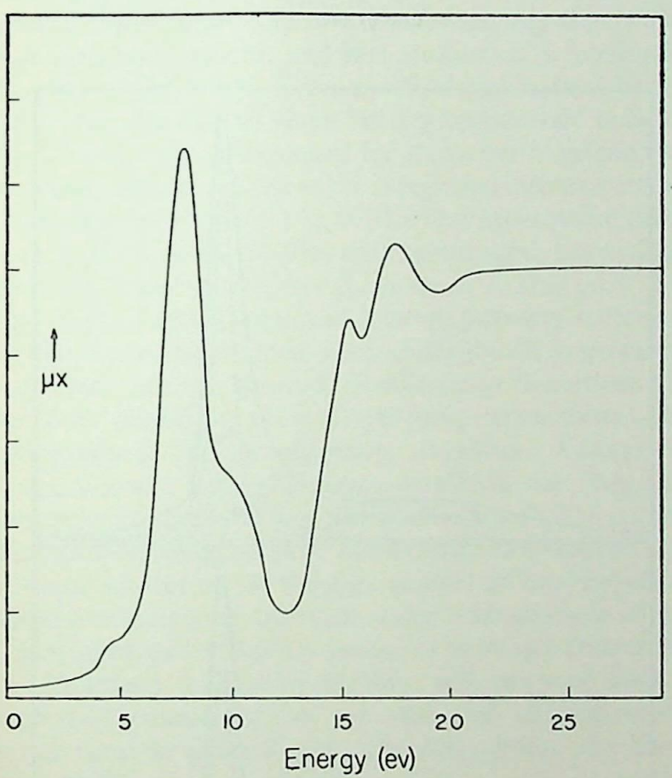

FIG. 3. *K*-absorption spectra (uncorrected) for gaseous chlorine [Stephenson, Krogstad, and Nelson, Phys. Rev. 84, 806 (1951)].

as they are able. Generally, it may be presumed that the inner electrons shift rather quickly to the respective new orbitals closer to the nucleus of the atom in question, but the slow-moving valence electrons may require more time. The alloted time is about the lifetime of the inner vacancy, of the order of 10^{-16} sec for K states. At the termination of this allotted time some of the valence electrons may have succeeded in following the new orbitals and the others may have been obliged to go to an unoccupied excitation orbital[27] or to the unoccupied part of the continuum. The energy of the system depends upon the particular configuration

[27] To illustrate, the 4*s* valence electron of monatomic gaseous potassium may go, upon production of the 1*s* hole, to the 5*s* orbital of the *new* system (i.e., according to the new Hamiltonian) leaving a vacancy in the new 4*s* orbital.

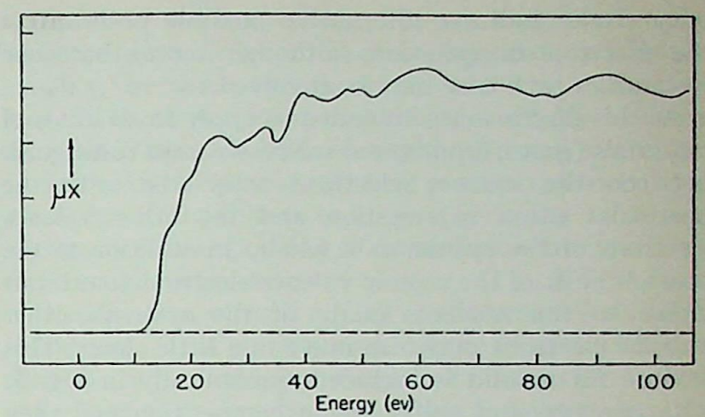

FIG. 4. L_{III} absorption spectra (uncorrected) for metallic silver [L. G. Parratt, Phys. Rev. 54, 99 (1938)].

of these electrons, and different configurations yield different energies. Without commenting further about their relative production probabilities,[28] we shall call these possible different states "valence-electron-configuration" (VEC) excitation states. They are reckoned as excitation states whether or not the inner electron is ejected completely free of the atomic field, although of course the energy depends also upon the particular final position of the ejected electron.

Figure 5 is a rough sketch which symbolizes in simple fashion the type of different electron configurations involved in the bound-ejected-electron and valence-electron-configuration excitation states for a solid. The

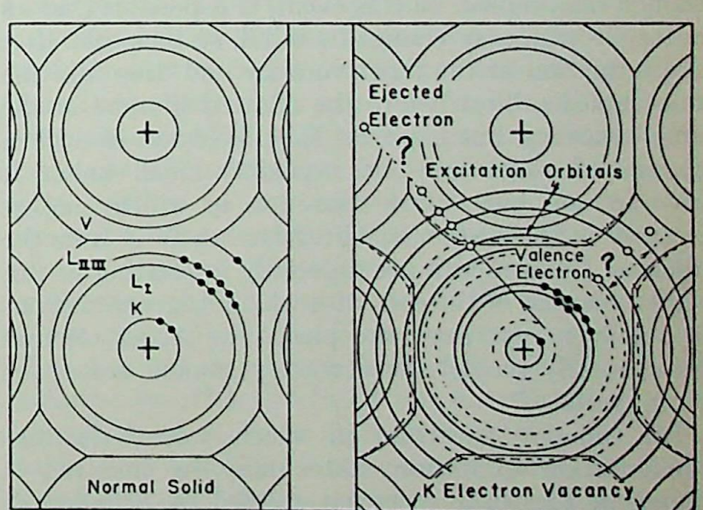

FIG. 5. Symbolic representation of different electron configurations in x-ray excitation states. For clarity, a restricted number of electron orbitals is shown: More than one valence electron and more than one ejected electron may be involved.

[28] There are many eigenvalues in the solution of Schrödinger's equation for a many-electron system following an abrupt change in the Hamiltonian, and we have mentioned only a few of them. This is done with the implied assumption that only a few have significant probabilities of production.

Also, we have chosen to use a semiclassical description of the states (in terms of specific electrons), rather than a general quantum mechanical description; the latter, although formulated exactly in equations, does not have much practical meaning without solution of the as-yet-unsolved many-body problem. Partial solutions of the quantum mechanical problem, using the best-known wave functions, are nevertheless very much needed.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

open circles indicate alternative possible positions of the electron in question, although more than one electron in each case may be involved.

As this discussion is intended to apply to all kinds of materials (gases, liquids, and solids) we must distinguish between the valence electrons associated with the particular atom in question and the other valence electrons of the system as a whole. In addition to the possible shift of the atomic valence electrons to orbitals closer to the nucleus, many of the system's other valence electrons may also move in a little closer. This feature for a solid is included symbolically in Fig. 5. The two types of shifts are in competition and they interact with each other since the objective of each is to shield the charge of the positive hole and thus to destroy the shift motivation. For example, insofar as the far-out excitation orbitals are concerned (corresponding to discrete energy levels in, or near the bottom of, the continuum), the in-flow of system electrons in a metal is expected to be much more important than in an insulator. The shielding thus effected by the system's electrons in a good metal is expected to inhibit especially the relative importance of the bound-ejected-electron excitation states in absorption,[29–31] as well as to alter the relative importance of the valence-electron-configuration excitation states in both absorption and emission.

But whether the system's valence electrons are thus effective or not, the new valence orbitals may be present though unoccupied. In this event, it is possible that an outer electron may change its mind, so to speak, after the formation of the inner vacancy and drop into the unoccupied orbital before the allotted lifetime of the inner vacancy has expired. The likelihood of such a change of mind may be negligibly small unless it involves an Auger-type transition in which another electron in the system is shifted farther away from the nucleus. Good metals are especially interesting in this regard because of the ease with which Auger transitions of small energy may take place, the Auger electron being merely moved the necessary amount across the Fermi surface.[32]

An emission spectrum in which valence-electron-configuration excitation states may be involved is shown in Fig. 6, a spectrum studied by Schnopper[33] with a two-crystal spectrometer. This spectrum is the $K\beta_{1,3}$ region for metallic manganese, the transitions supposedly being $K \rightarrow M_{II,III}$ where the $M_{II,III}$ electrons occupy the shells just inside the partially complete $M_{IV,V}$, N_I shells and the valence electrons in this metal. The directly observed spectral contour (dashed curve) has been corrected for the instrumental

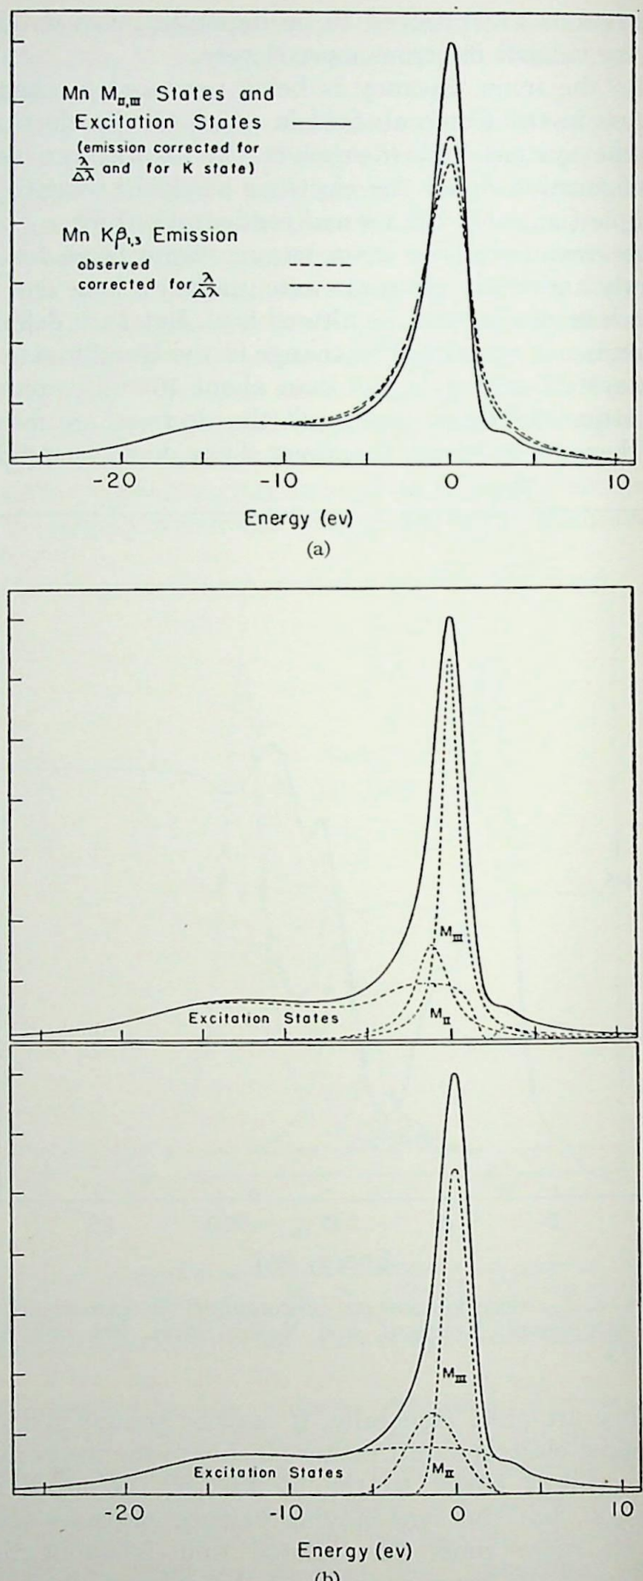

FIG. 6(a). The observed $K\beta_{1,3}$ emission and the $M_{II,III}$ states for metallic manganese. The observed contour is corrected first for the instrumental resolving power and then for the K state to give the M density-of-states contour.

FIG. 6(b). The M density-of-states contour of Fig. 6(a) resolved arbitrarily into conventional M_{II} and M_{III} components, the residue being indicated as excitation states. In the upper figure the M_{II} and M_{III} components are Lorentzian in shape; in the lower figure they are Gaussian.

resolving power,[34] and then corrected for the "resolving power" due to the K state[35] by the method of Porteus and Parratt.[17] The solid curve thus represents the product of the density of p-type states and the transition probability, *viz.*, $N_p(E)T(E)$. The $N_p(E)T(E)$ curve is then shown in the lower two parts of the figure as resolved into three components, M_{II} and M_{III}, and the remaining broad low-energy component indicated as excitation states. This resolution has been carried out first with the assumption that the $M_{II,III}$ states each has a Lorentzian shape, and, then, a Gaussian shape.[36] The excitation states are commonly referred to as the final state for the β_1 line.

The wavelength of a so-called $K\beta'$ component has been reported from photographic measurements by several investigators as near the low-energy side of the low broad component, and this component is commonly known as the β' line. Three possible explanations of the origin of this β' line have been proposed but none of them seems able to account for its rather large relative intensity, about 1.4 times the integrated intensity under the β_1 line as shown in Fig. 6. The first explanation takes it to be a complex satellite corresponding to the double-electron-jump transitions $KL_{II,III} \rightarrow L_IM_{IV,V}$.[37,38] No calculations of the expected relative intensity according to these transitions have been made, but it is generally expected that, in general, double-jump transitions are far less probable than single-jump transitions. For manganese, the single-jump satellites $KL_{II,III} \rightarrow L_{II,III}L_{II,III}$, *viz.*, the $K\alpha_{3,4}$ satellites, are only one percent as intense as the parent $K\alpha_1$ line.[39] The second explanation assigns the β' component to Compton and Raman scattering of the $\beta_{1,3}$ doublet as this radiation attempts to emerge from the x-ray tube anode in which it is generated.[40,41] This requires far more self-absorption in the anode than is reasonable, and, anyway, such a scattered component is not observed accompanying x-ray lines in general, e.g., the $K\alpha_{1,2}$ lines. The third explanation is that splitting of an x-ray state may occur as a result of interaction (angular momentum coupling) between the inner vacancy and an incomplete outer shell of electrons, e.g., the M_{IV} or M_V shell for the transition elements scandium through nickel.[39,42] In general, this type of splitting is expected to be very small and to contribute at most only to the width and asymmetry of the level or of an emission line involving the corresponding state.

It seems that most if not all of the broad low-energy component in Fig. 6 arises from valence-electron-configuration excitation states. Preliminary calculations have shown[43] that, according to this interpretation, the energy intervals and the relative intensity may be of the correct order of magnitude. It is suggested that the observed relative smoothness of this component, i.e., the absence of much obvious structure, is due to the profusion of very closely spaced excitation states and to the continuum of energies of Auger electrons in a metal.

A similar low-energy satellite, $K\beta''$, is observed accompanying the $K\beta_{2,5}$ lines for elements near manganese.[38,44,45] Both the $K\beta'$ and the $K\beta''$ satellites seem to depend somewhat alike on the chemical bonds of the emitting material. It is quite possible that most or all of this $K\beta''$ component should also be assigned to the role of excitation states of the valence-electron-configuration type. Later, it is proposed that most if not all of the asymmetry of the $K\alpha_{1,2}$ lines for these materials is also due to this type of excitation state.

It may be pointed out in our general discussion of excitation states that, in principle at least, another type of excitation state may arise due to the capture of a stray electron that may be just passing through the region, or of an electron from a neighboring atom. Stray capture is very improbable, but it might be considered under certain circumstances, especially for a metal. Capture of another atom's electron, called a cross-transition, has been discussed by several investigators, especially for insulators, but its relative probability has not been well evaluated. Finally, further comment should be made on the state in which there are two or more inner electron vacancies. As stated earlier, such a multiple-inner-vacancy state is the initial state for satellite emission and is of interest in absorption spectra. According to our terminology, these states are not excitation states unless one or more of the

[34] This correction presumes that the central part of the instrumental spectral window is given by the experimental $(1, -1)$ curve which has a full width at half-maximum of 0.6 ev and which has a shape between a Lorentzian and a Gaussian, and that the remote tails (the "flat" component) of the window are a little higher than the Lorentzian. The flat component is best obtained from an analysis of the thickness effect in an absorption curve.

[35] The K state is assumed to be of Lorentzian shape having a full width at half-maximum of 1.05 ev.

[36] In each case, the resolution was made on the assumptions (a) that the full widths at half-maximum of the M_{II} and M_{III} states are 1.2 and 2.4 ev, respectively, and (b) that the relative "intensity," or state-density, at the maximum ordinate is 4 to 1. The two M widths are estimated from the radiative and Auger transition probabilities, and from a sort of "best fit" criterion in effecting the actual resolution. The relative density follows from the ratio of quantum weights, *viz.*, 2 to 1, and from the ratio of widths.

[37] According to this transition, which Sawada[38] interprets as $(K \rightarrow L_I) + (L_{II,III} \rightarrow M_{IV,V})$, this satellite has no obvious "parent" line. Nevertheless, it is customarily called a *low-energy* satellite of $K\beta_{1,3}$.

[45] Unfortunately, studies to date of the shape and relative intensity of the $K\beta''$ and $K\beta_{2,5}$ lines are not reliably quantitative because the corrections as listed earlier have not been made. Careful corrections are imperative for these faint lines that straddle the absorption edge of the emitting material and that appear on a relatively intense sloping background that has absorption-edge structure in it.

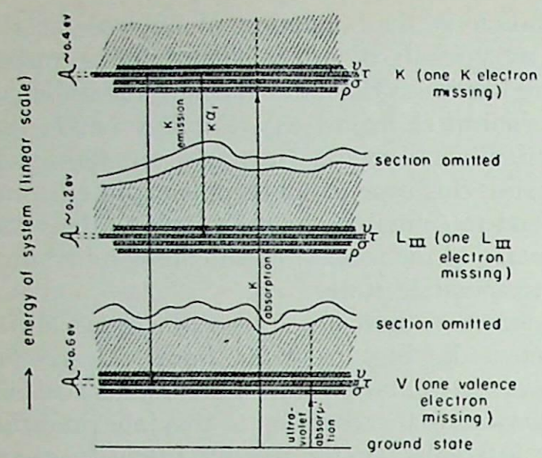

FIG. 7. Part of an x-ray energy level diagram (qualitative) for an insulator. Only a few (of many) discrete states are shown for each type of inner vacancy; each K state, for example, corresponds to a particular electron configuration of *all* the electrons in the system. All the many discrete levels in a given group, e.g., the K group, are involved in absorption spectra, but only one or a few are ordinarily involved significantly in emission spectra (see text). A different continuum of states is shown for *each* type of inner vacancy.

The Ritz-combination principle, according to which the energy of an emission line is the simple difference between two absorption-edge energies, has only qualitative validity; it is not generally valid in detail.

vacancies gives rise to an abnormal configuration of the valence electrons.

Three other phenomena could also be mentioned in this section, all of them of interest in absorption spectra only. These are the interactions of the ejected electron with the other atoms and electrons in a polyatomic system. These interactions—plasma oscillations, and scattering or diffraction—are better discussed later as factors in the transition probabilities, rather than treated as giving rise to separate states.

X-Ray Energy Level Diagram

Figure 7 presents a part of a qualitative energy level diagram which, it is believed, has provisions for the necessary and sufficient complexity to interpret ordinary x-ray spectra. It is designed to avoid the more obvious difficulties encountered with the conventional one-electron-jump type of diagram which is shown in Fig. 1. Figure 7 is drawn for a solid, specifically for an insulator; a similar diagram may be drawn for a metal—the zero energy would appear at or near the bottom of the V (valence) continuum; i.e., near the top of the V_τ band as this band appears in the figure. As compared with Fig. 1, the level arrangement has been inverted; the K group of levels, having the greatest energy, and the energy being positive, appears at the top.

Since the range of spectral energies of primary interest in solid-state work is about the same for all x-ray spectral regions, the diagram is drawn on a linear energy scale. For purposes of illustration, scale sections for only the K, L_{III} and V (valence) groups of levels are shown in Fig. 7, and only a few (four) of the *many* possible discrete levels in each case (except the V case, see later) are shown. A logarithmic scale would again be convenient if the relative energies of many groups of levels of a solid containing an atom of high atomic number were to be indicated coherently in the diagram, but, then, to show the multiplicity of discrete levels due to the splitting, a magnified insert of each group of high-energy levels (e.g., the K group or the L_{III} group) would be required.

The actual separations of the peak positions, the degree of overlap of adjacent states, as well as the relative prominence of the individual members of a split group, are generally not yet known. The diagram of Fig. 7 must be recognized as being merely qualitative in these regards. And a sensible terminology for the various levels in each group must await further knowledge.

Both emission and absorption transitions are indicated. The energy of the system in emission does not include the energy of the ejected electron if it has escaped completely from the system, i.e., escaped from the local region of interest in the solid. But if it has not escaped, it and its energy must be included as part of the system. Although, in principle, all of the discrete states and a few of the continuum states are potentially significant as initial states in emission, it turns out that, in ordinary practice with a conventional x-ray tube, the probability is generally high for a transition from only *one* initial state of a split group (i.e., from only one K state or from only one L_{III} state, etc.). However, this high probability for the involvement of only *one* state in each of the two complex groups of states in emission is *not* correct when the state in question is of low energy, i.e., of energy less than perhaps 20 ev. This point arises again in reference 70.

Let the K level marked "K_τ" refer to the electron configuration in which, conventionally, the K electron has been removed to "infinity" in the solid and left there with zero kinetic energy. (The condition of zero kinetic energy is of interest in absorption transitions only.) It is suggested that this is the significant K level in the ordinary K-emission spectra, whatever is the configuration of electrons appropriate to this level. ("Ordinary K emission spectra" refers to spectra from K states of single inner-vacancy produced by high-energy cathode electron bombardment as in a conventional x-ray tube.) In this sense, we may call K_τ the "unexcited K level."[46] All of the other discrete K levels refer to K states in which a different electron configuration obtains. This different configuration, as already pointed out, may be one in which the ejected K electron is still bound, albeit lightly, to the positive hole it left behind, and/or in which a different number of outer

[46] The terminology here becomes a trifle subtle: This particular K state, K_τ, is an ionization state by definition; all other discrete K states are excitation states, some being excited (but not ionized) on each of two or more counts and some being excited ionization states.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

electrons failed to jump down closer to the atomic nucleus as the electric field changed upon the production of, or subsequent to the production of, the K-electron vacancy.[47] The continuum of levels indicated by the diagonal lines above K_τ in Fig. 7 represent the theoretical normal density-of-states in the so-called unoccupied continuum, but also in this region are some unmarked discrete levels.[48] In the case of a solid, "normal" refers to the theoretical model in which there is no perturbation due to the inner vacancy; any perturbation effects are presumed to be included in the discrete levels or bands. The theoretical normal continuum has maxima and minima in it, and these are supposed to correspond to "Kronig structure" in x-ray absorption spectra, as discussed later.

One measurement of the difference between the energy of K_τ and about the lowest of the bound-ejected-electron excitation states is afforded by a comparison of the energy required to produce the K state when (1) a large excess energy is available in the process and (2) when no excess energy is available. In the case of metallic copper, the former energy is 8985.5 ev[59] and the latter is 8980.7 ev[1].

Again, what has been said about K states also applies in general to states in which the vacancy is in some other shell or orbital, including those states in which the vacancy is in one of the valence orbitals. But the valence states are significantly different.

By definition, the ordinary x-ray energy level diagram gives the energy of the system when one and only one electron has been lost from the shell or orbital designated in the level terminology. This means, in a strict sense, that the *normal* unperturbed valence band of the solid should not be included in the diagram. But the assumption is often made that a vacancy in a normal valence orbital does not significantly perturb the pertinent region of the solid, and hence that it does not significantly perturb the energy or shape of the normal valence band. So, with this assumption, we include the normal valence band in the diagram. This is the band labeled "V_τ" for which the ejected electron is at "infinity" with zero kinetic energy.

By identifying V_τ with the normal valence band, we have pre-empted excitation states, or bands of states, of the valence-electron-configuration type. Unless the perturbation, which is assumed in the previous paragraph to be negligible, is not negligible (or does not remain negligible as the number of valence vacancies increases slightly), all excitation bands are degenerate and are the same as V_τ. The other V bands indicated in Fig. 7—V_σ, V_ν—are representative of the various kinds of bound-ejected-electron excitation bands.

The width and shape of the valence band refer to the density of states regardless of admixed wave-function symmetries and regardless of the probability of position of the positive hole in the band. But, in particular, it may be that in some cases in absorption the position probability is sharply peaked near the top of the band, whereas in emission the vacancy may be more likely near the bottom.[49,30,31] Even if it were preferentially at the bottom initially, e.g., after the jump of a valence excitation electron (from an excitation orbital inside the normal valence orbitals) to an inner vacancy, the hole may tend to "move up" in the band as a consequence of a second valence electron jump, in this instance within the band. Such a double-jump radiative transition is perhaps not very probable.[50] However, it is conceivable that the effective position of the final valence hole may depend upon the particular solid and in some instances may even be time dependent. If such differences in the position probability are real, they are not properly a feature of the diagram *per se*, but rather are part of the transition probability correction (h) as listed earlier.

Another time-dependency feature in the relative transition probabilities has to do with radiationless (Auger) transitions or with the interaction with lattice vibrations, i.e., with phonons. If an inner vacancy state lives long enough for significant Auger or phonon interaction to take place, readjustment of the configuration of the outer electrons may occur in such a way as (a) to quench or partially quench some of the excitation states in favor of others or of the unexcited ionization state, and (b) to alter the wave-function symmetry of an outer bound electron and thus to introduce somewhat different excitation states. These changes in relative transition probabilities are in addition to the Auger broadening of states owing to reduction of lifetime, and also to broadening due directly to lattice vibrations as discussed later.

Of course, if the readjustment of the outer electrons is not part of the radiative transition, the angular momentum of the system must be conserved in the radiative transition itself. The angular momentum, which in absorption includes the angular momentum of any ejected electron *no matter where it is*, must be

---

[47] For example, the proposed states involved in Mn$K\beta'$ emission are among those symbolically represented as ρ and σ states, i.e., $K_{\rho,\sigma} \rightarrow (M_{II,III})_{\rho,\sigma}$, although these states are not intended to be interpretated so specifically in this generalized diagram.

[48] In a more general sense, when our concepts include the interactions among *all* the electrons and nuclei in the solid, no distinction *in kind* need be made between the continuum states and the discrete states either below or in the continuum.

[49] It is common practice in ultraviolet absorption spectroscopy with insulators to depict the first valence excitation band (called an "exciton") as a narrow level instead of as a band. This practice presumes that the position probability of the positive hole in the band is sharply peaked, usually taken as at the top of the band because of the calculated theoretical shapes of the bands or energy *vs* wave vector (one-electron model calculations) and by an application of the principle of conservation of the momentum of the system.

[50] However, Landsberg[32] calculated that the up-movement of the valence positive hole by an Auger or radiationless process in certain metals might take place in less than 10^{-16} sec, a very short time. If the desire for the hole to move up is this great, the double-jump radiative transition may not be so improbable.

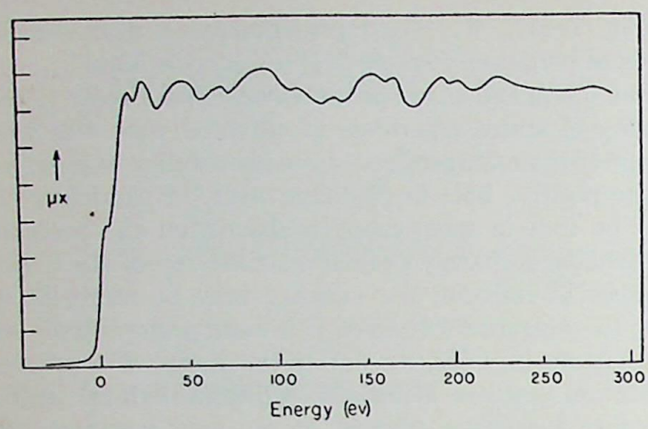

FIG. 8. Extended K-absorption structure (uncorrected) for metallic copper.

reckoned with respect to a reference axis passing through the local atom.

In the case of atoms in an electrically polarized environment, e.g., in a complex ion in a solution or in a solid, many or all of the orbitals of the bound-ejected-electron may be significantly compressed in radii and constrained within a region bounded by a strong localized potential barrier (perhaps by an electrical double-layer). For such atoms, the close-in structure in the absorption spectra are likewise appreciably altered and made much less sensitive to the more remote atomic environment.

Finally, it must be recognized that the diagram of Fig. 7 refers to ordinary x-ray states, and that different but similar diagrams must be drawn for x-ray states involving two (or more) inner electron vacancies. Of course, both emission (satellite) and absorption transitions may be indicated on such diagrams for the multiple-inner-vacancies.

Absorption Spectra: Extended Structure

To recapitulate, the important x-ray states in absorption spectra are (a) bound-ejected-electron excitation states, (b) valence-electron-configuration excitation states, (c) multiple-inner-vacancy states, and (d) the continuum states, including the effects of plasma oscillations and of scattering or diffraction of the ejected electron in the x-ray system. But, generally, the unexcited ionization state, *viz.*, K_τ or L_τ, etc., is *not* significantly involved in absorption spectra close (within say +20 ev) to an absorption discontinuity, notwithstanding widespread elementary notions of the contrary. For the final state in absorption, the geometrical extent of the x-ray system always includes the ejected electron and is therefore usually much larger than is the extent for a state in emission. All the high-up continuum levels are in the diagram for absorption interests only. For emission all these continuum levels become simply K_τ or L_τ, etc., since for them the ejected electron is reckoned simply as having escaped from the system; the energy with which it escaped is of no interest in the energy of the state.

For a monatomic gaseous absorber (e.g., see Fig. 2) *all* K-excitation states of the bound-ejected-electron type appear as levels below the K-ionization level when these levels are presented in a diagram of the type of Fig. 7. In a solid, the K_τ level is proposed as the closest equivalent to the atomic K ionization level. In Fig. 7, one excitation level is drawn above K_τ (or L_τ, etc.); this is partly arbitrary and partly due to the fact that, in a solid, K_τ does not have the simple "series limit" meaning that it has in a monatomic gaseous atom.[51]

In absorption, the relative prominence of the different types of excitation states, compared with the continuum of states, depends upon the particular absorbing material and the particular inner vacancy. For example, for crystalline potassium chloride, discussed later, the excitation states dominate in the region near the "main" K-absorption edge, whereas for metals the excitation states are less prominent. Extended absorption structure, due to scattering or diffraction of the ejected electron, is observed for all polyatomic systems,[52] and, for solids, it seems to be more prominent for metals than for insulators.

Figure 8 illustrates the extended structure typical of crystalline metals. Numerous irregular undulations are observed on the high-energy side of the apparent edge. Although very important in the first 20 ev, the excitation states cannot be responsible for much of the structure 50 or more ev beyond this region. The observed irregularities beyond about 20 ev are commonly referred to as Kronig structure in honor of the first investigator to propose their interpretation (in 1931).[26] According to Kronig, zero absorption is predicted if the ejected electron has such a combination of speed and direction in the crystal lattice that it suffers Bragg reflection[53] from the lattice planes; and a maximum in absorption is predicted if the ejected electron does not have such a combination and does not undergo Bragg reflection. The predicted abrupt changes in absorption become smoothed into mere undulations when various directions in the crystal lattice are simultaneously taken into account. In the band theory of solids, as it developed subsequent to about 1928, a "forbidden" region of energy corresponds to just those values of vector momenta of the electron that allow Bragg reflection (the boundary of a Brillouin zone). An allowed energy

---

[51] There is a strong tendency in the literature for the assumption that a similar or identical series-limit meaning holds in all kinds of absorption spectra. See reference 1 and G. H. Wannier, Phys. Rev. **52**, 191 (1937). Also, Vainshtein, Barinskii, and Narbutt, Zhur. Eksptl. i Teoret. Fiz. **23**, 593 (1952). For a solid, a series-limit for bound ejected-electron excitation states no doubt exists but it is not, in general, coincident with or very near to the bottom of the conventional solid-state unoccupied continuum, nor is it the same limit for different inner vacancies or for different atom species in the solid. This lack of coincidence is due mostly to the respective wave-function extents and symmetries, but partly to the time factors.

[52] H. Peterson, Z. Physik **80**, 258 (1933).

[53] The general scattering or diffraction of the ejected electron becomes Bragg reflection in a crystal if the electron is presumed to be a plane wave in the lattice.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

band is that for which the electron can travel freely through the lattice without reflection. Thus, after the spectra have been corrected for the various effects (a) through (h) listed earlier, and if the entire intensity pattern is considered, instead of merely the positions of the maxima and minima, the observed Kronig structure is just the x-ray absorption view of the theoretical normal density of states in the overlapping unoccupied bands of the solid.

In Kronig theory, the inner vacancy is presumed not to perturb the normal bands in any way. It is probable that the influence of this perturbation is such as to complicate seriously any Kronig interpretation of observed structure within 30 or so ev of the apparent edge, and to be a significant factor as far out as 75 or 100 ev. Also, in Kronig theory, the ejected electron is presumed to be a plane wave, i.e., an electron rather far removed from the vacancy site. Actually, for an x-ray state of short lifetime, the ejected electron does not have time enough to travel very far from the vacancy site (a 50-ev electron of normal effective mass would have time to travel a total distance of only about 4 A in 10^{-16} sec), and the plane wave presumption is perhaps not very good except for the very extended absorption structure.[54]

An extension of Kronig's interpretation has been offered by Hayasi.[55] According to Hayasi, if the Bragg reflection occurs at a Bragg angle near 90°, the ejected electron remains in the vicinity of the inner vacancy as in a type of standing wave pattern. An increase in the absorption probability results because of the greater overlap of the wave functions of the initial and final states. Thus, Hayasi predicts an absorption maximum for some of the energies at which Kronig predicts a minimum, or at least an increased absorption at some of Kronig's minima. In the final state, a "quasi-stationary" state as Hayasi calls it, the ejected electron is, in a sense, bound to the positive hole it left behind, and, in another sense, the electron is in a forbidden energy region in the solid. Insofar as the electron is bound to the positive hole, the final state is one form of what we have called an excitation state. Hayasi, like Kronig, ignores the lattice perturbation due to the inner vacancy. Moreover, for a short-lived inner-vacancy state, the ejected electron does not have time to establish itself as a very respectable standing wave.[56] For comparison with experiment we need more detailed and quantitative calculations on the basis of Hayasi's proposal, with inclusion of the vacancy perturbation, the time-dependencies, and all directions of ejection in the lattice.

Efforts to explain the observed details of absorption curves on the basis of Kronig's interpretation have resulted in some but not complete success. Hayasi's modifications may possibly help. The excitation states will probably account for most of the structure in the close-in regions. But it is quite likely that additional processes are involved in the complete explanation. It has been suggested that a correlation exists between the x-ray absorption structure and the discrete loss of energy of electrons as they penetrate thin solid foils.[57] We may distinguish two types of discrete energy loss. The first is in the production of multiple inner-vacancy states. In any type of absorber, the interaction of the electromagnetic field with the system may result in the ejection of two (or more) electrons from an atom instead of just one electron. One or both ejected electrons may come to rest in an orbital or orbitals still bound to the *two* positive holes left behind. Or the second electron may come from a different atom in the system. In any of these cases, the secondary electron-jump absorbs a discrete amount, or at least a minimum amount, of energy and provides an additional way in which the system can absorb the energy of the incident x-ray photon. (The minimum amount of energy absorbed by the secondary jump is essentially zero only for the special case of an electron at the Fermi surface in a metal.) When the photon energy and system are such that the probability for the secondary jump is reasonably high, the absorption should exhibit an increase.[58] There are many potential secondary electrons in a solid, and the discrete amounts of energy become very numerous when more than one secondary electron and more than one atom are considered. The absorption structure due to the production of multiple-vacancy states may indeed show only one or two maxima and an accompanying broad absorption tail of unresolved components.

The second process for a discrete loss of energy is by the induction of plasma oscillations. The ejected electron as it traverses the crystal interacts with the loosely bound valence electrons in such a way that the electrons oscillate collectively. The energy of the oscillation is taken from the absorbed photon via the kinetic energy of the ejected electron. If more than one mode of oscillation is induced, the electron loses more than one discrete unit of loss energy, and if more than one oscillation of a given mode is induced, the electron loses a multiple of a discrete unit. As in the case of

[54] In a recent paper, Shiraiwa, Ishimura, and Sawada [J. Phys. Soc. Japan **13**, 847 (1958)], discuss a modification of Kronig's theory by allowing the amplitude of the wave of the ejected electron to decrease rapidly with distance from the parent atom.

[55] T. Hayasi, Sci. Repts, Tôhoku Univ. **33**, 123, 183 (1949); **34**, 185 (1951); **36**, 225 (1952).

[56] To the degree that the general position of the Hayasi electron is localized, the uncertainty principle argues further against its being a plane wave with well-defined momentum. The Hayasi reflection at best should be considered as "quasi."

[57] E.g., see Leder, Mendlowitz, and Marton, Phys. Rev. **101**, 1460 (1956); Revs. Modern Phys. **28**, 172 (1956); E. J. Sternglass, Nature **178**, 1387 (1956); D. Pines, Revs. Modern Phys. **28**, 184 (1956); R. H. Ritchie, Phys. Rev. **106**, 874 (1957).

[58] Production of multiple-vacancy states in gaseous absorbers should be about as probable as in, say, ionic crystalline absorbers. Reports indicate very little absorption structure for gases that can be attributed to multiple vacancies. For this reason these states may not play a very significant role in absorption, but the argument is not generally conclusive.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

ejection of a second electron, plasma-oscillation production represents an additional way in which the system can divert the energy of the x-ray photon. An increase in the absorption probability results for those particular photon energies properly tuned.

The energy spectrum of x-ray photo-ejected K electrons from metallic copper has been analyzed magnetically[59] and found to consist of a secondary maximum and a long low-energy tail. It is not yet clear which of the two types of inelastic scattering of electrons is primarily responsible for the observed structure.

As implied earlier, these two discrete-loss processes also take place when no primary inner electron vacancy is produced; in fact, this is normally the situation in the experiments of penetration of electrons through thin solid foils.[57] But the probability with which each process takes place is believed to be increased when the primary inner vacancy is made at the same time. For example, in producing the multiple-vacancy state, the primary electron ejection may, by the abrupt change of the Hamiltonian of the system, trigger the secondary electron jump. This may be especially so in case the secondary electron is a valence electron. (In case the second vacancy is in the valence band, the state would be, according to our terminology, a valence-electron-configuration state.)

In each of the aforementioned possible factors in the interpretation of the extended structure in absorption, a reference "zero energy" is involved. It is usually very difficult or impractical to disentangle this zero energy from the observed structure with the requisite accuracy to make definitive correlations between experiment and theory. To date, only the maxima and minima in the structure have been considered. It would be much more informative if complete absorption patterns were correlated. Then we could better see what absorption remains to be accounted for by additional processes such as discrete loss.

Widths and Lifetimes of X-Ray States

With a sufficiently open energy scale, preferably linear, the width (and the gross shape) of at least one member of each group of levels may be conveniently shown on one side of the diagram of Fig. 7. It should be mentioned that the level width and shape in the case of crystalline solid materials should include the effects of lattice vibrations at a particular temperature. These effects are discussed in some detail later in connection with the interpretations of the spectral curves for potassium chloride. Typically, lattice vibrations at a temperature of about 300°K contribute a few tenths of an ev (or less) to the full width at half-maximum, and contribute a Gaussian factor in the shape. The numerical values of widths indicated in Fig. 7 are about right for chlorine in crystalline potassium chloride if the effects of lattice vibrations are neglected.

The widths of the energy levels corresponding to a few inner-vacancy-states, excluding the effects of lattice vibrations, are given in Table I. These widths, deduced from measurements with the two-crystal type of spectrometer whose resolving power is rather well known, are believed to be essentially atomic values, i.e., unperturbed by (or else corrected for) the physical or chemical environment. Corrections have been made for the instrumental spectral window, for the backgrounds, and for the overlapping lines.

Determination of the lifetime of a state follows from the width according to the uncertainty relation $\Delta t \Delta E \simeq h/2\pi$; a full width at half-maximum of $\Delta E = 1$ ev corresponds to a lifetime of $\Delta t \doteq 6.6 \times 10^{-16}$ sec.

The K width for gaseous argon, 0.5 ± 0.05 ev, obtained from the K-absorption transition $K \rightarrow N_{II,III}$ (or $1s \rightarrow 4p$), is perhaps the most reliable value in the table, and this serves as a sort of anchor point in the determinations of some of the other values.[60] This argon K width is reasonably consistent with the combination of (a) experimental values of the fluoresence yield, and (b) a calculation for the sum of the theoretical radiative transition probabilities.[61] The K and L_{III} widths for gold were taken from the width of the respective absorption edge.[62] This is admittedly not a reliable method for obtaining a level width because of the unknown role of component structure due to the excitation states. However, it happens that both of these gold widths are in fairly good agreement with the calculated theoretical values.[62,63] Furthermore, for the gold L_{III} width, the consistency argument of Richtmyer, Barnes, and Ramberg is reasonably persuasive. (This argument considers the widths of *many* different emission lines.) The same type of argument supports the silver values.[64,65] For every element in the table other than argon and gold, the state widths were obtained from the $K\alpha_1$ emission line. All emitters were

[65] As judged now with benefit of the new correction procedures,[17] a small over-correction for the instrumental spectral window was reported in reference 64 for most of the silver L series lines. The corrections reported in reference 62 for the gold L lines are also rather dubious, but this is not of great importance now.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

solids[39] except krypton which was gaseous.[66] For titanium, manganese, and copper, the $K\alpha_1$ line is markedly asymmetrical and correction for this asymmetry is discussed in the next paragraph. In each case, the corrected line width was divided between the K and L_{III} states, each state being assumed to be a singlet and of Lorentzian shape. In making the division, two criteria were kept in mind: (1) the radiative components of the K widths should be a reasonably simple function of atomic number Z, and (2) the ratio of the width of the K-radiative component divided by the total K width should agree reasonably well for each Z with the experimental value of the fluorescence yield.[67] The K-radiative widths so obtained are listed in Table II. The K fluorescence yields by this method are also listed. It turns out that the dependence of the radiative width on the atomic number is in good accord with the theoretical Z^4 prediction.[68] (The radiative component of the L_{III} width is very small, much less than the uncertainty in the total L_{III} width.)

As stated in the foregoing, the $K\alpha_1$ lines for titanium, manganese, and copper (and, of course, for some other elements not included in the table) are asymmetrical in shape. When the widths and asymmetries of these lines are each plotted *vs* atomic number through the range $Z=16$ to 42, it becomes obvious that the apparent excess width is closely related to the asymmetry.[39] Illustration of the line shape, after correction for everything except asymmetry, is given in Fig. 9. It is proposed that the excess width on the low-energy side is essentially attributable to transitions between excitation states of the valence-electron-configuration type, just as in the case of the β' structure in the Mn$K\beta_{1,3}$ region discussed earlier.[69] Tentative calculations show

that the energy separations between K_τ and the pertinent K excitation states, between $(L_{III})_\tau$ and the pertinent L_{III}-excitation states, and between the $(M_{III})_\tau$ and the pertinent M_{III}-excitation states, are such that now we observe mere asymmetry instead of the plateau region observed in the $\beta_{1,3}$ region. The line from the transition $K_\tau \rightarrow (L_{III})_\tau$ is presumed to be symmetrical and to be obtained by subtracting the mirror image of the high-energy side of the maximum ordinate of the corrected observed curve from the low-energy side. It is the width of this symmetrical component that is used in deducing the K and L_{III} level widths.[70]

In support of this analysis of the asymmetry are the facts that the widths so corrected for asymmetry have a fairly smooth dependence on atomic number over a range of Z that includes both symmetrical and asymmetrical lines, and that the radiative component of the K width varies as Z^4. In support of the contention that these widths are essentially atomic, i.e., relatively free

[66] E. Wilhelmy, Z. Physik **97**, 312 (1935).

[67] Broyles, Thomas, and Haynes, Phys. Rev. **89**, 715 (1953); E. S. Burhop, *The Auger Effect* (Cambridge University Press, London, 1952).

[68] The report by W. H. Zinn [Phys. Rev. **46**, 659 (1934)] of a Z^4 dependence of the *total* widths is based on measurements of the widths of absorption edges that are evidently replete with excitation structure. These measurements are not reliably interpreted in terms of level widths. Typical of this difficulty, Zinn used the "corrected" K-level width for silver as 25 ev, whereas its actual value is near 7.5 ev. However, the Z^4 prediction is expected to be fairly good for reliable total widths when the Auger contribution is small, as for K widths for $Z \gtrsim 45$.

[69] Some of the asymmetry may be due to the other effects mentioned in connection with the $K_{1,3}$ region, *viz.*, unidentified satellites, Compton and Raman scattering, and interaction between the inner L_{III} vacancy and the incomplete $M_{IV,V}$ electron shells. However, these effects are here presumed to be of negligible importance; but whether they are or not is not relevent to the present argument for obtaining the level width. The pertinent assumption is that all such effects distort the line $K_\tau \rightarrow (L_{III})_\tau$ on only one side.

[70] A final caution may be expressed in regards the numerical widths of x-ray energy levels. If, as is supposed, the excitation states are responsible for asymmetry in an emission line, these states may also contribute to the width of the symmetrical component of the line. In other words, the widths as listed in Tables I and II for single energy levels may be a little too great. If the symmetrical part of an apparently single energy level is itself the sum of several closely spaced narrower components, then, even if each component is of Lorentzian shape, the symmetrical component may be expected to be non-Lorentzian, perhaps more nearly Gaussian. Thus, in the question as to whether the width in Tables I and II is about right for a single state or refers to the width of a composite of excitation states, we find two experimental features of interest: (1) the relative magnitude of the width, and (2) the shape of the state. As judged from present information, the K and L_{III} state widths as listed seem to refer in each case to essentially singlet states, but the evidence is not clear in the cases of M, N, etc., states. E.g., the $M_{II,III}$ states of Fig. 6 are wider than the K state for manganese, and the $M_{II,III}$ states may well be Gaussian in shape. These M states may be wide because of (a) a high probability for Auger transitions, (b) phonon interactions (discussed later), or (c) static interactions of neighboring atoms (solid-state broadening).

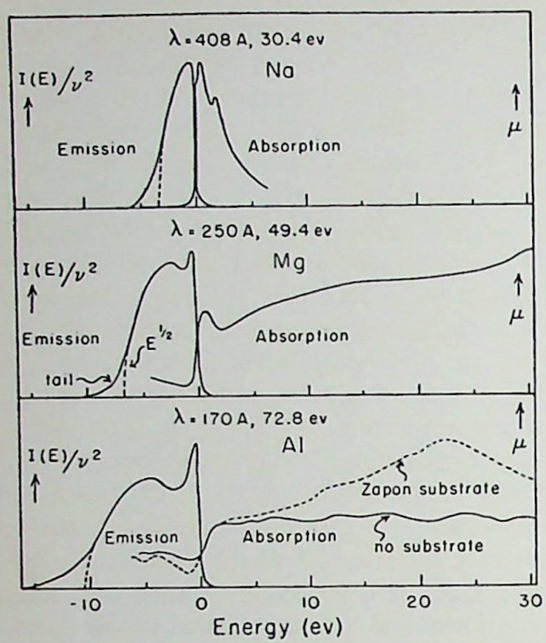

FIG. 10. L_{III} emission and absorption spectra for metallic sodium, magnesium, and aluminum. The same energy-interval scale is used for all the curves; zero is taken as at the estimated position of the Fermi energy. The curves are taken from various authors.[71]

of solid-state effects, is the fact that the gases argon and krypton are included in this atomic number dependence without distinction from the solids.

V. EXPERIMENTAL CURVES AND INTERPRETATIONS

The work in this subject is far too extensive and intensive to be summarized adequately in a few pages. In the preceding sections, only a few topics were selected for discussion; and, in this section, only a few additional curves are selected as illustrative of the experimental results and interpretations.

The interpretations are not clean-cut, in general. For the most part, the corrections listed earlier have not been made to the observed spectral curves; and, in particular, the recognition and use of excitation states is relatively new. A few satisfactory features can be pointed out, but the reader is warned to expect some confusion. An interpretational "break-through," however, may not be far away.

Sodium, Magnesium, and Aluminum

First, we mention briefly the L_{III} spectra of metallic sodium, magnesium, and aluminum. These spectral curves, reproduced in Fig. 10 from various authors,[71] were obtained with sufficiently high resolving power that no correction for this effect need be made. Also, great care was taken (except possibly in the case of sodium absorption) to translate the observed blackening of the photographic plates to an x-ray intensity (or absorption) scale.

There are several features of interest in these curves, but to see them in perspective we first recall the general electronic aspect of these solids. The electron configuration of atomic sodium, atomic number 11, is $1s^2 2s^2 2p^6 3s$ in which the $3s$ electron is nominally in the solid-state valence band, i.e., in the occupied part of the conduction band. For magnesium, atomic number 12, we find two nominal $3s$ electrons; and for aluminum, atomic number 13, we add one more electron, this time in the nominal $3p$ band. It is the combination of $3s$ and $3p$ bands from which the electron comes to fill the inner L_{III} vacancy in the L_{III} emission transition.

The dipole selection rule dictates that only an electron having wave-function symmetry of s type or d type, as viewed from the L_{III} vacancy, may fall radiatively into the L_{III} vacancy (p-type symmetry). Hence, to the extent that the nominal $3p$ band is involved, there must be admixture of s- and/or d-type symmetries in it.[72,73] The selection rule actually applies to the wave functions of the *states*, but, as pointed out earlier, interpretation of this rule in terms of the one-electron model suffices if the primary jumping electron is the only electron in the entire system whose angular momentum changes.

In the electron configuration for sodium, the nominal $3s$ band is half occupied; hence, sodium is a good conductor. The $3s$ band in magnesium is fully occupied and, hence, since magnesium is a good conductor, the $3s$ and $3p$ bands must overlap. Aluminum is a metal because the $3p$ band is only partially occupied. Magnesium has a different crystal structure than sodium and aluminum, but theoretical calculations suggest that the overlap is similar for all three of these metals, the principal difference being in the measure of occupancy. The so-called reduced width of each emission band (i.e., the base width corrected for the "tail" as indicated by the respective dashed curve in the figure) is conventionally taken as a measure of the occupancy of the $3s$, $3p$ bands. The energy widths of the $3s$, $3p$ bands, as obtained directly from the measured bands, are 3.05, 6.4 and 10.6 ev, respectively, and this is interpreted as showing the increase of electron occupancy as we go from sodium to aluminum. It is possible that the role of excitation states is not important in the width and shape of these curves, but, on the other hand, it is conceivable that the valence-electron-configuration type of excitation states do influence the curves in some manner similar to that discussed earlier for the Mn$K\beta_{1,3}$ region. If the excitation states are important, then only the relative magnitudes of the observed widths may be significant in showing relative

[71] The emission curves are taken from W. M. Cady and D. H. Tomboulian, Phys. Rev. 59, 381 (1941); the absorption curves from H. M. O'Bryan, Phys. Rev. 57, 557, 995 (1940), J. R. Townsend, Phys. Rev. 92, 556 (1953), and D. H. Tomboulian and E. M. Pell, Phys. Rev. 83, 1196 (1951).

[72] Although for quadrupole radiation, p to p transitions are allowed, this radiation is very feeble compared with dipole radiation.

[73] It is also important to note that, at least in hydrogenic theory, the transition probability for p to s is much less than (of the order of one-tenth) for p to d.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

electron occupancy, not the numerical magnitudes themselves.

The narrow spike observed at the high-energy side of the emission band for both magnesium and aluminum is conventionally explained as a sharp rise in the density of $3p$ states just before the top of the $3s$ band is reached.[74] The spike is markedly higher for aluminum. This explanation requires that there be a *very* large admixture of *s*- and/or *d*-type electrons in the bottom part of the $3p$-electronic band. The theoretical density of states, according to the one-electron model, with complete disregard for the wave-function symmetries, i.e., for the transition probabilities, is indeed much like the observed emission curves for all three metals with the Fermi energy appropriately placed. But the calculations have not yet succeeded in giving the degree of admixture of wave-function symmetries of the electrons, or of indicating the role of the possible excitation states. These facts should be taken into account before the explanation of the spike or of the general shape of the curve is considered to be satisfactory.

Next we note that the edge of each of the observed emission bands at the Fermi energy is abrupt, as expected from the degenerate-electron gas theory if the inner electron vacancy causes no perturbation. Indeed, when the small corrections are made for the spectral window of the spectrograph and for the width of the initial L_{III} state, the remaining width of the observed emission edge has been attributed to the effect of the thermal motion of the electrons of the emitting anode.[75,76] Reckoned as between the 5% and 95% points on the edge, the temperature width as deduced from the Fermi distribution formula is 0.06 ev at 110°K, and is 0.45 ev at 670°K. The experimental widths at each of several temperatures in this range are found to be in agreement with these theoretically predicted values.[77,75] However, these three metals are most unusual, apparently unique, in that their L_{III} spectra exhibit this abrupt emission edge, an edge that corresponds so nicely to the Fermi surface predicted theoretically for unperturbed metals. This prediction for metals is based on an assumption that the Fermi surface does not touch a zone boundary.[78]

The long tail on the low-energy side of each of these emission bands (some 8% or more of the total band intensity) is at least partially accounted for, according to Skinner[75] and Landsberg,[32] by Auger transitions that occur as the final-state positive hole "bubbles up" from near the bottom of the occupied part of the valence or conduction band of electronic "levels." In this explanation, the Auger process greatly reduces the lifetime of each of the low-lying levels in the band, and the width of each level is correspondingly increased; the tail is thus simply the lower side of the symmetrical spread of each low-lying level. According to this Auger explanation, the intensity in the tail appears at the expense of intensity in the rest of the band, particularly in the lower half. Hence, if a large part of the tail were to be thus explained, the corresponding redistribution of intensity in the band proper would somewhat invalidate the popular comparison of the reduced band shape with the free-electron parabolic relation $I/(\nu)^2$ *vs* $E^{\frac{1}{2}}$ (or *vs* $E^{\frac{3}{2}}$ in the case of *K*-band emission). Other proposals to account for this tail, or part of it, have also been made.[79]

In Seitz's proposal[79] the tail may be due to a series of occupied excitation orbitals just below the valence band. Accordingly, a photon of slightly lower energy is emitted if the primary-jumping electron comes from an occupied excitation orbital instead of from the normal valence band. In these two possible types of transitions, the initial states of the system are presumably the same, and the final state in *each* case is one in which the positive hole is in the valence band. Hence, the proposal must be essentially that the energy position

---

[74] For sodium, there is no evidence in the curve of Fig. 10 for the $3s$, $3p$ band overlap according to this interpretation, but a suggestion of such overlap is seen in Skinner's curves [H. W. B. Skinner, Phil. Trans. Roy Soc. London **A239**, 95 (1940)]. Also, this suggestion appears in a recent work by Fisher, Crisp, and Williams (private communication).

[75] H. W. B. Skinner, Phil. Trans. Roy. Soc. London **A239**, 95 (1940).

[76] This is one of the very few cases in the long wavelength region in which correction for either type of resolving power has been attempted.

[77] Incidentally, it is a truly remarkable experimental accomplishment to know the temperature of the local regions of the anode emitting the x-rays, and also to carry out the necessary photographic procedures across such a steep edge to obtain a *reliable* intensity curve.

This interpretation of the edgewidth does not take into account the effects of lattice vibrations, discussed later in connection with the potassium chloride curves, nor of self-absorption in the x-ray tube anode.

[78] It is often said that lithium, sodium, and potassium are our most nearly ideal metals, ideal in the sense of meeting some of the conditions assumed in a theoretical treatment. Lithium *K* emission does not show an abrupt edge [D. E. Bedo and D. H. Tomboulian, Phys. Rev. **109**, 35 (1958)], and this may possibly be accounted for, according to Dr. V. Heine (private communication), if the Fermi surface touches a zone boundary. Potassium *K* emission, although recorded [E. L. Jossem and L. G. Parratt, Phys. Rev. **98**, 1151 (1955)], awaits corrections (especially for the resolving power due to the *K* state, for self-absorption and for the background due to the $K\beta_1$ line) before the answer can be definite. There is a suggestion of the type of distortion observed with lithium. Lack of abruptness in these cases may possibly be attributed, in addition to the distortion due the Fermi surface touching the zone boundary, to the role of excitation states or to the nominal *s* and *d* types of symmetry in the conduction band. Since the final state in *K* emission must have *p*-type symmetry, the experimental curves tell us the actual (admixed) *p*-type distribution only.

Dr. S. E. Williams, University of Western Australia, reports (private communication) a new observation that the L_{III} emission of potassium metal may also be abrupt, having a width of "0.22 ev including the instrumental width at 1 A resolution." He estimates that his potassium target was at a temperature near its melting point.

R. H. Kingston [Phys. Rev. **84**, 944 (1951)] reports the *M*-emission edge of potassium metal to be rather sharp also.

of the positive hole is lower in the band when the jump occurs from one of the excitation orbitals than it is when the jump occurs from the normal band.[80] This sort of argument is also discussed (with an indefinite conclusion) in the case of K emission of potassium chloride by Parratt and Jossem[31] where the excitation spectra are presumed to be more intense than the normal band spectra. [As to the expected relative intensity of these two types of spectra, note that the transition probability (independent of relative quantum weights) in each case is proportional to the degree of overlap of the wave functions of the initial and final states, and that the overlap is greater for the excitation spectra simply because the excitation orbital is closer (more tightly bound) to the nucleus.]

If Seitz's proposal were interpreted as implying different initial and final states for the two different radiative transitions, as different valence-electron-configuration excitation states, the explanation of the tail would be essentially the same as is discussed earlier for the $K\beta'$ "tail" in the Mn$K\beta_{1,3}$ region of Fig. 6, and suggested also for the $K\beta''$ satellite accompanying the $K\beta_{2,5}$ lines and for the asymmetry of the $K\alpha_{1,2}$ lines. Indeed, with this interpretation, the significance of the "reduced width" scheme by which the tail is separated from the main emission band, becomes artificial, and we are really talking about the shape of the emission as a whole.

It is conceivable that, if the Skinner-Landsberg explanation of the low-energy tail is even qualitatively correct, the symmetrical Auger-broadening of the states in the band must be sufficient also to produce at least some of the small but definite tail observed on the high-energy side of the band, even though the states in the uppermost part of the band are themselves negligibly broadened. However, Skinner has proposed another explanation,[75] *viz.*, that this high-energy tail is due to the "satellite" band $L_{III}M \rightarrow MM$, i.e., to the transition between an initial state containing both an L_{III} and an M vacancy and a final state containing two M vacancies. According to the usual satellite argument for states of double (or multiple) *inner* vacancy, the unscreened or residual electrical field, which is present as a consequence of the extra inner vacancy, produces a little extra energy in both the initial and final states in such respective amounts that the emitted satellite photon has a slightly greater energy. Note, however, that the extra M vacancy in the case of any of the present three metals is a vacancy in the valence or occupied part of the $3s$, $3p$ electronic bands, and we have presumed above that if the vacancy is in the normal valence band it does not alter the energy of this band. Such a vacancy in the normal valence band also does not alter the energy of the initial L_{III}-vacancy state either. If these presumptions are valid, the $L_{III}M \rightarrow MM$ band is negligibly shifted and is indistinguishable in shape from the parent $L_{III} \rightarrow M$ band.

But, if the extra vacancy in the initial state is in an M-excitation orbital, then, according to our terminology, the state is called an excitation state of the valence-electron-configuration type, and the energy of the state and of the emitted photon is shifted. By the usual satellite argument, the satellite occurs on the high-energy side of the parent line or band, whereas we have discussed the excitation spectra of this type as shifted to the low-energy side. In the latter case, we have presumed that the normal or unexcited $(L_{III})_\tau$ and V_τ states of ionization in the energy level diagram are those for which there exists one (or more) vacancies in the valence excitation orbitals. When less than the normal number of vacancies is found here, the state is an excitation state, and photon emission therefrom is of lower energy than is the normal line or band. In other words, in terms of the earlier discussion of the manganese K-emission spectra, if the definition of a satellite state were to be extended to include a valence orbital vacancy as the second vacancy (instead of another *inner* vacancy), the Mn$K\beta_{1,3}$ lines would be satellites of the $K\beta'$ parent line or lines, and most of the $K\alpha_1$ line would be a satellite of the low-energy "asymmetrical" component. Or, in terms of the present L_{III} spectra, if the excitation orbitals play a role similar to that proposed for manganese, the observed high-energy spike with its abrupt edge may be a satellite of the low-energy part of the emission. It seems better to retain the definition of a satellite state as given earlier.

The relative intensity of the $L_{III}M \rightarrow MM$ band, as proposed by Skinner without excitation orbitals and regardless of its energy position, would be seriously reduced (as suggested by Skinner) by the rapid transfer of the M vacancy in the initial state from the atom in question to a neighbor and then out of the x-ray system. The time for such a transfer depends upon the position of the M vacancy in the valence band, being probably much less than the L_{III} lifetime if the vacancy is at or very near the top of the band. One Auger transition, $L_{II} \rightarrow L_{III}M$, always places the extra M vacancy very near the top; the $L_{II}-L_{III}$ energy difference is very small, e.g., it is 0.3 ev in the case of magnesium,[2] and therefore the M vacancy thus produced occurs within 0.3 ev of the Fermi surface. But there are other

[80] The discussion given by Seitz[79] is in terms of the one-electron-jump type of "energy level" diagram. He discusses further whether or not the normal valence band "broadens" as a consequence of the inner electron vacancy enough to "absorb" the excitation levels and thereby to obliterate the excitation spectra. (This is presumably not a question of different energies of the initial state; the initial state is presumed to be of the same energy regardless of whether an excitation electron or a normal valence electron jumps to fill the inner vacancy.) The significant questions are where in the band is the final positive hole, and what is the energy of the final state. The answers are *not* given by the one-electron-jump diagram since the excitation level (and any "broadening" of the valence band proper) ceases to exist with the filling of the inner electron vacancy. This is a typical example, of which there are many in the literature, of the difficulties in interpretation with the one-electron-jump type of diagram in solid-state spectroscopy.

Auger transitions that more frequently place it lower in the band.

Instead of the extra vacancy being in the M band, it may in some cases be in the L_{II} or L_{III} shell, as produced by the Auger transition $K \rightarrow LL$. In this event, the satellites $L_{II}L \rightarrow ML$ or $L_{III}L \rightarrow ML$ are shifted well beyond the Fermi energy and are observed[75] completely separated from the parent band. In shape, these satellites are a small replica of the parent $L_{II,\ III} \rightarrow M$.

The probability for Auger decay of the L_I state is especially very great, and *no* L_I-emission band for any of these metals has ever been reported. Also, the Auger transitions $L_{II} \rightarrow L_{III}M$ and $L_{II} \rightarrow MM$, which "rob" intensity from the L_{II}-emission band, cause the L_{II} band to have only about 1/20 of the intensity of the L_{III} emission for Mg, whereas, on the basis of quantum weights, we would expect an intensity ratio of $\frac{1}{2}$.

As mentioned in the foregoing, some fraction of the intensity thus "robbed" from the L_{II} emission, and likewise some of the intensity "robbed" from the K and L_I emission, reappears as part of the $L_{III}(M)^n \rightarrow M(M)^n$ band where $n \geq 1$; in fact, most of the apparent $L_{III} \rightarrow M$ band is of emission for which one or more extra M vacancies of the normal valence type are present. There is no point in calling most of this emission a satellite or satellites.

Now we turn to the absorption spectra of these three metals. The first point to be made is that the high-energy edge in emission and the low-energy edge in absorption agree in position (at the Fermi energy) as may be theoretically expected of a good metal in the absence of excitation structure. Such agreement is sometimes found for those good metals for which the proper edges can be unambiguously identified, but the proper identification is usually very difficult or impractical. In fact, because of the prospective role of excitation states, the agreement in the present uncorrected experimental curves is perhaps better than we should expect.

Concerning this agreement *vs* disagreement of the emission and absorption edges at the Fermi energy, two effects should be noted in addition to the role of excitation states. First, if the lifetime of the initial state in emission is rather long, significant phonon-interactions may take place and shift the energy of this state before the emission transition occurs. The energy shift is expected to be such as to increase the high-energy side of the emission and, hence, produce disagreement in the positions of the respective edges. Second, if the lifetime of the initial state allows relaxation of the crystal lattice (to relieve the stress set up by the inner vacancy), the energy of both the initial and final states are thereby changed, usually, but not always, reduced.[81] The energy of the inner state is expected to be changed more than that of the outer state, and, hence, such relaxation would also produce disagreement in the respective edges. The lifetime of the MgL_{III} state is probably greater than 10^{-13} sec (Skinner reports[75] the width at 5% maximum to be 0.02 ev), and this is approaching the time required for significant phonon interactions. The lattice relaxation time is a little longer, about 10^{-12} or 10^{-11} sec. These phonon and relaxation effects are not expected to be important when the initial state lifetime is less than about 10^{-13} sec.[82]

There seems to be no obvious explanation of the observed shapes of these three absorption curves beyond the edges. From the conventional interpretation of the emission spectra in terms of the overlapping $3s$, $3p$ bands, we would expect sodium to show strong absorption corresponding to the high-energy emission for magnesium and aluminum. Perhaps it does, but the evidence suggests the presence of additional absorption structure in the range 0 to 5 ev. The magnesium absorption spike, at less than 1 ev from the Fermi energy, seems to be narrower than would be expected on the argument of the aluminum and the $3p$ band, and the aluminum absorption shows no clear maximum in the range 0 to 5 ev.

The fact of *two different* absorption curves in the case of aluminum raises further questions. One of these curves was recorded with the aluminum condensed by evaporation technique onto a Zapon substate; in the other case the aluminum foil was self-supporting. The vacuum-deposited specimen shows a relatively strong broad absorption band beyond about 5 ev above the Fermi energy. There is reason to believe[71] that this strong absorption occurs in a metal-substrate interface region roughly 500 A thick. It is possible that some metal atoms were more or less deeply embedded in the material of the substrate, and that some outer electrons were stripped off the metal atoms in the embedding process. Thus, the neighborhood environment of the boundary aluminum atoms or ions may be quite different than in bulk aluminum metal. There is possibly established, therefore, a wide variety of excitation and ionization states that combine in effect to give the strong but very broad absorption. This type of strong absorption is observed also for celluloid and polystyrene substrates, and indeed for other metals than aluminum.

In general, the interpretation of these spectra, either emission or absorption, is not as yet complete. In this section, we make no effort to present an exhaustive discussion nor a final interpretation. Our purpose is to

[81] The dependence of state energy on the lattice spacing is mentioned later in connection with temperature effects in potassium chloride.

[82] Kostarev [A. I. Kostarev, Zhur. Eksptl. i Teoret. Fiz. 22, 628 (1952); or see M. A. Blokhin, Bull. Acad. Sci. USSR, Phys. Ser. 20, 701 (1956), English translation] proposed that because of lattice relaxation, *every* valence emission curve should be shifted to higher energies in order better to match the edge positions. Kostarev, however, does not discuss the fact that many x-ray states have a lifetime much less than the relaxation time; for these short-lived states, his arbitrary shift would be out of order.

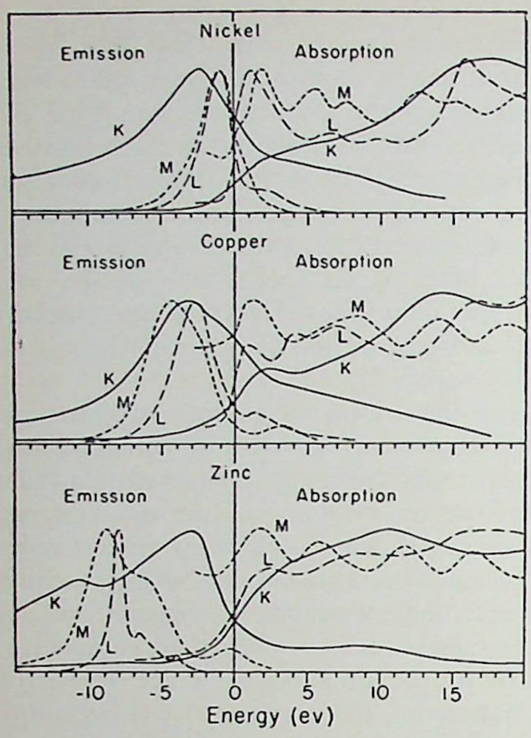

FIG. 11. K, L_{III}, and M_{III} spectra for metallic nickel, copper, and zinc. The curves are taken from various authors.[83]

illustrate typical features of interpretation, and to this end we choose different spectra to emphasize different features.

Nickel, Copper, and Zinc

Figure 11 shows a composite of the K, L_{III}, and M_{III} spectra for three more metals, *viz.* nickel, copper, and zinc.[83] These curves are also normalized and plotted on the same energy-interval scale to facilitate comparison of shapes. The zero of the energy scale is arbitrarily taken in each case as at about the first inflection point of the uncorrected absorption curve[84], the Fermi energy in a good metal is expected to be somewhere near this position. This presumes, as in the case of the sodium, magnesium, and aluminum, (1) sufficient admixture of wave-function symmetries that the different inner vacancies will not, by the selection rule, affect the position of this inflection point, and (2) that excitation states are of negligible importance in this part of these absorption spectra. Neither of these presumptions is generally valid, but there appears now to be no better zero-position criterion. Also, it should be realized that just what is called the first inflection point often depends upon the instrumental resolving power and the precision of the intensity measurements.

The M emission and absorption, as directly observed, consists of overlapping M_{II} and M_{III} bands, but only the M_{III} bands are shown in Fig. 11. In making the necessary resolution, we have taken the energy separation between the M_{II} and M_{III} bands to be small, about 2.5, 2.2, and 2.0 ev for Zn, Cu, and Ni, respectively, in both emission and absorption. Further, we have assumed the relative intensities of the two absorption bands to be 2 to 1 on the basis of quantum weights. In emission, however, the Auger transition $M_{II} \rightarrow M_{III}V$, where V refers to the valence band (admixed $3d$ and $4s$ bands), probably increases this ratio from 2 to 3 or more (and very slightly broadens the M_{II} band); for present purposes, the M_{III}-emission bands in Fig. 11 are deduced from the observed curves with the presumption that the intensity ratio is about 3:1.

None of the experimental curves has been corrected for the corrections (b), (c), (e), (f), (g), and (h) as listed earlier. Although a correction (d) for background intensity has been made in each case by the respective investigators, this correction is often arbitrary. This arbitrariness is probably most pronounced when the background is either changing rapidly with energy (as in the K-emission curves because of the tail of the β_1 line) or is large and somewhat uncertain (as in the M_{III} emission). It is entirely possible that the so-called base width of the K-emission bands in Fig. 11 are too great by 50%, and of the M_{III} bands too narrow by 50%.[85] If the M_{III} bands are as wide and complex as is reported by Bedo and Tomboulian,[85] it seems likely that, in accounting for these features, we must assign a prominent role to the excitation states.

The correction for both kinds of resolving power is large in the K spectra, intermediate in the L spectra, and probably small or negligible in the M spectra. The correction for self-absorption by the anode of the x-ray tube has recently been reported to be very large, at least in certain K-emission spectra.[40] To the extent that an emission band or line, after having been corrected for the instrumental resolving power, straddles an absorption edge, the effect of self-absorption is markedly asymmetrical and causes the emission curve to appear too low on the high-energy side. The self-absorption correction is no doubt important, especially in K spectra for which the jump-ratio at the absorption edge is great.[86] The intensity of the high-energy

[83] Curves for this figure were taken as follows: K emission from J. A. Bearden and C. H. Shaw, Phys. Rev. 48, 18 (1935); K absorption from W. W. Beeman and H. Friedman, Phys. Rev. 56, 392 (1939); L emission from Spielberg, Soules, and Shaw, to be published; L absorption from A. Sandström, Nova Acta Reg. Soc. Sci. Upsaliensis 9, No. 11 (1935), and C. B. van den Berg, thesis, Gröningen University, 1957; M emission from Skinner, Bullen, and Johnston, Phil. Mag. 45, 1070 (1954); and M absorption from Tomboulian, Bedo, and Neupert, J. Phys. Chem. Solids, 3, 282 (1957).

[84] Conventionally, this position in the uncorrected absorption curve is taken as the energy of *the* absorption edge (although the first inflection point in the *transmission* curve is sometimes used, with even less theoretical justification).

[85] D. E. Bedo and D. H. Tomboulian, Bull. Am. Phys. Soc. Ser. II, 3, 192 (1958); see also Tech. Rept. "The $M_{2,3}$ valence band spectrum of manganese" (July, 1958), Contract DA-30-115-ORD-669.

[86] We are currently in the process of repeating the work of Hanson and Herrera[40] on the K spectra of copper and nickel. The self-absorption correction is not as large as they reported since (1) they did not first correct the observed emission for instrumental resolving power, (2) they used an experimental curve for the absorption edge before it had been corrected for the instrumental resolving power, and (3) their correction for

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

satellites is very much stronger than is apparent before the correction for self-absorption is made, and careful correction for the satellites becomes imperative.[87] We would expect that, after all the pertinent corrections have been made, any remaining overlap of the emission and absorption spectra (at the Fermi energy) should be accounted for as the effects of thermal motion of the conduction electrons and of lattice vibrations in the emitting anode and in the absorber.

We may remind ourselves that, by application of the selection rule to the principal jumping electron, the K emission refers to transitions to a final state having an electron vacancy of p-type symmetry in valence band. In this application, the wave-function symmetry of the valence vacancy is viewed from the position of the K shell of the emitting atom. The K-absorption process leaves the system with one inner K vacancy and with the ejected electron having p-type symmetry whether it is in an excitation orbital or in some unoccupied part of the conduction continuum. In the L_{III} and M_{III} emission or absorption spectra, the final state vacancy or the ejected electron, respectively, has either s or d symmetry.[88]

As a help in the interpretation of the experimental curves, we may first become acquainted with the theoretical prediction (one-electron model) of the density of states in the solids under study. Such a prediction, which neglects the perturbation of the inner vacancy, is sketched in Fig. 12. This is a "composite" of calculations by several investigators.[89] The double maximum in the $3d$ band is predicted by all the calculations. The base width of the theoretical $3d$ band seems to be about 2.7 ev for nickel (Koster) and about 3.4 ev for copper (Howarth). Extrapolation of these calculated results to zinc is probably not justified because of its different crystal structure. The Fermi energy is indicated for nickel and copper, and it is estimated for zinc. Ten electrons go into the bands for nickel, 11 for copper, and 12 for zinc. In Fig. 12, the Fermi energies are placed for the respective areas to be in this ratio. As drawn, the Fermi energy for copper is about 2 ev above the top of the $3d$ band and also about 2 ev below the bottom of the $4p$ band.

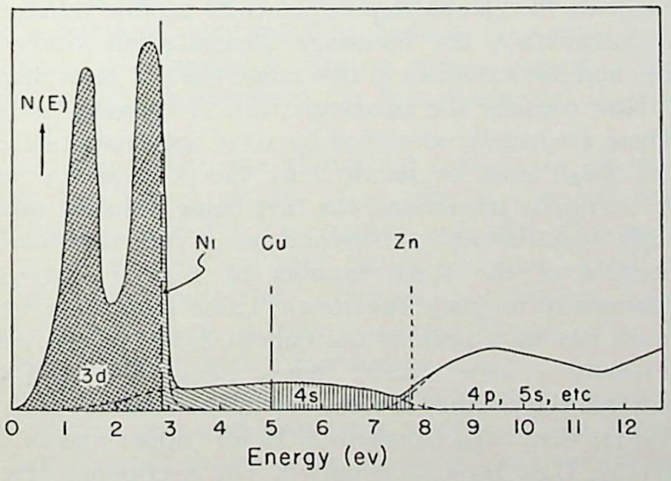

FIG. 12. "Theoretical" density of valence states for metallic nickel and copper, and (questionably) for zinc. This is a composite sketch from several different calculations based on the one-electron model.[89] Estimated Fermi energies are indicated.

Because of the dipole selection rule, we expect quite different shapes in the K emission on one hand and in the L_{III} and M_{III} emission on the other hand, neglecting excitation spectra in each case. Insofar as Fig. 12 applies and insofar as the observed spectra show the normal unperturbed states of the solid, the L_{III} and M_{III} curves should both reflect the s and d band structure of Fig. 12, weighted heavily in favor of d because of the relative transition probabilities and because of the greater density of states, whereas the K curves should show merely the admixed p symmetry in these bands. (In K-quadrupole radiation, the transition of s symmetry to d symmetry is allowed but, as mentioned in the foregoing, the intensity of this radiation is very faint relative to dipole radiation.)

First consider the L_{III} and M_{III} emission. The successive shift of the observed L_{III} and M_{III} emission from the Fermi energy, as we go from nickel to zinc, seems to confirm the $3d$-electronic band as most probably containing the final electron vacancy. On the other hand, it is most disconcerting that there is no (or very little) evidence in these observed curves for the theoretically predicted double maximum in the $3d$ band. The full widths at half-maximum of the observed L_{III}-emission bands are about 2, 3, and 1 ev, respectively, and predicted width at half-maximum of the $3d$ band is about 2 ev for nickel (Koster) and a little wider for copper (Howarth). No theoretical prediction is available for zinc. Even after allowing about 0.5 ev (very rough) in the observed curves for resolving power, etc., the width agreement is fairly good, somewhat unexpected and probably fortuitous in view of the double-peak disparity. The widths at the base are not in agreement. Moreover, the observed M widths at half-maximum are uniformly greater than 2 ev. There is no obvious reason in the one-electron metal why the L_{III}-emission shapes should be different from the M_{III} shapes. And the very wide K bands are not easily explained, even after an estimated 3 ev (very rough)

the background radiation (the side of the nearby intense β_1 line and the continuous radiation) was not quite right.

[87] The serious tangle of satellites as often reported in spectral curves recorded photographically [e.g., see Y. Cauchois, Phil. Mag. 44, 173 (1953), and references cited therein] is frequently a consequence of overexposure of the photographic film and a failure to correct properly to a linear intensity scale. But the correction for satellites is usually not an easy one because of the poorly known background intensity, a background that may contain essential structure itself.

[88] Again note that, at least in hydrogenic theory, the transition probability for p to s is much less than for p to d.

[89] E.g., see E. Rudberg and J. C. Slater, Phys. Rev. **50**, 150 (1936); J. C. Slater, Phys. Rev. **49**, 537 (1936); G. F. Koster, Phys. Rev. **98**, 901 (1955); G. C. Fletcher, Proc. Phys. Soc. (London) **A65**, 192 (1952); D. J. Howarth, Proc. Roy. Soc. (London) **A220**, 513 (1953); C. Kittel, *Introduction to Solid State Physics* (John Wiley and Sons, Inc., New York, 1956), Chap. 12.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

allowance is made for the correction for resolving power, self-absorption and satellites.

Considerable point is usually made of the apparent coincidence in the energy positions of the abrupt high-energy side of emission and the low-energy side of absorption for the metals sodium, magnesium, and aluminum. This coincidence is always sought for good metals, but it is not so readily seen for most metals. The curves for nickel, copper, and zinc are typical.

In general, we find some spotty agreements in terms of the theoretical predictions based on the one-electron model; but more disagreements. Perhaps some of the apparent difficulties would disappear if proper corrections were made to the observed curves, when more sanitary conditions and materials are used, etc.[90]

In particular, the correction for excitation spectra may be by no means negligible. For example, it is likely that the excitation orbital which forms inside the occupied valence band (see earlier discussion of the $K\beta'$ line for elements in this region of atomic numbers) is not similarly occupied in all K states in the emitting anode of the x-ray tube. If this is the case, then the K emission may be broadened as a result of the energy separations of overlapping excitation states, and also may be accompanied by the $K\beta''$ "satellites."[38,44]

Similar arguments apply to the L_{III} and M_{III} emissions for which the energy separations of the respective excitation states are expected to be somewhat smaller than for the K states. Further, the relative probability of the jump of a normal valence electron, compared with the jump of an excitation valence electron, may possibly be greater in the L_{III} than in the M_{III} emission because of the overlap of the respective wave functions and because the perturbation is stronger in the L_{III} case. If this is so, and if the final-state vacancy following the excitation electron jump is always at a particular favored place in the valence band (as mentioned earlier as a possibility), then we might expect the L_{III} emission to be narrower than the M_{III} emission and to be displaced slightly in energy position. We may continue this speculation: If the favored position of the positive hole in the final state is indeed responsible for the L_{III} emission's being narrower than the M_{III}, and also responsible for the relative energy positions of the L_{III} and M_{III} bands, then perhaps we may conclude that, after the excitation electron has jumped into the L_{III} vacancy, the positive hole is near the top of the $3d$ band. However, in the case of nickel, the L_{III} emission is only a little narrower than the M_{III}, and there is no significant difference in the peak positions. Such speculations are interesting, but very little significance should be attached to their conclusions at this time.

Also contributing to a difference in the energy positions and shapes of the emission bands is the difference in lifetimes of the respective initial states. Thus, in these states, effects of phonon interactions and degrees of lattice relaxation are different.

The L_{III} emission for nickel and copper shows in each case a small bump on the high-energy side of the Fermi energy. It is likely that this bump is a conventional satellite. It is possible, but perhaps not likely, that much of the asymmetry in the L_{III}- and M_{III}-emission bands for copper and zinc is due to high-energy satellites. Satellites, being essentially atomic in character, may generally be identified by observations with elements in a mono-step sequence of atomic numbers. Unfortunately, the necessary identification study of $L\alpha_1$ and $M\gamma$ satellites in this range has not been made.

Now consider the amazingly wide K-emission bands. These are usually identified by x-ray spectroscopists as the $K\beta_{2,5}$ lines or bands, *viz.*, the $K \rightarrow M_{IV,V}$ and $K \rightarrow N_{II,III}$ transitions, the first being nominal quadruple radiation and the second being very improbable because of the small number of $N_{II,III}$ electrons (nominally no such electrons). These bands are very faint, having a peak of only about 1/100 of the peak intensity of the nearby $K\beta_{1,3}$ lines, $K \rightarrow M_{II,III}$, whereas the number of electrons in the nominal $M_{IV,V}$, $N_{II,III}$ (i.e., $3d_{3/5,5/2}$) shells is 10 for copper and in the $M_{II,III}$ (i.e., $3p_{1/2,3/2}$) is only 6. The K-emission bands are obviously severely suppressed but, even so, are more intense than would be expected for normal quadrupole radiation. We conclude that the emission is actually due to an admixture of p-type symmetry in the nominal $3d$, $4s$ energy bands, but that this admixture is not very great or else the K bands would be more intense than they are. The relative feebleness of this $K\beta_{2,5}$ radiation is believed to be an important point in regards the degree of admixture in general.

Mott[91] has suggested that, from an interpretation of the van der Waals forces, an appreciable percentage of

[90] The curves reproduced in Fig. 11 are believed to be the most reliable reported to date for these spectral regions. However, the following is illustrative of the experimental situation. The K-emission curves of Bearden and Shaw[83] have been challenged by Hanson and Herrera[40]; the L_{III}-emission band of copper has been reported by several investigators with large disagreements (compare the two curves by Cauchois [Y. Cauchois, Phil. Mag. 44, 173 (1953), and references cited therein] and by Shaw *et al.*[83] as shown in Fig. 24 of reference 3 with the curve in Fig. 8 of van den Berg[83]); and the $M_{II,III}$ emission is in similar trouble (compare Fig. 3 of Skinner *et al.*[83] with Fig. 3 of E. M. Gyorgy and G. G. Harvey [Phys. Rev. 87, 861 (1952); see also Phys. Rev. 93, 365 (1954)] and with Fig. 2 of D. E. Bedo and D. H. Tomboulian [Phys. Rev. 113, 464 (1959)], and see Bedo and Tomboulian[85] who suggest that the assumed background is often highly arbitrary. And the L_{III}-absorption curve of our Fig. 11 has unfortunately a rather vaguely specified ordinate scale.

It is possible that the largest single factor in the experimental disagreements is the unknown intensity scale in much of the photographic work. For example, Cauchois reports that the measured L_{III} band width (and presumably the shape and the apparent structure) for nickel depends upon the exposure time. This dependence is probably not due to a change in materials or structure of the emitting anode of the x-ray tube; rather, the general situation seems to be identical to that in the early work in measuring the relative intensity of satellites {e.g., compare Fig. 1 of F. K. Richtmyer and R. D. Richtmyer [Phys. Rev. 34, 574 (1929)] with Fig. 3(b) of reference[62]} in which discrepancies of a hundred percent were not uncommon.

[91] N. F. Mott, Phil. Mag. 44, 187 (1953).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

admixed p symmetry may exist at and just below the Fermi energy in both nickel and copper. This is not believed to be likely because of the low intensity of the K emission, but if it were it would possibly account for the extra bump of intensity observed at -2 ev for copper, and it would presumably give rise to an abrupt edge in the nickel emission somewhat as is observed for, say, aluminum. Such an edge is not found for nickel.

The observed K emission above the Fermi energy may perhaps be relatively too intense to be accounted for as satellites.[92] It is barely possible that there is an appreciable number of stray electrons hovering around in the crystalline anode just above the Fermi surface; if so, and if enough of these hovering electrons drop into the K vacancies, we may be able to explain such a high-energy tail. It is also barely possible that such transitions take place in the case of the L_{III} and/or M_{III} emission. Such transitions, however, would seem to be very improbable.[93]

The large intensity maximum in the K-emission band near the Fermi energy in zinc asks for explanation. As we have stated above, it is likely that the density of states and the Fermi energy as displayed in Fig. 12 are not applicable to zinc. In particular, it may be that the low-energy tail of the $4p$-electronic band is occupied in zinc, and that the observed intensity maximum in question reflects this occupation as dipole radiation. If this is so, and if excitation states do not invalidate the one-electron model, the zinc K emission should exhibit the abrupt high-energy edge expected for metals under these conditions; perhaps it would if the corrections were properly made to the curve. But, even so, it is probable that an energy gap of a few volts would exist between the K emission and absorption edges.

Turning now to the absorption curves, the "jump-ratio" for nickel at the M_{III} edge is about 2 but decreases to about 1.3 for copper and zinc. This may be taken as evidence that the $3d$-electronic band in nickel is not quite fully occupied, but that in both copper and zinc it is fully occupied. Figure 12 is, of course, in accord with this evidence.

Obvious component structure appears in the absorption curves near and above the position of the Fermi energy. It is not clear whether this structure corresponds simply to a variation in the unperturbed $N_a(E)T(E)$ curve or is evidence of excitation states, plasma oscillations and multiple-inner-vacancy states.[94]

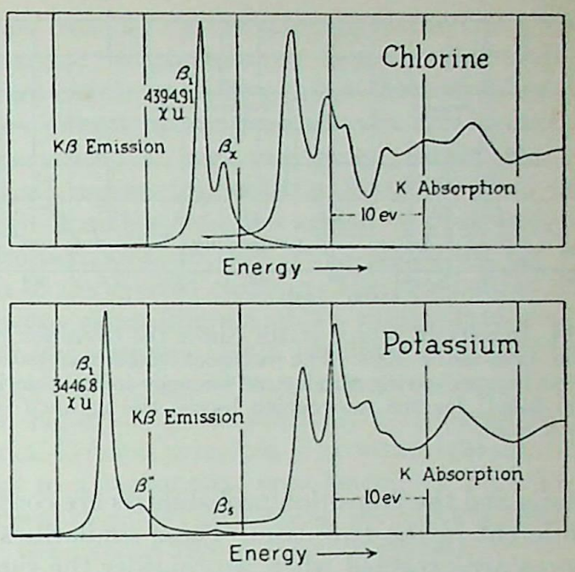

FIG. 13. K emission and absorption spectra (uncorrected) for crystalline potassium chloride.

The band structure of the transition metals is of considerable current interest, primarily because of their electrical and magnetic properties. In this interest, correlations of the results of x-ray measurements have been barely attempted[95] but the possibilities are very promising, especially after the observed curves for selected solid materials have been properly corrected for the various effects (a) through (h) as listed earlier.

Potassium Chloride

Figure 13 shows uncorrected curves for an insulator.[96] Here, the valence band in crystalline potassium chloride, nominally the Cl $3p$ electrons, is probably so far removed from the Fermi energy that the K emission band, designated β_1, is very narrow; the observed full width at half-maximum of β_1 is 1.21 ev. On the high-energy side of β_1, there is observed the line β_x for chlorine and β'' for potassium, and also a rather long faint tail in each case. β_x or β'', and the tail, are probably a complex of satellites and, if so, are of no great interest to us now.

In absorption, the excitation states are no doubt responsible for at least the most prominent maxima—indeed, the overlapping of the excitation spectra and the unperturbed solid-state band spectra is so great that we are at a loss to say where any feature of the unperturbed solid-state spectra may be.

The absorption structure is roughly similar for either the chlorine or the potassium inner vacancy although

[92] Stephenson [S. T. Stephenson, Phys. Rev. 58, 877 (1940)] reports that much of this apparent satellite structure may be an inverse view of the Kronig structure brought out in the self-absorption process. If so, this structure should disappear when proper correction for self-absorption is made.

[93] Many investigators have speculated about this possibility in attempts to explain the apparent satellite structure: e.g., see Y. Cauchois, Compt. rend. 201, 1359 (1935), T. Hayasi, Sci. Rept. Tôhoku Univ. 25, 785 (1936), 31, 1 (1942), and van den Berg.[83]

[94] Photographically recorded CuK absorption curves[55] show in the range 0 to 15 ev four wiggles (component structure) not indicated in Fig. 11. We are currently restudying this region with a two-crystal spectrometer.

[95] E.g., see N. F. Mott and K. W. H. Stevens, Phil. Mag. 2, 1364 (1957).

[96] These curves are from the paper by Parratt and Jossem.[31] The method used in reference 31 for correcting the emission line widths for the instrumental resolving power is not valid at these wavelengths, as has been shown by the better method of reference 17. An interesting emphasis on the need of a *proper* correction in the absorption curves is demonstrated by Parratt, Hempstead, and Jossem [Phys. Rev. 105, 1228 (1957)] in the so-called "thickness effect."

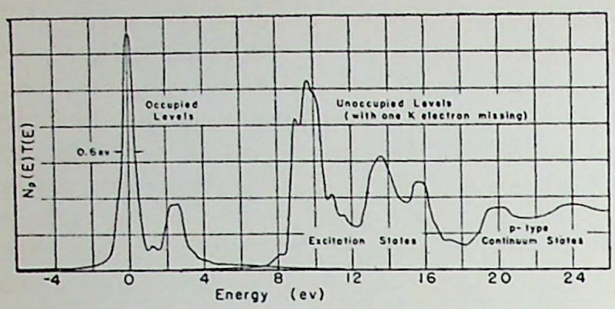

FIG. 14. Density of p-type states (times the transition probability) in crystalline KCl. The occupied electronic levels are those for a crystal having an electron vacancy in the chlorine $3p$ (valence) band; for the unoccupied levels, the vacancy is in a chlorine K shell.

the details and the transition probabilities are considerably different in the two cases. These similarities and differences are expected when we consider the similarities and differences in the immediate neighborhoods of the respective atoms in the crystal.

The chlorine curves for the other alkali chlorides also show[97] different details in the absorption structure, but all of these curves are characterized by pronounced maxima and minima. For LiCl and NaCl, the deep minimum that appears between the first two maxima for KCl and RbCl is effectively filled up, indicating either a smaller energy interval between the most prominent excitation states or else a greater number of such states. The structure for CsCl is again different, but the crystal structure of this chloride is body-centered-cubic whereas the other chlorides are of face-centered-cubic structure. The K-absorption curves for potassium in the potassium halides likewise show both similarities and differences.[98] Similar strong absorption maxima and minima for chlorine are also observed when the chlorine is in a gaseous phase, either in HCl or in free Cl_2[99] (see Fig. 3); this might be expected since the bound-ejected-electron excitation states are vestigial molecular or atomic states.

Figure 14 presents the $N_p(E)T(E)$ graph for potassium chloride. For this graph the chlorine K data shown in Fig. 13 have been fully corrected except for corrections (e), (g) and (h). The corrections for both kinds of resolving power were made by the method of Porteus and Parratt[17]: First, the observed transmission curve was corrected for the instrumental spectral window, and then the absorption curve (the logarithm of the thus-corrected transmission curve) was corrected for a Lorentzian K state.

Now, we see that the chlorine $3p$-valence band is indeed much narrower than has been customarily believed from early theoretical calculations (This problem is discussed in reference 31.) A recent calculation by Howland,[100] however, concludes that the base-width of this band is about 1.5 ev, in sensible agreement with the curve in Fig. 14. But, more recently, Howland has extended his theoretical calculations to predict a shape of this band as well as its width[101]; he predicts a half-maximum width of 1.32 ev, a value much greater than the observed 0.6 ev width, and he predicts a low-energy shoulder in the band which is much more prominent than the slight shoulder seen in Fig. 14.

This feature, just referred to as a slight shoulder, may be evidence of the spin-doublet states $3p_{\frac{1}{2}}$ and $3p_{\frac{3}{2}}$. The separation between these two states in gaseous atomic chlorine is about 0.11 ev and is expected to be about the same in crystalline KCl. It is possible to have two components of identical shape (near Gaussian) and separated by 0.11 ev, each with a width of about 0.5 ev, and with the $3p_{\frac{3}{2}}$ component on the high-energy side being twice as intense as the $3p_{\frac{1}{2}}$ component, such that their sum agrees with the curve of Fig. 14 within the accuracy with which the curve is known. Another interpretation of the slight shoulder would assign it to one or more excitation states of the valence-electron-configuration type, similar to the situation with the transition metals of the manganese group.

From the absorption part of the spectrum, it is significant that the number of evident excitation states is larger than has been previously recognized or theoretically discussed for x-rays. The prominent states here are no doubt of the bound-ejected-electron type.

The question arises as to the meaning of the width of a single component excitation state as it appears in the "unoccupied" part of Fig. 14. This width is the residual width after correction of the true spectrum for the "atomic" K state which is less wide than any K-excitation state. If a full-width K-excitation state had been used in the correction procedure, the result would have been degenerate (a Dirac delta-function[102]). The saving difference between these two K state widths is to be found primarily in the effects of phonons in the lattice. This needs further discussion.

Lattice Spacing and Phonons in KCl

First, we point out an effect due to the average value of the lattice spacing. Then we discuss the effect of statistical time and/or spatial variations in this spacing. The first is relatively easy to discuss insofar as we have knowledge; the second, the effect of the phonons, is a little more involved.

The energy of any x-ray state, i.e., of a system containing an inner electron vacancy, depends upon the total electric field in which the vacancy finds itself. As the lattice expands, e.g., by an increase in temperature, the contribution of electric field due to the presence of neighboring atoms (or ions) is generally altered, and so

is the energy of the x-ray state. The magnitude of the energy shift is probably small but is not easily deduced theoretically. It is believed that the shift is generally to a higher energy for x-ray states in atoms in a metal, and probably also for the anion in an ionic crystal, but to a lower energy for the cation in the ionic crystal.[103]

However, the ground state, i.e., the initial state in any absorption transition, is by definition not altered by the expansion of the lattice. Hence, the energy shift appears directly in the position of the main absorption edge. For a given solid it is expected that the shift is about the same for all states of energy greater than a few hundred ev; it is too difficult to predict the relative shift for states of less energy, e.g., for the valence state. Hence, for an emission line from a transition between states each of energy greater than a few hundred ev, the energy shift caused by the thermal expansion of the lattice, is expected to be small.

In absorption, a lattice spacing effect, in addition to the shift in energy of the main edge, comes into the Kronig and Hayasi structure since the energy positions in this structure depend upon Bragg reflection of the ejected electron in the lattice. The interference conditions in Bragg reflection are temperature sensitive since they depend upon the lattice spacing. The energy dependence of the interference conditions turns out to be an inverse quadratic function of temperature.

Incidentally, the argument may be advanced that a sensitive method for studying the chemical bonds around an atom in a solid, since these bonds affect the lattice spacing, may be in interpretations of the energy positions of (inner-state) $\rightarrow$ (valence-state) emission (e.g., $K \rightarrow V$), and/or of the inner-state absorption edge, as the chemical composition of the solid is varied. However, in compounds or alloys the role of the excitation states of both the valence-electron-configuration and the bound-ejected-electron types depend upon the chemical composition. It is likely that in a given alloy, even one having a uniform phase, the so-called normal valence configuration may not be the same for all atoms. Alterations in the excitation states probably have a small effect on the peak positions of emission lines but have possibly a large effect on the absorption spectra. In any case in such a chemical-bond study, they must be considered in addition to the effect due to the change in lattice spacing alone.[104,105]

Now consider the broadening of the energy of x-ray states due to phonons or lattice vibrations. (Some authors object to calling this a thermal effect because lattice vibrations are present even at absolute zero of temperature.) It was mentioned earlier that only a localized region of the solid is effectively involved in the energy of each state. This region is, of course, as great as the pertinent electron orbits, including the effective orbit of the ejected electron. The localization is due to the very short lifetime of an x-ray state and to the relatively long time for a phonon (or any other likely energy-bearing agent[106]) to travel through the lattice. This factor in localization is a consequence of the Franck-Condon principle. The x-ray system, therefore, refers to a region that may be only a very few lattice spacings in extent (excluding the ejected electron if it is in the remote part of the continuum).

The energy of a state is affected by the relative positions of all the electrons and nuclei in this localized region, and lattice vibrations give rise to fluctuations in this energy. Of course, the observed spectra represent a statistical average of the spectral energies from all the compressed or expanded regions that are emitting or absorbing the x-rays; the effect generally is to broaden an emission line, an absorption line, or an absorption edge. The statistical vibration broadening in either emission or absorption, considering all vibration frequencies and localized regions, is essentially Gaussian in shape.

For an ionic crystal, there are two kinds of lattice vibrations: (1) the so-called optical branch in which the adjacent positive and negative ions vibrate out of phase,[107] and (2) the acoustic branch in which adjacent ions vibrate approximately in phase. Vibrations frequencies extend from zero to about 10^{13} cps. Hence, after a time greater than about 10^{-12} or 10^{-13} sec, a completely new time and spatial distribution of compressed and expanded regions is expected.

For a metal crystal, the energy smear in an inner-vacancy state due to the vibrations in the electric field may be about a tenth of an ev or so at room temperature, and for an ionic crystal it may be somewhat greater because of the optical phonons. The smear is conveniently expressed as the root mean square of the

---

[103] Interesting studies of the temperature effects in K emission and absorption for ferromagnetic alloys have been reported by V. A. Kazantsev [Bull. Acad. Sci. USSR, Phys. Ser. **20**, 97 (1956), English translation, and Doklady AN SSSR **101**, 477 (1955)]. Although he gives simple interpretations in terms of the one-electron-jump type of diagram, the role of excitation states probably does not invalidate the general conclusions in regards the main trends of energy change.

[104] Nordling, Sokolowski, and Siegbahn report [Arkiv Fysik **13**, 483 (1958)] that the apparent K and L_{III} states for copper change in energy by 4.4 and 2.5 ev, respectively, from metallic Cu to CuO.

[105] Das Gupta reports [Phys. Rev. **80**, 281 (1950)] that the energy shift of the $K \rightarrow V$ or $L_{III} \rightarrow V$ emission peak correlates qualitatively with the heat of formation of a compound or alloy. This is in agreement with our expectations. However, in seeking quantitative agreement, Das Gupta assumes that the heat of formation is due entirely to the energy shift of the valence band alone, there being no shift in the inner state. This assumption does not seem reasonable.

[106] The electron vacancy in the x-ray state has some mobility in the lattice; this feature also extends the local region of interest. Not much is known [T. Takeuchi, Progr. Theoret. Phys. **18**, 421 (1957)] about the transfer of *inner* electron vacancies from one atom to the next, although this mobility is believed to be very small.

[107] The transverse mode of this type of vibration is excitable by an electromagnetic field, such as a light wave; hence the term "optical." We are concerned primarily with the longitudinal modes. The strongest polarization in the crystal occurs when adjacent ions vibrate 180° out of phase.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

amplitude of the vibrations of the state energy, and this for a Gaussian shape of the state is a little less than the half-width at half-maximum. For metallic potassium, the smear so expressed is calculated to be 0.15 ev at room temperature; for potassium chloride, the smear is about 0.15 ev at 0°K, about 0.16 ev at 100°K, about 0.19 ev at the Debye temperature, 230°K, and perhaps 0.23 ev at 373°K.[108] Such fluctuations are present in the energy of each x-ray ionization state. The magnitude and phase of the energy fluctuations are about the same for all ionization states in a given atom in the solid for which the effective diameter of the vacancy orbital is small compared with the atomic volume, i.e., for all states whose radiative lifetimes are less than about 10^{-13} sec.

It follows, then, as a prediction, that any emission line arising from a transition between ordinary x-ray states both of which have radiative lifetimes short compared with about 10^{-13} sec has an energy width that is rather insensitive to the lattice vibrations. But each absorption line, band or edge is expected to be broadened, regardless of the lifetime of the final state. Radiative lifetimes less than about 10^{-13} sec are expected for all x-ray states except those for atoms of the lowest atomic numbers and except for those states corresponding to a vacancy in the valence band.

For a singlet state of very short lifetime, shorter than about 10^{-13} sec, the shape is expected to be Lorentzian, as determined by the statistics of random-decay phenomena; and the shape of spectral lines (either emission or absorption) involving such states is also expected to be Lorentzian, and the shape of the *main* absorption edge, if the continuum of "unoccupied" states starts abruptly and is uniformly dense, is expected to be an arctangent. Indeed, within experimental error, the Lorentzian shape is observed for emission lines between *singlet* states both having very short lifetimes. However, in emission involving a longer lived state, e.g., the valence state, there is evidence that the tail on either side of the observed line is less high than Lorentzian, indicating a significant Gaussian contribution in the final state. (For example, the valence state derived from the β_1 line in Fig. 14 shows this effect.) In the longer wavelength range, Bedo and Tomboulian report[78] that the shape of the lithium K state, as interpreted from the K emission, is more nearly Gaussian than Lorentzian; this is to be expected if the K-state lifetime is of the order of, or greater than, about 10^{-13} sec,[109] a lifetime that is reasonable from other arguments.

Now consider a short-lived excitation state of the bound-ejected-electron type. The sensitivity of such a state to lattice vibrations depends upon the diameter of the orbit of the bound-ejected electron. If this electron remained very close to the position of the electron vacancy, its negative charge would effectively cancel the positive charge of the vacancy, and the energy of the state would suffer only minor fluctuations due to vibrations of the electric field. On the other hand, if the excitation orbit were large compared with the lattice spacing, such that the electric fields near a large number of atoms were sampled in the orbit, the lattice vibration sensitivity would be about the same as for an ordinary unexcited x-ray ionization state.[110] It is believed that most excitation orbits are of an intermediate size for which no prediction of the lattice vibration sensitivity is made at this time.

Another broadening effect in each excitation state, of either the valence-electron configuration or the bound-ejected-electron type, is due to the finite lifetime of the electron (or electrons) excitation orbital (or orbitals) as a consequence of all modes of decay other than the filling of the inner vacancy. The most likely types of such decay transitions are those due to Auger or phonon interactions. This type of broadening, Lorentzian in shape, is very small in the present KCl spectra, but the broadening by phonon interactions is possibly important when the inner vacancy has a longer lifetime, e.g., in absorption spectra in the long wavelength region.[111] However, even in the long wavelength

---

[108] These energy fluctuations are calculated from formulas supplied by Professor A. W. Overhauser. For the longitudinal modes in a monovalent metal,

$$[\langle (ev)^2\rangle]^{\frac{1}{2}} \doteq \left(\frac{NC^2k\theta}{6\rho u^2}\right)^{\frac{1}{2}}\left[1+\left(\frac{8T}{3\theta}\right)^2\right]^{1/8},$$

where N = number of atoms/cm³, ρ = density in g/cm³, u = velocity of longitudinal sound in cm/sec, T = absolute temperature, θ = Debye temperature, k = Boltzmann constant, and C = Fermi energy; and for the longitudinal optical modes in an ionic crystal of two types of ions,

$$[\langle (ev)^2\rangle]^{\frac{1}{2}} \doteq 8\frac{(3\pi^2)^{1/6}e^2}{n^2a^{7/2}}\left[\left(\frac{M_2}{M_1}\right)^{\frac{1}{2}}+\left(\frac{M_1}{M_2}\right)^{\frac{1}{2}}\right]\left(\frac{h}{\pi\rho\omega}\right)^{\frac{1}{2}}\left(\frac{2}{\exp(h\omega/\pi kT)-1}+1\right)^{\frac{1}{2}},$$

where e = electronic charge in esu, n = optical index of refraction, a = lattice constant, M_1, M_2 are masses of the two kinds of ions, h = Planck constant, ω = average optical mode frequency, and the other quantities are as defined in the foregoing. The particular type of mode for which the equation is devised is probably the most important one in the respective type of crystal. Inclusion of the other modes, e.g., transverse modes, may increase the total smear somewhat but probably not by more than the uncertainty in the value calculated from the one equation. This uncertainty is estimated to be less than a factor of 2, and the indicated trend with temperature is believed to be very much better than a factor of 2.

[109] Or, if the valence state, i.e., the *final* state in this Li K emission, has a long lifetime, the emission may also be predominantly Gaussian as a consequence of this lifetime and lattice vibrations, independent of the shape of the K state. If the proposal of Skinner-Landsberg[32] for metals is correct, the lifetime of the low-lying valence states for lithium are shortened by Auger transitions and the shape of such a low-lying state in the band becomes essentially Lorentzian.

[110] This presumes that the dynamic phonon-electron interaction is negligible during the short lifetimes of interest; but the statistical static interactions cause a broadening which may increase or decrease the effect in the ordinary unexcited x-ray ionization state.

[111] This broadening has been calculated by A. Radkowsky [Phys. Rev. 73, 749 (1948)] and found to be appreciable for

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by eGangotri Foundation USA

region, this broadening effect may be overpowered by the vibration Gaussian contribution which is also a consequence of the longer state lifetime.

Excitation States for KCl in Absorption

Our discussion of the excitation states shown in Fig. 14 may now be completed. The "atomic" K state used in the correction procedure was obtained, as discussed in connection with Table I, from $K\alpha_1$-emission lines and from the strong resonance absorption line in gaseous argon. Because of short lifetimes, this state does not contain the broadening effects of the phonons. So corrected, each component excitation state in Fig. 14 is expected to show phonon width and to be essentially Gaussian in shape, the width being roughly the same for all excitation states. The structure shown in Fig. 14 is consistent with this view. The band of excitation states about 4 ev wide in the center of the figure evidently contains many—at least six—overlapping component states, and the very steep sides of this band indicate component widths of the order of 0.2 ev. Such a width is in agreement with the calculated phonon width given above for KCl at room temperature. The rugged structure extends over a range of about 10 ev, and the total number of excitation states is probably greater than 15. Beyond about 20 ev from the valence band, the density of states has relatively small undulations in it, roughly the sort of undulations expected in the theoretical Kronig structure.

An experimental study of the chlorine K absorption in potassium chloride has been carried out at temperatures from 100°K to 373°K.[112] Two of these curves in Fig. 15, not corrected for resolving power, show: (1) a general shift of the order of 0.2 ev to lower energies, except for the first maximum in the region labeled p-type continuum, (2) broadening of the excitation states, and (3) some alterations in the component structure.[113] It seems reasonable to suppose from these

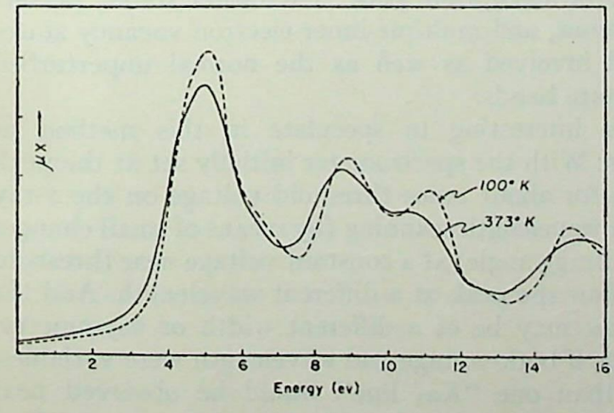

FIG. 15. Temperature dependence in the chlorine K-absorption spectrum of crystalline KCl.

results that the excitation electron in the first excitation state is essentially shared with the near-neighbor potassium ions, in agreement with the usual theoretical model.

A feature of great solid-state interest in a curve of the type shown in Fig. 14 is the magnitude of the energy gap between the normal valence band and the bottom of the conduction continuum. We discuss this feature now. Nominally, the bottom of the continuum refers to the states of s-type symmetry whereas Fig. 14 gives the density of states of p-type symmetry. Final states of s (or d) symmetry are involved in the ultraviolet absorption, and the desired energy gap has long been interpreted from this absorption as 9.46 ev in crystalline potassium chloride.[114] This interpretation, although the numerical value of 9.46 ev may possibly be changed to about 8.3 ev as a result of recent work,[115] would place the bottom of the s-type continuum at about the position of the central band of excitation states in Fig. 14. Admixture of p type in the nominal s-type states is no doubt present, and some fraction of the density of states in the region labeled excitation states in Fig. 14 should therefore be interpreted as part of the normal continuum. There is no obvious feature of the curve by which we can identify either the bottom of the continuum or even the existence of the continuum as some appropriate fraction under the excitation states. Possibly the deep minimum at about 16 ev above the valence states represents the bottom of the p-type continuum. States to the right of this minimum are designated p-type continuum states in the figure but we do not wish thereby to imply that the continuum necessarily begins here.

In general spectroscopy, it is common to add the energies of two or more selected lines to get the energy of a third; e.g., $(K \rightarrow L_{III})+(L_{III} \rightarrow M_{III})=(K \rightarrow M_{III})$. By a similar argument,[116] in which the energy positions of absorption edges are included, we may possibly derive some help in identifying the gap between the valence states and the bottom of the continuum. In KCl the valence states are the Cl M_{III} states, and we may write the gap-equations as

$$\begin{aligned}\text{gap (to } p\text{-type continuum)} &= K_{\text{abs}}-(K \rightarrow M_{III}) \text{ from Fig. 14} \\ &= M_{I\ \text{abs}}+(L_{III} \rightarrow M_I) \\ &\quad +(K \rightarrow L_{III})-(K \rightarrow M_{III}) \quad (1)\end{aligned}$$

[112] Parratt, Hempstead, and Porteus (to be published).

[113] The observed excitation states in ultraviolet absorption in KCl are also temperature sensitive as to both the apparent energy-positions and widths [Hartman, Nelson, and Siegfried, Phys. Rev. 105, 123 (1957)]. The vibrations in the electric field in the region of a valence orbital are believed to be too complex for even qualitative prediction at this time.

[114] E.g., see N. F. Mott and R. W. Gurney, *Electronic Processes in Ionic Crystals* (Oxford University Press, London, 1948), second edition, p. 95.

[115] The arguments of E. A. Taft and H. R. Philipp [J. Phys. Chem. Solids 3, 1 (1957)] may be applied to the experimental curves of Hartman, Nelson, and Siegfried [Phys. Rev. 105, 123 (1957)] for potassium chloride.

[116] The author is indebted to Professor E. L. Jossem for developing this argument in the present application.

The argument is essentially the Ritz-combination principle mentioned earlier as being valid in a gross description but not valied in detail. Our present interest is gross.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

gap (to s-type continuum)

$$= M_{III\ \mathrm{abs}} \text{ from ultraviolet absorption}$$
$$= L_{III\ \mathrm{abs}} + (K \rightarrow L_{III}) - (K \rightarrow M_{III}). \quad (2)$$

The only real help to be gained in this type of argument lies in a less ambiguous recognition of the appropriate[117] M_I and L_{III} absorption energies than is the case for K absorption in Fig. 14—the excitation spectra are expected to be somewhat different because of the different positions of the electron vacancy. The M_I state has the same symmetry as the K state, *viz.*, s type, but the L_{III} state has p-type symmetry. The gap-equations (1) and (2) are written separately for the p type and for the s-type continua because it is believed that the experimental values may well be different for these two gaps, and it is alleged theoretically that the admixture of p-type symmetry at the very bottom of the nominal s-type continuum is most unlikely.

The energies of all three chlorine emission lines in the gap-equations have been accurately measured for KCl —$K \rightarrow M_{III} = 2815.12$ ev, $L_{III} \rightarrow M_I = 182.75$ ev, and $K \rightarrow L_{III} = 2622.23$ ev—but the chlorine L- and M-absorption edges for KCl have not been recorded. The Cl $M_{I\ \mathrm{abs}}$ for LiCl has been determined by O'Bryan[118] who remarks that the absorption bands "show a width from 2 to 4.5 ev at the head with less intense continuous absorption extending to shorter wavelengths." The energy at the center of the strong absorption band is 29.7 ev. O'Bryan's description of the absorption curve also fits fairly well the Cl K-absorption curve for LiCl as reported by Parratt *et al.*[97] It is reasonable to conclude that 29 ev is probably a minimum value for the Cl M_I absorption energy for KCl. The Cl L_{III}-absorption energy is also to be deduced indirectly from measurements, and, again, only an approximate value can be obtained. We use the Cl L_{III}-absorption energy for gaseous CCl_4, 200.6 ev, as reported by Prins,[119] and add to this energy about 3.5 ev for the following reasons: 1.5 ev are added as a guess as to the separation between the first strong absorption peak and the appropriate absorption edge. The remaining 2 ev comes from a comparison of the Cl K-absorption spectra for gaseous CCl_4 by Nilsson[120] with the Cl K absorption for KCl by Parratt *et al.*[97]; the K edge shifts by about 2 ev in going from the gaseous CCl_4 to solid KCl. We assume that the L_{III} edge shifts by the same amount. Thus, the approximate energy of the Cl L_{III} absorption is taken to be 204 ev.

Substitution of these numerical values in Eqs. (1) and (2) gives

gap to p-type continuum = 19 ev
gap to s-type continuum = 11 ev.

The uncertainty in the 11-ev value may be 2 or 3 ev, and the 8 or 9 ev previously reported for the s-type case may possibly be a better value than the 11 ev. The 19 ev for the p-type case was deduced as a *minimum* value, and it also may be uncertain by a few ev. The M_I- and L_{III}-absorption edge energies are based on uncorrected curves recorded photographically and, in some instances, with low instrumental resolving power. Nevertheless, the conclusion that there is a difference of several ev between the effective bottoms of the s- and p-type continua is experimentally the best we have to date. This conclusion may easily be altered to say that there is only a very small amount of p admixture in the difference region.

These arguments are interesting and suggest desirable supplementary measurements for the future. At the present time, they are not sufficiently quantitative to provide a convincing basis for the energy-gap interpretation of the curve of Fig. 14; they do however tend to confirm the division of the curve into the general regions labeled excitation states and p-type continuum.

Other Types of X-Ray Curves

There are other ways in x-ray spectroscopy to study the electronic band structure of solids, but these we barely mention.

One way is to record and interpret a curve of the emission intensity of a characteristic line, say the $K\alpha_1$ line, with each of various values of the anode voltage in the neighborhood of the threshold excitation voltage.[121] This method purports to examine the unoccupied levels of the solid by inquiring as to just where and with what probability the inner electron can be ejected to them by cathode-electron impact. It is analogous to the x-ray absorption method except that the radiative selection rules do not apply. When scrutinized more carefully, the correlation between electron energy and the emitted x-ray intensity is as complex as the interpretations in absorption work: Excitation states, plasma oscillations, and multiple-inner-electron vacancy states are all involved as well as the normal unperturbed solid-state bands.

It is interesting to speculate in this method as follows: With the spectrometer initially set at the peak of $K\alpha_1$ for about twice threshold voltage on the x-ray tube, a wavelength scanning (by means of small changes in the Bragg angle) at a constant voltage near threshold may show the peak at a different wavelength. And the line now may be of a different width or asymmetry. Perhaps if both voltage and wavelength were variables, more than one "$K\alpha_1$ line" would be observed near threshold voltage; if so, they would correspond to different radiative combinations of K and L_{III} normal and excitation states. It is believed likely, however, that only one broadened $K\alpha_1$ line would be observed in this fashion because, if more than one were to appear,

[117] The difference between the "unexcited" x-ray level (the level referred to earlier with the subscript τ) and the energy of the absorption edge is presumed in this argument to be roughly the same for the various cases.

then, in an appreciable fraction of the emission transitions, (1) the bound-ejected electron would have to jump differently by a few ev or (2) the valence-electron configuration would have to change differently. With regard to the latter possibility, it may be noted that the time required in the formation of the perturbation due to the inner vacancy near threshold voltage is somewhat longer than it is with much excess voltage on the x-ray tube, and consequently the respective probabilities for producing the various excitation states, especially of the valence-electron-configuration type, are perhaps altered.

Another method of studying the electronic band structure of solids is by the spectral details observed near the short-wavelength limit of the continuous x-radiation.[122] The cathode electron comes to rest, or nearly so, wherever it can find an acceptable unoccupied level in the solid. The x-ray intensity pattern gives information concerning the positions of the respective levels and the density of states. In this method, the excitation states are probably not involved, but the plasma oscillations and the multiple-vacancy states are present to complicate the interpretations.

1. INTRODUCTION

OXIDE semiconductors, such as rutile, differ from the elemental semiconductors, silicon and germanium, in several respects. Probably the most important is the high melting point, which increases the difficulty of obtaining specimens of high purity. A related effect is the high concentration of vacancies which is "frozen" into the specimens at elevated temperatures. Oxygen vacancies are believed to exceed the cation vacancies in rutile. The formation of an oxygen vacancy in the otherwise pure oxide provides

* Work supported by the U. S. Atomic Energy Commission.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

a source of two electrons having an activation energy less than the energy required to raise an electron to the conduction band in the stoichiometric material. Thus the transport properties of the oxide are altered by departures from stoichiometry, just as they are by the presence of impurities.

The second respect in which oxide semiconductors differ from silicon and germanium is the separation of the cations by the oxide ions. This separation leads to a reduction of the overlapping of the cation wave functions. It is undecided whether the wave functions of the cation 3*d* electrons are to be considered as overlapping, or "noninteracting." This question has been discussed by Verwey, *et al.*,[1] Mott,[2] Zener and Heikes,[3] and very recently by Morin.[4] It seems probable that the titanium 3*d* levels (or band) do not overlap the bottom of the much wider 4*s* conduction band. To the extent that electrical conduction is due to 3*d* electrons, one expects a low mobility compared with the electron mobility in silicon and germanium.

Finally, one has the difficulty of distinguishing between chemisorbed oxygen and oxygen from the adjacent bulk material. In other words, our concept of a surface is less precise than in the case of elemental solids.

For these reasons, it is appropriate and timely to examine critically all the available literature on the physical properties of rutile. In the following pages these properties are interpreted in terms of two electronic models. The attempted correlation of the various types of measurement (electrical conductivity, thermopower, etc.) by the use of these models is not satisfactory. It was therefore decided to discuss many physical properties that are not obviously significant from the point of view of the two models.

2. CRYSTAL STRUCTURE

2.1. Introduction

Titanium dioxide exists in three crystalline modifications, rutile, brookite and anatase, all of which have been prepared synthetically. Titanium dioxide precipitated from sulfate or chloride solutions at room temperature is amorphous even after drying at 110°C.[5] At elevated temperatures anatase is precipitated from sulfate solutions, but hydrolysis by direct boiling of chloride solutions produces rutile as the initial crystalline product. Other forms are converted to rutile when heated to temperatures between 700 and 920°C. The transition is not reversible. The stability of anatase is increased by the presence of 0.1% of certain anions.[6] The preparation and mutual transformation of these oxides are discussed in Barksdale.[7]

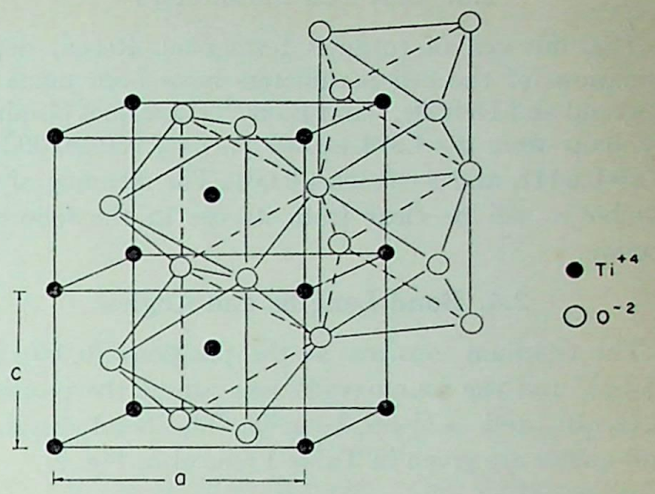

FIG. 1. Crystal structure of rutile (TiO_2). (Courtesy of R. G. Breckenridge, W. R. Hosler, and *The Physical Review*.)

Moore[8] has described the method of preparation of rutile single crystals by the Verneuil flame fusion method. When removed from the furnace the crystals are opaque black because of a slight deficiency of oxygen, but have the rutile crystal structure. After heating in a stream of oxygen the crystals become transparent, with a slight yellow coloration.

2.2. Crystal Structure

The crystal structure of rutile is usually described in terms of an ionic model based on the ions Ti^{4+} and O^{2-}. Although Syrkin and Dyatkina[9] consider that rutile may be regarded as intermediate between ionic and molecular in type, one notes that the Ti—O separation in the O—Ti—O grouping is actually slightly greater than the remaining four Ti—O spacings. This increased separation has been explained[10] as resulting from the repulsion between one oxygen ion and the four equidistant oxygen ions in the same octahedron.

The oxygen ions are arranged in the form of somewhat distorted octahedra (Fig. 1). Each octahedron shares one edge with adjacent members of the chain. Alternatively, the crystal structure may be visualized as chains of ions —O—Ti—O—O—Ti—O. All chains in the same layer are parallel, and the chains in adjacent layers are perpendicular to one another and to the *c* axis.

2.3. Unit Cell Parameters

The unit cell of rutile is tetragonal. Recent determinations of the cell parameters have been made by Legrand and Delville,[11] and Baur.[12] The values obtained by Baur were $a=4.594\pm0.003$ A, $c=2.959\pm0.002$ A, $c/a=0.6441$, and $x=0.306\pm0.001$. The meaning of the symbol x will be clear from its use in the following section.

2.4. Bond Lengths and Angles

The titanium ions are at the positions (0,0,0) and $(\frac{1}{2},\frac{1}{2},\frac{1}{2})$, and the four oxygen ions are at the positions $\pm(x,x,0)$, and $\pm(\frac{1}{2}+x,\frac{1}{2}-x,\frac{1}{2})$. The bond distances and angles are given in Table I (see also, Fig. 2).

2.5. Interatomic Distances from Ionic Radii

The ionic radii (Zachariasen quoted by Kittel) of the cation and anion are, respectively, $R_C=0.60$ A, and $R_A=1.46$ A.

In ionic crystals, the interatomic distance D_N is given by the relation $D_N=R_C+R_A+\Delta_N$, where N is the coordination number of the cation, and Δ_N is a correction which depends upon N. In rutile the cation has six nearest O^{2-} neighbors, hence $N=6$. From collected crystallographic data of other compounds, Δ_6 is found to be zero, or more correctly, R_C and R_A are calculated on the basis that $\Delta=0$ for $N=6$. The Ti—O separation calculated in this way (2.06 A) is somewhat greater than the observed values (1.944 and 1.988 A), indicating a slight departure from the rule. It is usually assumed that such a discrepancy reflects the contribution of the covalent forces to the crystal bonding.

TABLE I.

Bond	Type[a]	Number of bonds of its type per unit cell	
	(a)		
Ti—O	1	4	1.944±0.004 A
Ti—O	2	2	1.988±0.006 A
O—O	3	8	2.780±0.002 A
O—O	4	2	2.520±0.012 A
O—O	5	2	2.959±0.002 A

Angle	Bond[a] types	Number of angles of its type per unit cell	
	(b)		
O—Ti—O	1, 1 (smaller angle)	2	80.8°
O—Ti—O	1, 1 (greater angle)	2	99.2°
O—Ti—O	1, 2	8	90.0° (by symmetry)

[a] The numerals refer to the bonds indicated in Fig. 2.

[12] W. H. Baur, Acta Cryst. **9**, 515 (1956).

2.6. Other X-Ray Investigations

By the use of Weissenberg photographs, Baur[12] has been able to carry out a Fourier projection of the elementary cell of rutile on the plane perpendicular to [001] (Fig. 3). This figure shows that the electron density does not fall to zero at any point between the oxygen and Ti_{II} ions. The "bridge" between cations and anions is an indication of a covalent contribution to the bonding. These results have been corroborated by the results obtained by a group of Spanish workers.[13,14]

2.7. Madelung Constant

Assuming purely ionic bonding and regular octahedra as the building blocks, Born and Bollnow[15,16] carried out a Madelung calculation for rutile. This analysis predicted a maximum Madelung constant when the axial ratio c/a was equal to 0.721. The observed ratio

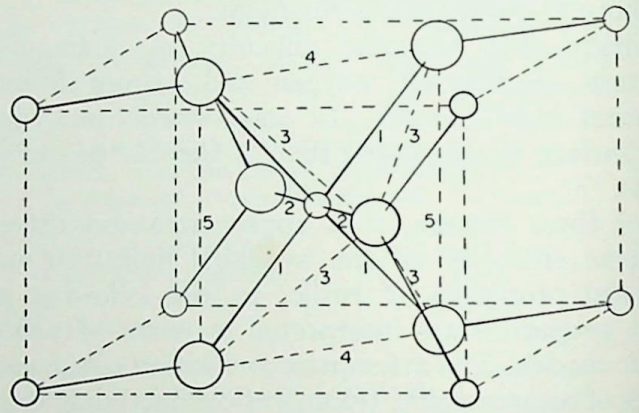

FIG. 2. The atomic arrangement of the tetragonal crystal rutile. Large circles represent oxygen atoms, small circles titanium atoms. The numbers refer to the bond types listed in Table I.

is $c/a=0.6441$. The calculated value of the Madelung constant is 4.816.

Making the assumption that the bonding is completely ionic (based on Ti^{+4} and O^{-2} ions), and taking into account also the repulsive contributions to the total energy, Lennard-Jones and Dent[17] have calculated the expected value of the parameter x (see "Bond Lengths and Angles"). In their method the same fixed separation r was assumed for all six Ti—O bonds, and the potential energy of the crystal was calculated as a function x. The value of the parameter x, necessary to minimize the potential energy was then obtained. Repeating this procedure for a number of values of r, a curve of x *versus* r was plotted. Using the experimental

data available at that time, SnO_2 and PbO_2 were found to lie on the theoretical curve. Using Baur's[12] experimental value of $x=0.306\pm0.001$ for rutile, one obtains a value of $r=2.05\pm0.03$ A from the theoretical curve, which is somewhat higher than Baur's experimental value of 1.988 ± 0.006 A. Once again, one finds a discrepancy which probably reflects a covalent contribution to the bonding in rutile.

2.8. Neutron Diffraction

Using thermal neutrons, Shull and Wollan[18] have obtained Laue diffraction patterns of a number of single crystals, including rutile.

3. X-RAY PROPERTIES

3.1. Soft X-Ray Spectra

Confirmation of the band structure theory of solids is obtained from soft x-ray emission experiments. The probability of a transition from an electronic state in a higher band to a vacant lower state depends, among other factors, on the number of electrons in the upper state. Consequently the distribution of intensity with wavelength provides information concerning the density of states as a function of energy.

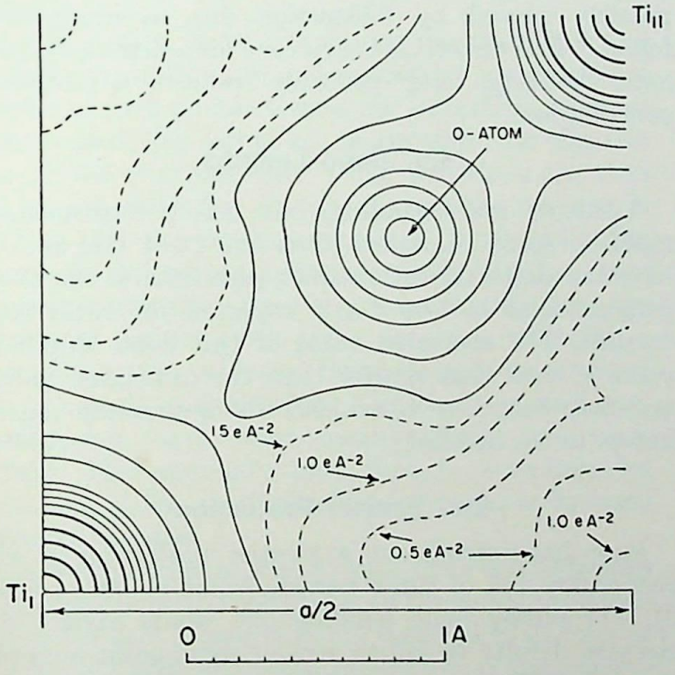

FIG. 3. Fourier projection of rutile on the [001] plane (after W. H. Baur[12]).

Soft x-ray absorption experiments also provide information concerning the energy levels in a solid. The K-absorption edge corresponds to the transition (consistent with the selection rules) of a $1s$ electron to the lowest empty level. Experimental values of the absorption coefficients are plotted against photon energy in Fig. 4.

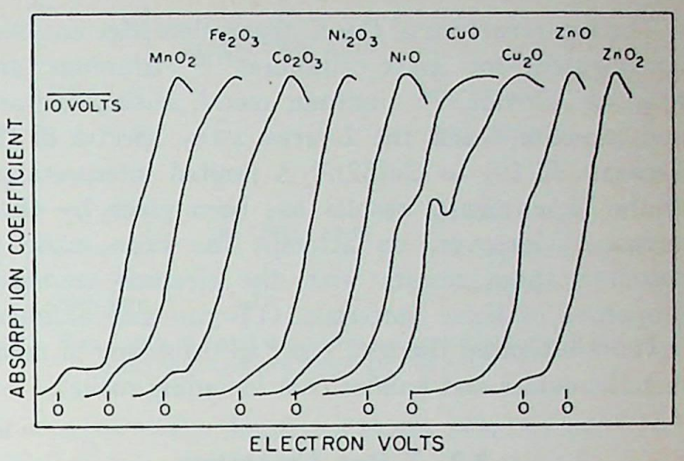

FIG. 4. K-edge structures for oxides of some of the transition metals (after Hanson and Knight[20]).

The distinguishing features of these curves are a small low-energy absorption, followed by a steep rise in absorption coefficient. On the high-energy side of the absorption edge the curve exhibits a fine structure characteristic of the environment of the atom (the type of bonding, etc.).

The shapes of such curves are determined by the absorbing atoms, their immediate surroundings, and by type of structure of which they form a part. Kiestra[19] has summarized his conclusions in the following words:

"(a) In a region close to the edge, the behavior of the absorption coefficient is mainly a property of the atom in question.

"(b) In the following region the fine structure is determined by the immediate surroundings of the atom.

"(c) In the region of highest energy, the fine structure depends essentially on the whole crystal lattice.

"For the transition metals and their compounds (a) comprises the region up to about 40 eV from the edge, (b) the region between about 40 eV and 150 eV, and (c) the region above 150 eV."

Recently, Hanson and Knight[20] have investigated the K-absorption edge structure of the fluorides, oxides, and sulfides of a number of transition metals. These workers found that oxides in which the metal assumed a higher valence exhibited greater low-energy absorption than the same metals in their lower valence form. In highly ionic compounds, the low-energy absorption is less than in compounds between elements exhibiting less difference in electronegativity.

When it is suspected that there is an appreciable change in symmetry and crystal bonding, as in barium titanate at the Curie temperature, the investigation of the K-absorption edge of titanium might prove to be of interest.

The fine structure of the K-absorption edge has been investigated for pure titanium,[21,22] titanium and titanium dioxide,[23,24] titanium metal, rutile, anatase, and brookite,[25] and the L-series x-ray spectra of the elements K(19) to Ge(32).[26] A limited interpretation of the experimental results has been given by these authors. Moreover, no attempt has been made to correlate these results with the electron transport properties of these materials. O'Bryan and Skinner[27] have investigated the soft x-ray spectroscopy of many metallic oxides and halides (not including rutile).

3.2. X-Ray Absorption

Brewster[28] lists values of the mass absorption coefficient of rutile. At the wavelengths 0.01, 0.1, 1, and 2 A, the values of the mass absorption coefficient are, respectively, 0.05434, 0.1790, 38.71, and 250.4, respectively. The linear absorption coefficient is equal to the product of the mass absorption coefficient and the density.

4. CRITERIA OF BOND TYPE

4.1. Introduction

When the covalent contribution to the bonding is small, as in the alkali halides, a quantitative estimate of its effect may be made. When a quantitative estimate cannot be made, however, it is usual to make use of certain criteria of covalency, such as the type of crystal structure, atomic radii, bond lengths, position in the periodic table and electronegativity difference of the components, Pauling's rules, etc.

It should be emphasized that the following criteria of the extent of the ionic contribution to the bonding are not necessarily in close agreement. Their value is therefore more qualitative than quantitative in nature.

4.2. Dielectric Constant

The optical and static dielectric constants of covalent crystals are almost equal. In contrast, the static dielectric constant of highly ionic crystals is considerably greater than the optical dielectric constant. The values for rutile single crystals are $K=173$ and $K_{opt}=8.4$ in the c direction, indicative of a strong ionic character.

4.3. Electronegativity

Mulliken[29–31] defines the electronegativity of an atom as the mean of its ionization potential and its electron affinity, thereby making use of observable quantities. The concept of electronegativity is less precise when more than one valence electron is involved.

Hannay and Smyth[32] have derived a formula which enables the extent of the ionic character of a bond to be estimated from the electronegativities of the bonded partners. This approach yields a value of 43% ionic character for the Ti—O bond in rutile, which is about the same as that of HF and KI.

4.4. Magnetic Susceptibility

The tetravalent titanium and the divalent oxygen ion both have noble-gas configurations. The *temperature-dependent* paramagnetic susceptibility of stoichiometric rutile should therefore be zero, whether the bonding is ionic or covalent. Feeble (Van Vleck) *temperature-independent* paramagnetism, however, is observed, possibly caused by "distortion due to interatomic forces.[33] This distortion is evidence for a departure from ionic bonding, and probably reflects a covalent contribution.

4.5. Bond Lengths

Assuming ionic bonding, but taking into account repulsive forces, Lennard-Jones and Dent (see Sec. 2) have calculated the cation-anion separation in the plane perpendicular to the c axis expected for rutile-type crystals. The measured value of this bond length in rutile is somewhat shorter than the calculated value, and may be taken as evidence for a covalent contribution to the bonding.

4.6. Fourier Projection

Baur has carried out a Fourier projection of the elementary cell of rutile perpendicular to [001] (Fig. 3). For purely ionic bonding one would expect the electron density to fall to zero at some point between the ions.[34] The considerably higher electron density between the oxygen and Ti_{II} ions in Fig. 3 is evidence for a covalent contribution to the bonding.

4.7. Solubility

The low solubility of rutile in polar solvents such as water, is taken as evidence for a considerable covalent contribution to the Ti—O bonding.

4.8. Pauling's Rules

One may consider the reduction in stability in the rutile structure resulting from the sharing of one edge by adjacent octahedra (Pauling's third rule[35]) to indicate a departure from purely ionic bonding. This reduction in stability is probably compensated by a corresponding increase in the covalent contribution to the bonding, made possible by this structure.

5. PARAMETERS FOR THE EVALUATION OF EXPERIMENTAL DATA OF SEMICONDUCTORS

5.1. Introduction

It is desirable, whenever possible, to present experimental data in terms of parameters derived from a (more or less simple) model. In the present case, neither the accuracy nor the consistency of the available experimental data permits a choice to be made between the commonly used models. For this reason, the properties of rutile are discussed in terms of two simple models.

In this section, these two models are examined, and the experimentally observed quantities are expressed in terms of such parameters as the ionization potential of the donors, the forbidden energy gap, the effective mass of the electrons, etc. These equations are then used as an indication of the appropriate manner in which to plot the experimental data. In the following sections the experimental data pertaining to the electron transport properties of rutile are introduced, and the parameters derived from these data are given. In a later section, the values of these parameters obtained from magnetic susceptibility, electrical conductivity, thermopower, and other measurements, are summarized. This summary may then be examined for indications of the most satisfactory model to be used in discussing rutile.

It is assumed (as in Fig. 5) that there is a forbidden gap of several electron volts between the valence and conduction bands.[36] Donor sites are believed to lie one- or two-hundred millivolts below the bottom of the conduction band. There may be overlapping of donor wave functions leading to the formation of donor bands. In this case the effective mass is expected to be much higher in the donor band than in the conduction band.

The various symbols used in later sections are defined below:

$n_0 = 2(2\pi mkT_0/h^2)^{\frac{3}{2}}$ = the constant 2.52×10^{19} electrons/cc and is defined for $T_0 = 300°$K. This quantity is the so-called "effective number of states."

n_c = the concentration of electrons in the conduction band (per cm^3). Electrons in donor bands, which may incidentally contribute to the conduction, are excluded.

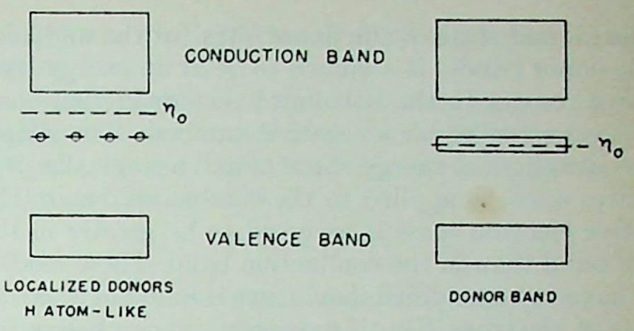

FIG. 5. Two types of band structure assumed in the discussion of the transport properties of rutile.

$M = (m_e/m)$ = the density-of-states effective electron mass.

$t = (T/300)$ = the absolute temperature divided by 300°K.

e = the electronic charge in coulombs.

η = the height of the Fermi level in joules, measured from the bottom of the conduction band.

k = the Boltzmann constant (units depend upon the context-joules per degree when transport properties are in question).

T = the absolute temperature in °K.

N_d = the concentration of donor atoms (per cm^3).

E_d = the energy of the donor sites with respect to the bottom of the conduction band, in joules.

b = the electron mobility in cm^2 volt^{-1} sec^{-1}.

E_g = the energy gap, i.e., the separation of the valence and conduction bands, in joules.

We take the criterion for the applicability of Maxwell-Boltzmann statistics to be $-\eta/kT > 3$.

5.2. Donor Sites in Rutile

Nonstoichiometry is believed to result in the presence of oxygen vacancies, together with twice that number of electrons, probably on Ti^{+3} sites.† No distinction will be made between nonstoichiometric rutile and rutile containing pentavalent impurities. In both cases the formation of donor sites will result. The presence of acceptor levels is considered if and when necessitated by experimental evidence. Two cases are considered corresponding to the two models: (a) noninteracting hydrogen-like donor sites, at sufficiently small concentration, in which case a single s electron is considered to move in the field of a net positive charge and (b) interacting donor sites, when the overlapping of the donor wave functions is appreciable. This interaction may lead to the formation of a donor band, and possibly to associations of hydrogen molecule-like donors, or associations of helium-atom-like donors and vacancies, in which two electrons are considered to move in the field of a net positive charge of two.

[36] W. Crawford Dunlap, Jr., *An Introduction to Semiconductors* (John Wiley & Sons, Inc., New York, 1957).

† The experiments of Gray and McCain indicate that heating of rutile in an atmosphere of hydrogen leads to a loss in weight of the rutile. This result is evidence for the creation of oxygen vacancies rather than hydrogen interstitial atoms. T. J. Gray, *The Defect Solid State* (Interscience Publishers, Inc., New York, 1957), p. 287.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

The ground state of the donor sites (or the midpoint of the donor bands) is assumed to lie at an energy level E_d with respect to the bottom of the conduction band (E_d is expected to be a negative number). The simple model of spherical energy surfaces and a single density-of-states mass, is applied to the conduction band. The effective electron mass is assumed to be greater in the donor band than in the conduction band. These models may have to be modified if evidence is found of a second source of electrons (i.e., if oxygen vacancies behave as helium-like centers).

Because of the random distribution of donors, the donor bands may have "tails" so that some overlapping of the conduction band may occur. However, this modification is not introduced into the mathematics because of the obvious difficulties. It can be shown[37] that these models lead to the following results:

$$n_c = n_0 M^{\frac{3}{2}} t^{\frac{3}{2}} \exp(\eta/kT). \tag{5-1}$$

5.2.1. Noninteracting Donor Sites

We usually make the additional assumption that the Fermi level η lies more than $3kT$ higher than the donor impurity levels.‡ This assumption implies that less than one impurity site in twenty is ionized, and leads to the following relation[38]:

$$n_c = \tfrac{1}{2} N_d \exp(E_d - \eta)/kT, \tag{5-2}$$

where N_d = the concentration of donor atoms (per cm^3), and E_d = the energy of the donor sites with respect to the bottom of the conduction band.

If Eqs. (5-1) and (5-2) are combined, one obtains the following expression for the concentration of conduction electrons in terms of the ionization potential of the donor impurity sites[39]

$$n_c = \left(\frac{n_0 N_d}{2}\right)^{\frac{1}{2}} M^{\frac{3}{4}} t^{\frac{3}{4}} \exp E_d/2kT. \tag{5-3}$$

5.2.2. Donor Bands

When the wave functions of the donor sites overlap, the energy levels of the isolated donors must be replaced by bands. Since there are N_d energy levels in the band, and each level may accommodate two of the N_d electrons, the donor band is only half filled at 0°K. Thermal excitations of electrons to the conduction band tend to lower the Fermi level as the temperature is raised. However, it can be shown that the Fermi level remains near the donor band provided that $N_d \gg n_c$. In this case it is appropriate to use the height of the Fermi level η as an indication of the position of the donor band. For this purpose η is expressed in terms of observable quantities by taking logarithms of both sides of Eq. (5-1) and multiplying by kT.

5.3. Interpretation of Hall Data

The Hall constant R for nondegenerate n-type semiconductors (discussed also in Sec. 8) is related to n_c by the relation[40]

$$n_c = r/eR = -6.25 \times 10^{18} r/R. \tag{5-4}$$

The magnitude of the coefficient r, which depends on the type of scattering,[40] lies between 1 and 2.

5.3.1. Noninteracting Donor Sites

Combining Eqs. (5-3) and (5-4) one obtains

$$1/(-R) = \text{constant} \times t^{\frac{3}{4}} \exp(E_d/2kT), \tag{5-5}$$

or

$$[\ln(-R) + \tfrac{3}{4} \ln t] = K_1 - E_d/2kT, \tag{5-6}$$

in which K_1 is a constant which is dependent on M, N_d and on the coefficient r of Eq. (5-4). When the quantity $[\ln(-R) + \frac{3}{4} \ln t]$ is plotted against reciprocal temperature, one obtains $-E_d$ from the slope, and if one knows N_d, and if M is temperature independent, one obtains M from the value of the intercept, K_1, made by this straight line.

5.3.2. Donor Bands

In Sec. (5.2.2) the height of the Fermi level has been discussed in the case in which the overlapping of the donor wave functions leads to the formation of donor bands. Provided that $N_d \gg n_c$, it may be shown that the Fermi level lies below, but near, the midpoint of the donor band. It is reasonable to assume that the electron mobility in the conduction band is much greater than in the donor band. It is therefore appropriate to plot the high temperature Hall data in terms of Eq. (5-1), which may be rewritten with the known quantities on the left-hand side, as follows

$$\ln n_c - \ln n_0 - \tfrac{3}{2} \ln t = \tfrac{3}{2} \ln M + \eta/kT. \tag{5-7}$$

At sufficiently low temperatures, however, as the concentration of conduction electrons decreases, the effect of the electrons in the donor band is expected to dominate. Maxwell-Boltzmann statistics are inapplicable to these latter electrons.

5.3.3. Hall Mobility

The electrical conductivity may be expressed

$$\sigma = n_c e b. \tag{5-8}$$

[37] See Eq. (5.33a) of reference 36.

‡ Because of the high value of the dielectric constant of rutile, E_d may prove to be so small that this assumption is justified only at very low temperatures, and for sufficiently high donor concentrations. The effect of the high dielectric constant will be counteracted to some extent if the effective mass ratio is also high. See p. 267 of reference 36.

[38] The justification for the factor $\frac{1}{2}$ in Eq. (5-2) found in Appendix III of E. Spenke, *Elektronische Halbleiter* (Springer-Verlag, Berlin, 1956).

[39] Apart from the factor 2, and the sign of E_d, this is Eq. (5-31) of reference 36. E_d, of course, is measured with respect to the bottom of the conduction band.

[40] Figure 6.53 of reference 36.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by eGangotri

Combining Eqs. (5-4) and (5-8) one obtains an expression for the mobility b in terms of the Hall coefficient and the electrical conductivity σ:

$$b=0.84\sigma(-R/r). \tag{5-9}$$

5.4. Interpretation of Electrical Conductivity Data

5.4.1. Intrinsic Semiconductors

If the density-of-states masses of electrons and holes are equal, then the Fermi level is in the middle of the energy gap, i.e., $\eta=-E_g/2$. Combining Eqs. (5-1) and (5-8) and

$$\sigma=n_0ebM^{\frac{3}{2}}t^{\frac{3}{2}}\exp(-E_g/2kT). \tag{5-10}$$

In this case the temperature dependence of the exponential factor is usually so great in comparison with that of the factors b and $t^{\frac{3}{2}}$ that Eq. (5-10) may be written

$$\sigma=K_2\exp(-E_g/2kT). \tag{5-11}$$

E_g may then be evaluated from the slope of a plot of $\ln\sigma$ *versus* reciprocal temperature.

5.4.2. Impurity Semiconductors

Isolated donors.—In the case of noninteracting impurities, one combines Eqs. (5-3) and (5-8) to give

$$\ln\sigma=\tfrac{1}{2}\ln(n_0N_d/2)+\ln e+\ln b+\tfrac{3}{4}\ln M+\tfrac{3}{4}\ln t+\exp(E_d/2kT). \tag{5-12}$$

Without some assumption concerning the temperature dependence of the mobility b, E_d cannot be evaluated from conductivity data alone. (The assumption of a single density-of-states electron mass for the conduction band necessarily implies that M is considered to be temperature independent.)

Breckenridge and Hosler[41] (following Fröhlich[42,43]) attempt to interpret their data by using the following relation for the mobility when the scattering is predominantly due to optical lattice vibrations:

$$b=A(\exp(\theta/T)-1), \tag{5-13}$$

where θ is the Debye temperature. After the appropriate substitution

$$\ln\sigma-\tfrac{3}{4}\ln t-\ln(\exp(\theta/T)-1)=K_3+(E_d/2kT), \tag{5-14}$$

in which K_3 is a constant which depends on N_d, A, and M. An assumption concerning the value of θ permits the left-hand side of Eq. (5-14) to be evaluated from conductivity measurements, and plotted against reciprocal temperature. From the slope E_d may be determined. Since K_3 is dependent on the unknowns N_d, A, and M, it is not feasible to attempt an interpretation of the intercept of this plot in the absence of further information.

Actually, (as shown in Sec. 8) the Hall mobility data of Breckenridge and Hosler for slightly reduced rutile are adequately represented above room temperature by the empirical relation

$$b=aT^{-2.5}, \tag{5-15}$$

where T is the absolute temperature, and a is a constant independent of temperature. Substitution of this relation into Eq. (5-12) enables one to write

$$\ln\sigma+1.75\ln t=K_4+E_d/2kT. \tag{5-16}$$

Donor bands.—At sufficiently low temperatures the electrons would be expected to lie in the donor band. The donor-band conductivity in this low-temperature range should depend on temperature chiefly through the mobility factor b. Little information would be obtainable concerning the position of the donor band with respect to the conduction band.

At higher temperatures the electrons in the conduction band should make a greater contribution to the conductivity than the electrons in the donor band. Provided that information is available concerning the electron mobility, the data on electrical conductivity at higher temperatures may be used to give information concerning the Fermi level, and hence the approximate position of the donor band. Making the usual assumptions concerning the applicability of Maxwell-Boltzmann statistics and of the concept of a single effective electron mass to the electrons in the conduction band, we may combine Eqs. (5-1) and (5-8) to yield the following relation:

$$\ln\sigma-\ln n_0e-\tfrac{3}{2}\ln t=\tfrac{3}{2}\ln M+\ln b+\eta/kT \tag{5-17}$$

in which the quantities on the left-hand side are all known. When the assumption implied in Eq. (5-13) is valid, we may combine Eqs. (5-13) and (5-17) and express the result in the form

$$\ln\sigma-\tfrac{3}{2}\ln t-\ln(\exp(\theta/T)-1)=K_5+\eta/kT. \tag{5-18}$$

When the $T^{-2.5}$ relation [Eq. (5-15)] is valid, one may write

$$\ln\sigma+\ln t=K_6+\eta/kT. \tag{5-19}$$

5.5. Interpretation of Thermopower Data

5.5.1. Impurity Semiconductors

Noninteracting donors.—Equating Eqs. (5-1) and (5-2) one obtains

$$n_0M^{\frac{3}{2}}t^{\frac{3}{2}}\exp(\eta/kT)=\tfrac{1}{2}N_d\exp(E_d-\eta)/kT \tag{5-20}$$

which may be expressed in the form

$$\tfrac{1}{2}\ln n_0+\tfrac{3}{4}\ln M+\tfrac{3}{4}\ln t+\exp(\eta/kT)=\tfrac{1}{2}\ln N_d+E_d/2kT-\ln 2. \tag{5-21}$$

Noting that

$$\eta/kT=Q/k+Q^*/kT \tag{5-22}$$

[41] R. G. Breckenridge and W. R. Hosler, Phys. Rev. **91**, 793 (1953).

CC-0. Bhabha Atomic Research Centre (BARC). Digitized by S3 Foundation USA

[see Eq. (7-2)], where Q^* is approximately equal to $2kT$, one obtains

$$eQ/k+\tfrac{3}{4}\ln(T/300)=K_7+E_d/2kT \qquad (5\text{-}23)$$

in which the constant K_7 includes Q^*/kT, and the impurity concentration term, and the effective mass term, which are assumed to be temperature independent. The thermopower, Q, is defined in Sec. 7.1.

Donor bands.—At sufficiently low temperatures, the contribution of the electrons in the conduction band is negligible. In this temperature region, the electrons in the donor band are expected to exhibit degeneracy, and the dynamic term Q^*/kT of Eq. (5-22) should make the major contribution to the thermopower. This contribution (approximately $2k/e$) is almost temperature independent.

At higher temperatures, where the electrons in the conduction band make the main contribution to the thermopower, the height of the Fermi level is related to the thermomower through Eq. (5-22). Replacing Q^* by its approximate value $2kT$, one obtains

$$E_f=\eta/e=(Q+2k/e)T. \qquad (5\text{-}24)$$

Thus when the donor sites interact to form donor bands one expects an almost temperature-independent value for QT in the higher temperature range. At still higher temperatures where thermal excitation raises a large proportion of the electrons from the donor band to the conduction band, the Fermi level falls below the donor band with increasing temperature, and Q should tend to a constant value.

5.5.2. Correlation of Thermopower and Conductivity Data

Impurity semiconductors.—When the temperature is sufficiently high for the contribution of the electrons in the conduction band to dominate the contribution to the conductivity of the electrons in the donor band, the correlation between thermopower and conductivity data is independent of the interaction between donor sites. Equations (5-1) and (5-8) may be combined to yield

$$\ln\sigma=\ln(n_0e)+\ln b+\tfrac{3}{2}\ln M+\tfrac{3}{2}\ln t+\eta/kT. \quad (5\text{-}25)$$

When the foregoing assumption, Eq. (5-13), concerning b is permissible, one obtains

$$\ln\sigma-\tfrac{3}{2}\ln t-\ln(\exp(\theta/T)-1)=K_8+\eta/kT \quad (5\text{-}26)$$

in which K_8 is a constant which depends on A and M. The thermopower Q may be expressed in the form $Q=(\eta-Q^*)/eT$, where Q^* is a quantity of the order of magnitude of $2kT$.§ Whence

$$\ln\sigma-\tfrac{3}{2}\ln t-\ln(\exp(\theta/T)-1)=K_8+(eQ/K)+Q^*/kT. \quad (5\text{-}27)$$

If an assumption is made concerning θ, the left-hand side of this equation may be evaluated from conductivity measurements. However, the quantity K_8 involves both the effective mass ratio M and the mobility factor A. Hence, in the absence of further information, no correlation between electrical conductivity and thermopower is possible.‖ To the extent that the term Q^*/kT is temperature independent, however, it should be possible to correlate dQ/dT with the rate of change of the left-hand side with temperature.

A similar conclusion is reached when the mobility b is inversely proportional to a power of the absolute temperature, as in Eq. (5-15).

5.5.3. Correlation of Thermopower and Hall Data

Correlation of thermopower Q with the Hall coefficient would involve one fewer variable (b), and would therefore be preferable to the correlation with electrical conductivity.

6. ELECTRICAL CONDUCTIVITY

6.1. Rutile Single Crystals (Intrinsic)

Cronemeyer[44] has measured the intrinsic conductivity of rutile single crystals in the temperature range 300° to 1400°C, using specimens approximately 1×1×10 mm in dimensions. The four-terminal method of measurement was used (see his Fig. 3); hence, the measured conductivity should be independent of the electrode material. However, the conductivity was found to be field dependent when the field strength was greater than 10 v/cm for the intrinsic conductivity, and greater than 0.1 v/cm for reduced (presumably nonstoichiometric) samples.

Cronemeyer's results may be represented by the following equations, in which σ represents the electrical conductivity in (ohm cm)$^{-1}$, and T is the absolute temperature:

Direction perpendicular to the c axis

623° to 1123°K

$$\ln\sigma=7.92-17\,600/T \qquad (6\text{-}1)$$

1123° to 1673°K

$$\ln\sigma=11.10-21\,200/T. \qquad (6\text{-}2)$$

Direction parallel to the c axis

773° to 1223°K

$$\ln\sigma=8.43-17\,600/T \qquad (6\text{-}3)$$

1223° to 1673°K

$$\ln\sigma=11.30-21\,200/T. \qquad (6\text{-}4)$$

‖ However, in some materials, such as NiO, it is possible to equate the density of states with the number of cations. This simplification, which results from the localization of the cation wave functions, facilitates a correlation of thermopower and conductivity data without requiring a knowledge of the effective electron mass. See F. J. Morin, Bell System Tech. J. 37, 1047 (1958).

§ References are given in Sec. 7.

The respective activation energies calculated from these data are 1.53, 1.84, 1.53, and 1.84 ev. For intrinsic samples, the energy gaps are assumed to be approximately twice these values. In deriving these results the temperature variation of the $(T/300)^{\frac{3}{2}}$ and mobility factors of Eq. (5-1) have been neglected.

Cronemeyer associates the 3.06-ev energy gap obtained in this manner with the optical absorption edge at 3.02 ev.

A more recent investigation of the conductivity of single crystals of rutile has been carried out by Y. L. Sandler.[45] Preliminary published results indicated a somewhat higher conductivity in the temperature range 250° to 700°C, and a somewhat smaller energy gap of 2.8 ev.

6.1.1. Field Strength Dependence

Below 900°C, Cronemeyer's measurement[44] of the intrinsic conductivity of rutile showed some field strength dependence for fields greater than 10 v/cm. Measurements made at 820°C showed an increase in conductivity of about fifty percent when the field was increased to about 20 v/cm. Nonlinearity apparently begins at an even lower field strength (0.1 v/cm) in reduced samples.

6.1.2. Current versus Time

Sandler[45] has observed the current *versus* time characteristics of rutile single crystals. Measurements were made at temperatures up to 720°C for various applied steady voltages. Only curves for 654°C are given in the report. Although it was not explicitly stated, the two-terminal method was probably used, with evaporated gold electrodes. The discussion seems to indicate that the specimens were in an atmosphere of pure oxygen. To ensure that the observed time-dependent effects were not due to surface conduction, a guard-ring electrode was used.

The curves were characterized by relaxation times that decreased as the applied voltage increased. For 1.06-v potential difference, the relaxation time was about two minutes. The author considered that the data might be explained in terms of space-charge polarization and field emission.

6.1.3. Ionic Conductivity

Large currents could be passed through the rutile crystals for hours without destructive effect. Hence Cronemeyer concluded that the conductivity of rutile was essentially electronic.

6.1.4. Dependence on Area of Cross Section

The conductivity was observed to increase by a factor of fifteen when the cross-sectional area was increased from 3×10^{-2} to 6×10^{-2} cm^2. Cronemeyer suggested the possibility that this was due to "carrier injection with predominant recombination at the surface."

6.1.5. Other Phenomena

Sandler[45] has investigated the effect on the conductivity of rutile crystals of the heating during the process of depositing the evaporated gold electrodes. Electrodes were formed at 100 and 300°C. The conductivity ceased to be an exponential function of reciprocal temperature below 270°C, and below 500°C, respectively.

In the presence of water vapor, the conductivity was considerably increased. By the use of a guard electrode, it was shown that the effect was not due to surface conduction, but was probably due to the effect of moisture on the crystal-electrode interface.

6.2. Rutile Ceramic (Intrinsic)

Dependence of electrical conductivity on oxygen pressure is probably associated with departures from stoichiometry.¶ The conductivity of rutile containing intentionally introduced oxygen vacancies is discussed in a later section. The workers referred to in this section made no deliberate attempt to reduce their specimens more than the degree of reduction incidental to the conditions of measurement.

Earle[46] measured the electrical conductivity of pressed disks of rutile as a function of the pressure of the surrounding oxygen. His results may be expressed in the form

$$\ln\sigma = A - B\ln p, \tag{6-5}$$

where σ is the conductivity in (ohm cm)$^{-1}$, p is the oxygen pressure in atmospheres, and A and B are temperature dependent parameters.

At pressures below 30 mm of mercury B was found to be $\frac{1}{2}$ at 626°C, and equal to $\frac{1}{3}$ in the temperature range 755° to 968°C. Above 30 mm of mercury, B was equal to $\frac{1}{4}$. At 50 mm of mercury and 1000°K the conductivity was 1.6×10^{-6} (ohm cm)$^{-1}$. The activation energy was about 1.7 ev, and appeared to be independent of the oxygen pressure. Evaporated gold electrodes were used.

Earle investigated the possibility of ionic conductivity, and believes that its contribution was negligible under the conditions of his experiment.

Hauffe[47] also investigated the dependence of the electrical conductivity of rutile on the pressure of the surrounding oxygen gas. His results may be expressed by the same formula, but with different values of A

[45] Laboratory for Insulation Research, Massachusetts Institute of Technology, Progress Rept. No. XVII (1955).

¶ The effect of oxygen pressure on surface conductivity is also important. The effects of oxygen and other gases on the surface conductivity of silicon and germanium are discussed in *Semiconductor Surface Physics*, R. H. Kingston, editor (University of Pennsylvania Press, 1956).

[46] Marshall D. Earle, Phys. Rev. **61**, 56 (1942).

[47] K. Hauffe, *Reaktionen in und an festen Stoffen* (Springer-Verlag, Berlin, 1955), p. 136.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

and B. At 800°, 900°, and 1000°C, the values of B were, respectively, 1/4.8, 1/4.4, and 1/5.3.

Combining measurements made at these three temperatures, and using the approximate value of $\frac{1}{5}$ for B, Hauffe's results may be represented roughly by the relation

$$\ln\sigma = -\tfrac{1}{5}\ln p - 22\,400/T \qquad (6\text{-}6)$$

in which p is expressed in atmospheres, and T is the absolute temperature. The coefficient of $1/T$ yields an activation energy of 1.93 ev.

Gorelik[48] has measured the electrical conductivity of "pure" sintered rutile, and rutile to which various amounts of the oxides of the alkaline earths had been added. His results for "pure" rutile may be expressed by the following formula in the temperature range 380° to 490°K:

$$\ln\sigma = 2.5 - 11\,700/T. \qquad (6\text{-}7)$$

The corresponding activation energy is 1.02 ev. Gorelik's investigation of the effect of a magnetic field on the electrical conductivity is discussed in another section.

6.3. Reduced Rutile

The term "reduced rutile" is used here to signify that an attempt has been made to introduce oxygen vacancies by heating the specimen in oxygen at reduced pressure, or in an atmosphere of hydrogen or some other reducing gas. It is implied that the specimens have been quenched so that the vacancy concentration is higher than that corresponding to the equilibrium at the temperature and pressure at which measurements are made.

When an oxygen vacancy is created, the two electrons associated with the ion must be retained in the crystal to preserve electrical neutrality. There is some uncertainty whether these electrons (a) are associated with the oxygen vacancies to form helium-like donor sites, or (b) whether the electrons convert two Ti^{+4} sites into Ti^{+3} sites.

In case (a) one, or possibly two, activation energies are expected for electron transport phenomena when the vacancy concentration is too low for the formation of impurity bands. Because of the formation of donor bands one expects the disappearance of the activation energy at sufficiently low temperatures when the vacancy concentration is high.

6.3.1. Experimental Results

Breckenridge and Hosler[49] measured the electrical conductivity of reduced rutile single crystals and ceramics. The conductivity of these samples lay in the range 0.03 to 10 (ohm cm)$^{-1}$, depending on the degree of reduction, which was carried out in hydrogen at elevated temperatures.

[48] S. I. Gorelik, J. Exptl. Theoret. Phys. U.S.S.R. **21**, 826 (1951).

[49] R. G. Breckenridge and W. R. Hosler, Phys. Rev. **91**, 793 (1953).

The curves of the logarithm of the conductivity *versus* reciprocal temperature were fairly flat, and in most cases had negative slopes at 1000 and at 77°K.

There are so many disposable parameters in the simple model [Eq. (5-12)] (Debye temperature θ, impurity concentration, effective mass, etc.) that it is unlikely that its use in the interpretation of these data can yield significant information, except in conjunction with Hall data. The values of the electron mobility obtained from Breckenridge and Hosler's conductivity and Hall data are discussed in Sec. 8.

Kataoka and Suzuki[50] have made measurements of the electrical conductivity and thermopower on reduced rutile ceramic. When these results are plotted[51] according to Eq. (5-16) assuming isolated donor levels, the slopes correspond to values of the donor ionization potentials in the range 0.29 to 0.35 ev. An exception to this result (0.23 ev) was the sample of highest conductivity (20 ohm^{-1} cm^{-1}) for which the explanation could be partial degeneracy.

When the results are plotted[51] according to Eq. (5-19) assuming a donor band, the resulting values of the Fermi level lie in the range 0.12 to 0.15 ev, with the exception of the sample of highest conductivity which yielded a value of 0.09 ev.

Boltaks[52] and co-workers have investigated the conductivity of sintered specimens of rutile which had been reduced in hydrogen or in carbon monoxide. They found that the temperature variation of the pre-exponential term in Eq. (5-12) could not be neglected. When allowance was made for the $T^{\frac{3}{2}}$ factor in Eq. (5-12) a linear plot of $\ln\sigma$ *versus* reciprocal temperature was obtained. From the slope of the tangent to this curve, the ionization potential E_d of the donor sites was estimated to be less than 0.2 ev at room temperature. Apparently no consideration has been given to the effect of the variation of the mobility b with temperature [Eq. (5-12)].

6.3.2. Single Crystals versus Ceramics

The measurements of Breckenridge and Hosler[49] may be examined to compare the properties of polycrystal-

[50] S. Kataoka and T. Suzuki, Bull. Electrotech. Lab. Tokyo **18**, 732 (1954).

[51] Measurements of electrical conductivity made by Kataoka and Suzuki may be represented within the experimental error by the following expressions between $1000/T = 1.5$ and $1000/T = 3.5$:

Specimen	$\log_{10}\sigma$
1	$2.12 - 250/T$
2	$2.02 - 550/T$
3	$1.72 - 520/T$
4	$1.40 - 500/T$
5	$0.60 - 400/T$
6	$-0.13 - 475/T$

In the same temperature range, $\log t = \log(T/300)$ may be represented approximately as a function of $1/T$ by the expression $0.62 - 184/T$. Substitution of these expressions into Eqs. (5-16) and (5-19) yields the activation energies and ionization potentials given in the text. The mobility has been assumed to be proportional to $T^{-2.5}$ (see Sec. 8-2).

[c] The corresponding resistivity and Hall curves are almost coincident.

line specimens and single crystals. When this comparison is made for specimens that have been reduced under similar conditions, there is no evidence for a significant difference between the single crystal and polycrystalline specimens with respect to mobility, effective mass, or activation energy.

In Table II some of Breckenridge and Hosler's results have been tabulated for the purpose of comparing the parameters for single crystal and ceramics. The comparison is justified only for pairs of samples that had been reduced (in hydrogen) at the same temperature for approximately the same length of time.

As an example of the difficulty of interpreting these results, one notes that the Hall coefficient of the National Lead single crystal (reduced 5 min at 500°C) is higher (by a factor of eight) than that of the ceramic specimen subject to the same reduction. However, the Hall coefficient of the Linde crystal is less than or equal (depending on the direction of the current with respect to the optical axis) to that of the ceramic specimen. Similarly, there appears to be no evidence that the effective mass ratio is greater for single crystals than for ceramic specimens.

6.4. Rutile Containing Added Impurities

6.4.1. Conductivity in Air at Normal Pressure

The effect of impurities on the electrical conductivity of rutile ceramics has been investigated by Hauffe,[47,53] by Grunewald,[54] and by Johnson.[55]

Johnson's samples were air-quenched from 1200 to 250°C and measurements were made at the latter temperature. The results should be accepted with some caution because little attention was paid to the state of reduction of the specimens, and the impurities may have assumed valences other than those expressed in the formulas given. In every case the effect of the impurity approached a saturation value when the concentration exceeded about one or two mole percent. This saturation value is given in the following summary.

6.4.2. Impurities of the Type X_2O

The oxides of lithium, potassium, and silver decreased the conductivity of rutile, while that of sodium produced an increase (Table III). The effect was small in comparison with some of the results discussed in the following.

6.4.3. Impurities of the Type XO

The effects of admixture of the oxides of beryllium, magnesium, calcium, strontium, barium, zinc, cadmium,

nickel, and cobalt were investigated. The effect was small, except in the case of beryllium (increase by a factor of 25), and calcium (decrease by a factor of 0.07). The effect of beryllium was considered to be possibly due to the donor electrons resulting from the formation of interstitials. In the case of calcium the explanation of the anomalously low value may be as follows. Comparison of Johnson's Table IV with his Fig. 1 suggests that the correct value for calcium is probably considerably higher than 0.07, a value which was apparently influenced by one low experimental point.

Gorelik[56] has investigated the effect of various concentrations of the oxides of the alkaline earths on the electrical conductivity of rutile in the temperature range 380° to 490°K. Values of the activation energies obtained from plots of the logarithm of the conductivity *versus* reciprocal temperature lay in the range 0.78 to 1.15 ev for additions of CaO and SrO. At a temperature of 418°K the admixture of about three moles of CaO per hundred moles of TiO_2 caused a fourfold increase in conductivity. Further increase in CaO content caused the conductivity to decrease until it reached one quarter of its initial value when the CaO content reached twenty-five moles per hundred moles of TiO_2.

One mole of SrO per hundred of TiO_2 yielded a fifty-fold increase in conductivity over the value for "pure" rutile. Further admixture of SrO caused a decrease in conductivity, so that an admixture of 50 moles of SrO per 100 moles of TiO_2 resulted in a value of conductivity only slightly higher than the value for "pure" rutile. Gorelik interpreted his results in terms of contributions from ionic and electronic conductivity. This interpretation was based partly on his investigation of the effect of a magnetic field on the conductivity of these specimens, and is discussed further in another section.

6.4.4. *Impurities of the Type X_2O_3*

With the exception of the oxides of boron and yttrium, the effect of oxides of this group is not pronounced. The low value assigned to the oxide of yttrium appears to be unduly influenced by a single experimental point, and one could well expect a value as high as 0.3 from Johnson's Fig. 1.

Admixture of 0.5 mole percent of chromium oxide decreased the conductivity at 1100°C, but produced a sharp increase in conductivity at 500°C. Further increase in admixture of this oxide caused little change in conductivity. The apparent activation energy was reduced by a factor of three by the admixture of 0.5 mole percent. This apparent change in activation energy appears to be associated with a different mechanism of conductivity. This conclusion is strengthened by the oxygen pressure dependence of the conductivity of this material, discussed in another section.

[56] S. I. Gorelik, J. Exptl. Theoret. Phys. U.S.S.R. **21**, 826 (1951).

6.4.5. *Impurities of the Type XO_2*

The effect of the oxide of silicon appears to be surprisingly high in view of the valence assumed by this element.

6.4.6. *Impurities of the Types X_2O_5 and XO_3*

Some of the largest effects were produced by oxides in these groups. However, the low values corresponding to the oxides of molybdenum and vanadium are remarkable. The difference between the elements molybdenum (atomic number 42) and niobium (atomic number 41) is interesting, as is the difference between the effect of the oxides of tungsten (atomic number 74) and tantalum (atomic number 73).

Table IV summarizes the effect of adding certain oxides to rutile containing 0.5 mole percent of niobium oxide. The large effect of aluminum oxide is readily explained. The trivalent ion has a noble gas configuration, hence a comparatively large amount of energy is required for the removal of the fourth electron. Aluminum occupies a titanium site in the crystal structure but remains in the trivalent state. The association of trivalent aluminum and pentavalent niobium ions preserves electrical neutrality without the formation of trivalent titanium ions. Hence the large reduction in the electrical conductivity of the niobium-doped rutile resulting from the addition of aluminum oxide.

Unfortunately this explanation does not account for the enormous difference between the effects of the other oxides listed in Table IV. The fourth ionization potentials are believed to lie in the range 50 to 64 ev (compare with that of aluminum: 120 ev).

The effect is not closely related to the ionic radius, since the value for trivalent gallium (0.26 A) is only slightly smaller than the ionic radius of trivalent chromium (0.64 A).

Gallium, indium, and chromium are known to exhibit more than one valence in the formation of oxides. The extreme values in the table are for the oxides of aluminum and yttrium, both of which form only trivalent ions with noble gas configurations. A satisfactory theory of these effects would have to explain the remarkable difference between the effects of these oxides.

6.4.7. *The Results of Hauffe and Co-Workers*

Hauffe[47] and co-workers have found that the admixture of a small amount of WO_3 to rutile increases the conductivity enormously (page 136 of reference 47). The effect is more pronounced at 600°C than at 900°C. These workers have also investigated the effect of admixture of the oxides of nickel, gallium, aluminum, and chromium on the electrical conductivity of rutile ceramic in the range 600 to 900°C. The effect of the oxides of aluminum, nickel, and gallium was small, and produced no apparent change in the activation energy for the impurity range 0 to 2.0 mole percent.

In_2O_3	÷ 990
Cr_2O_3	÷ 550

[a] See reference 55.

6.4.8. *Effect of Impurity Concentration*

Johnson attempted to estimate the percentage of foreign oxide that can be taken into solution at 1200°C and retained in this state during subsequent heat treatment, i.e., air-quenching to 250°C. This result showed a saturation effect in most cases at concentration above about 0.25 to 0.50 mole percent.

The conductivity was highly dependent on the heat treatment a sample received, and the rate of cooling determined the degree to which "exsolution" occurred. It would be of interest to establish the extent to which these effects are (a) dependent on the formation of impurity bands and (b) are determined by the solubility of the added oxide in rutile. In case (a) it is probable that there exists a correlation between these results and the paramagnetic susceptibility of these doped specimens.

7. THERMOPOWER

7.1. Introduction

The electrical circuit for the measurement of the thermopower (or Seebeck coefficient) of a semiconductor S with respect to a metal M, is represented schematically in Fig. 6. The junctions are maintained at temperatures T_1 and T_2, where T_2 is greater than T_1. The thermopower of S with respect to M is defined as

$$Q_S - Q_M = -d(V_2 - V_1)/d(T_2 - T_1) \qquad (7\text{-}1)$$

when the net current in the circuit is zero.

Since thermal emf's are additive, it has a meaning to talk of the absolute thermopower of a substance. This is particularly true of semiconductors, since they exhibit much larger thermoelectric effects than metals.

It is shown by Seitz[57] and by Domenicali[58] that the thermopower, Q, consists of the two terms,** and can be represented by

$$Q = (1/e)((\eta - Q^*)/T). \qquad (7\text{-}2)$$

Q^* is the heat transport per electron, which in semiconductors is approximately $2kT$, and so this term

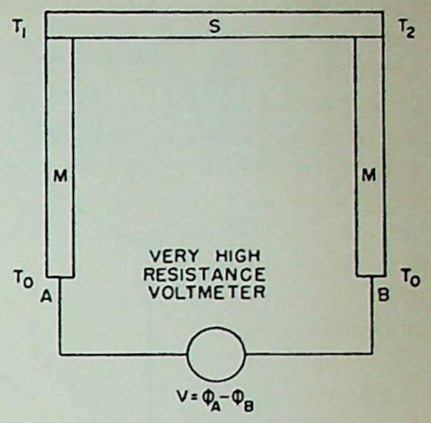

FIG. 6. Circuit for the measurement of the thermopower of a semiconductor S with respect to a metal M, using an electrostatic voltmeter V.

contributes about -170 μv per degree to the thermopower, at all temperatures. The first term on the right-hand side of Eq. (7-2) has the same sign as the Fermi potential of the electrons, η, so that when the Fermi level lies below the bottom of the conduction band this term is negative.

In practice, the small thermopower of the metal is usually neglected in comparison with the much larger value for the semiconductor, so that the measured potential difference is given by the expression

$$F_s = V_1 - V_2 = \int_{T_2}^{T_1} Q_S dT. \qquad (7\text{-}3)$$

The interpretation of Q_S in terms of the choice of band model is discussed in Sec. (5-5).

7.2. Experimental Results

Kataoka and Suzuki[59] have measured the thermopower of ceramic rutile in various stages of reduction. Their high resistivity specimens (3000 ohm cm at 300°K) exhibited a thermopower of -1.03 mv/°C in the range 0 to 90°C. The thermopower, as expected, decreased with increasing impurity content. The specimens of lowest resistivity (0.05 ohm cm at 300°K) exhibited a thermopower of -0.17 mv/°C between 0 and 100°C, falling to about -0.15 mv/°C between 150 and 200°C. Some of their curves of thermopower *versus* temperature were concave toward the temperature axis.

These workers claim to have established a correlation between thermopower and the conductivity of the specimens. The difficulties encountered in making such a correlation due to the uncertainty in the values of the mobility, the effective mass, and in the dynamic term Q^*/eT of the thermopower are discussed in Sec. (5.5.2).

However, the thermopower may be plotted against reciprocal temperature to yield a value for the ioni-

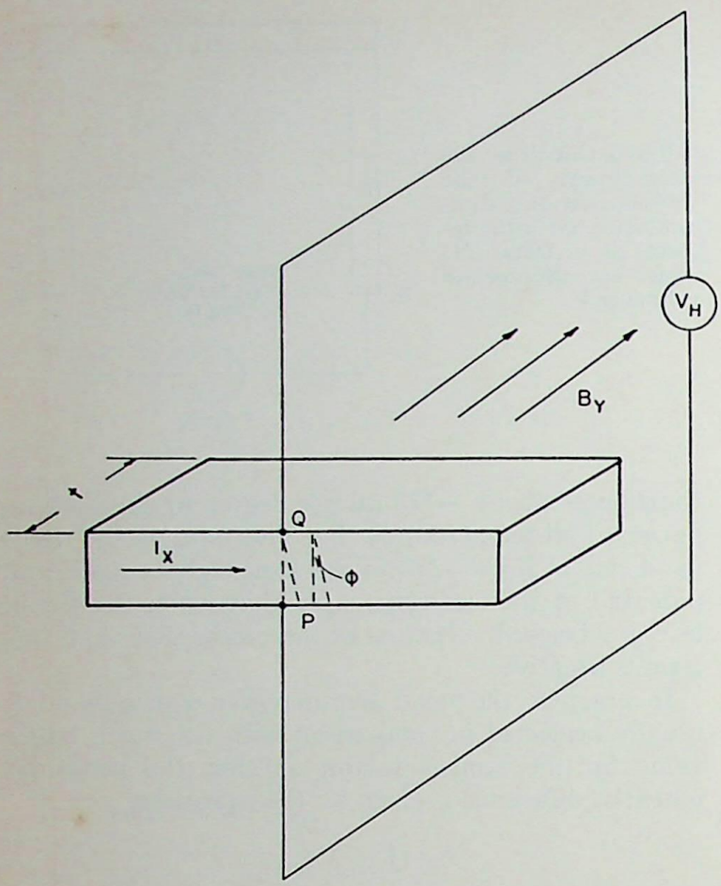

FIG. 7. Schematic diagram of apparatus for Hall effect measurements.

zation potential of the donor sites, to the extent that the simple band model used in deriving Eq. (5-23) is valid. This procedure, applied to the data on page 735 of reference 59 yields values of E_d (noninteracting donor model) in the range -0.02 to -0.13 ev. There appears to be no correlation between the values obtained in this way and those obtained from conductivity data, discussed in Sec. (6.3.1).

When the values of the Fermi level (donor band model) are obtained from these same data by the use of Eq. (5-24), one obtains values ranging from -0.31 ev to zero, the position of the Fermi level rising with increasing donor concentration (as evidenced by the resistivity measurements).

These workers have also shown that the thermopower of their specimens is dependent on the ambient atmosphere. At a pressure of 10^{-1} of mercury the thermopower of their specimens was more highly temperature dependent than at atmospheric pressure.

Boltaks and co-workers[60] have investigated the thermopower Q of sintered rutile that had been reduced in hydrogen or in carbon monoxide. In all cases the thermal emf was negative. Here, Q was found to decrease with increased reduction. The experimental values lay in the range -250 to -415 μv per degree. Thus, Q decreased with increasing temperature for the slightly reduced samples. The thermopower of the highly reduced samples, however, increased with increasing temperature. This latter effect may have resulted from partial reoxidation.

[60] Boltaks, Vasenin, and Salunina, Zhur. Tekh. Fiz. 21, 532 (1951).

8. THE HALL EFFECT

The Hall effect arises from the force experienced by a charge moving in a magnetic field. A high resistance voltmeter is connected to the electrodes P and Q on the lower and upper faces (Fig. 7) of the specimen of uniform rectangular cross section, and thickness t cm, in which a current I_x amp is flowing. The electrodes P and Q are assumed to be placed so that they are at the same potential before the application of a magnetic field. When a magnetic field B_y gauss is applied in a direction normal to the current I_x and parallel to the t direction, a potential difference $V_H(=V_Q-V_P)$ volts appears between the electrodes. The quantity $R=10^8V_Ht/B_yI_x$ is defined as the Hall coefficient. When lattice scattering predominates, the concentration of charge carriers n is related to the Hall coefficient by the formula

$$n=-7.40\times10^{18}G/R. \tag{8-1}$$

For n-type semiconductors, G is a function of the Fermi level which varies between 1 for nondegenerate samples, to $8/3\pi$ for completely degenerate samples.[61,62] When impurity scattering cannot be neglected, this value of n must be corrected[63] by a factor r, which has a value in the range 1 to 2 for ionized impurity scattering.

8.1. Hall Data of Reduced Rutile

Breckenridge and Hosler[61] have made Hall measurements on samples of rutile ceramic and single crystals which had been subjected to various degrees of reduction in hydrogen. These workers then attempted to interpret the values of the electron concentration n obtained by the use of Eq. (8-1) in terms of two sources of conduction electrons, one of which has a very small activation energy, so that it was considerably ionized even at liquid air temperature. Their results (Fig. 8) were interpreted in terms of the following equation

$$n=n_1\exp(\Delta E_1/2kT)+n_2\exp(\Delta E_2/2kT) \tag{8-2}$$

with $\Delta E_1\ll\Delta E_2$, and $n_1\ll n_2$.

Interpretation of ΔE_1 and ΔE_2 in terms of the ionization potentials of isolated donor type impurities is complicated by the effect of the $\frac{3}{4}\ln t$ correction term of Eq. (5-6). This correction is important even for ΔE_2, whereas the significance of the smaller ΔE_1 is almost entirely lost because of the magnitude of the correction term.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Attempts have been made below to interpret the Hall data of Breckenridge and Hosler[61] under the assumption that the form of the curves at higher temperatures (200 to 500°K) is determined by the electrons in the conduction band, to which Maxwell-Boltzmann statistics and the concept of a single effective electron mass are assumed to apply. In the first case, the source of these electrons is considered to be non-interacting donor sites at an energy E_d with respect to the bottom of the conduction band. The appropriate type of plot for the experimental data is suggested by Eq. (5-6), and from the slope a value of E_d may be obtained.

In the second case, the appropriate type of plot is indicated by Eq. (5-7), in which no assumption concerning the source of electrons is implied. However, the slope of the plot yields the height of the Fermi level, which will lie near the center of the donor band if it exists. In this case the plot yields also the effective mass of the conduction electrons.

At the temperatures considered, the effect of the magnetic field on the concentration of conduction-band electrons is believed to be entirely negligible.[64]

When the data of Breckenridge and Hosler's Fig. 11 are plotted in these two different ways for the temperature range 250 to 500°K, the results are as follows. With the exception of one very low value, for curve (*b*), the values of E_d (noninteracting donors) lie in the range -0.095 to -0.147 ev. With the same exception, the values of the Fermi level (donor band model) lie in the range -0.025 to -0.051 ev with respect to the bottom of the conduction band. The corresponding values of the effective mass ratio are in the range 0.16 to 1.6. Although Maxwell-Boltzmann statistics can scarcely be said to apply to these data, these values of the effective mass of the conduction electrons are much lower than the values usually quoted for rutile.

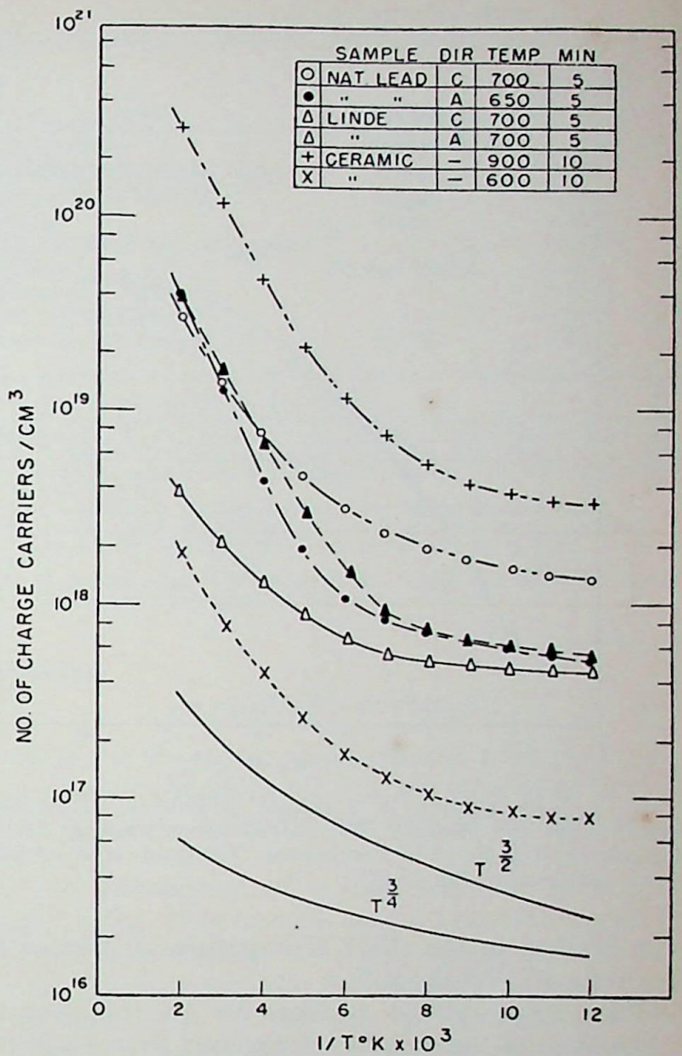

FIG. 8. Electron concentrations in specimens of rutile reduced in hydrogen under the conditions specified (after Breckenridge and Hosler[61]). Curves showing the temperature variation of the factors $T^{3/4}$ and $T^{3/2}$ of Eqs. (5-5) and (5-7) are shown for comparison.

8.2. Hall Mobility

An electric charge moving in the x direction normal to a magnetic field B_y, "sees," in addition, an electric field E_z, where

$$E_z = v_x B_y \quad \text{(mks units)}.$$

Since the mobility b is defined as v_x/E_x, we obtain

$$E_z/E_x = b_H B_y \quad \text{(mks units)}.$$

Hence the equipotential surfaces in a conductor are rotated by the magnetic field through an angle ϕ, where $\tan\phi = b_H B_y$. In cgs units

$$\tan\phi = 10^{-8} b_H B_y.$$

This simple relation is somewhat obscured by the usual derivation of the Hall mobility from the electrical conductivity and the Hall coefficient

$$\sigma = neb$$
$$-R = 1/ne$$
$$(-R\sigma) = b_H. \qquad (8\text{-}3)$$

The determination of b_H from simultaneous measurements of σ and R is entirely equivalent experimentally to the measurement of $\tan\phi$, so that the simple interpretation of the Hall mobility is unaltered.

Figure 9 illustrates a typical Hall mobility curve derived from the electrical conductivity and Hall data of Breckenridge and Hosler. These workers attempted to interpret their results in terms of the theory of scattering by optical lattice vibrations developed by Fröhlich and Mott,[65] and by Fröhlich, Pelzer, and Zineau.[66] The additional scattering at low temperatures

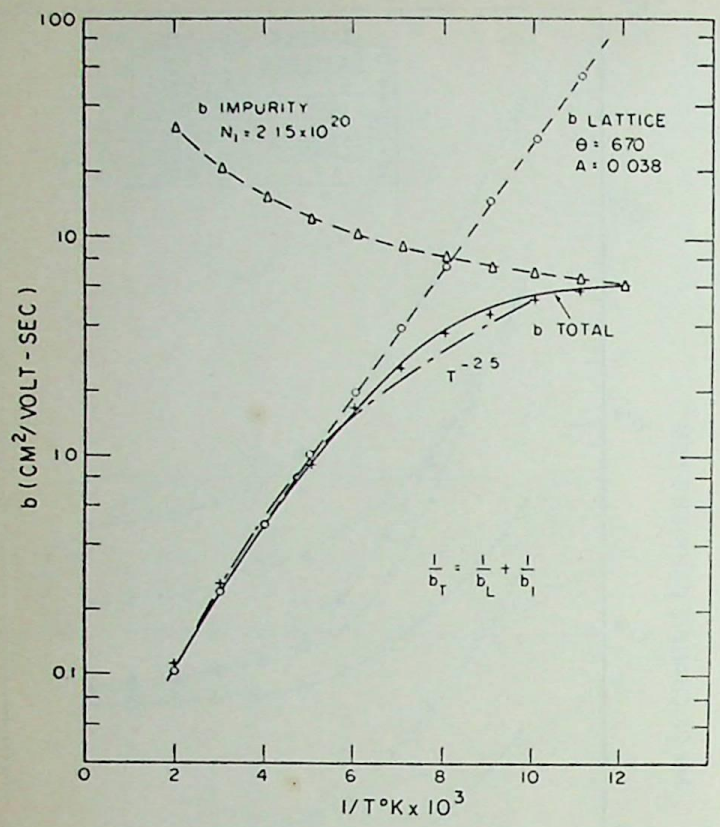

FIG. 9. Hall mobility in a sample of reduced rutile, after Breckenridge and Hosler.[61] The dotted curve, showing a $T^{-2.5}$ dependence, is included for comparison. The symbols and A refer to the constants in Eq. (5-13).

was ascribed to the effect of impurities as treated by Conwell and Weisskopf.[67]

When an empirical relation for the temperature dependence of the mobility is required to assist in the interpretation of conductivity data above about 200°K, a $T^{-2.5}$ law appears to be satisfactory. For comparison purposes, a $T^{-2.5}$ plot is included in Fig. 9.

8.3. Magnetoresistance

Gorelik[68] has investigated the effect of a magnetic field of 15 000 gauss on the electrical conductivity of "pure" rutile, and on specimens of rutile containing various proportions of the oxides of calcium and strontium. The entire change in conductivity did not occur immediately after the application of the magnetic field, but was practically complete after two minutes. The change in conductivity was small at room temperatures, but above about 160°C the fractional change in conductivity rose to steady values of one or two percent.

Gorelik has given an "explanation" of these effects in terms of the relative importance of the ionic and electronic contributions to the conductivity.

9. MAGNETIC SUSCEPTIBILITY

9.1. Introduction

In a semiconductor, such as rutile, one must consider the following four contributions to the magnetic susceptibility[69]: (a) the lattice susceptibility, (b) the carrier susceptibility, (c) the contribution of the impurities, including effect of departures from stoichiometry. This effect may be differentiated into two cases (i) the effect of noninteracting sites, and (ii) the effect of donor (or acceptor) bands; and (d) the effect of surface states, including adsorbed gases.

9.2.(a) Lattice Susceptibility

Van Vleck[70] gives the following expression for the lattice susceptibility, and points out that there is no sharp dividing line between diamagnetic molecules and feebly paramagnetic ones:

$$\chi_{\text{mole}}=-\frac{Le^2}{6mc^2}\sum\langle r^2\rangle+\tfrac{2}{3}L\sum_{n'\neq n}\frac{|m^0(n';n)|^2}{h\nu(n';n)}. \quad (9\text{-}1)$$

In Eq. (9-1), $m^0(n';n)$ is a nondiagonal element of the vector matrix for the magnetic moment of the system, evaluated in the absence of a field, $\nu(n';n)$ is the frequency corresponding to the $n';n$ transition. L is Avogadro's number, e the electronic charge in esu, m the electronic mass in grams, and c is the speed of light in cm/sec. $\sum\langle r^2\rangle$ is the mean value of the radius of an electron orbit, summed over all the electrons.

When the second term of Eq. (9-1) predominates, the contribution represents a small, almost temperature-independent paramagnetism. Using the simple ionic model, the ions in the oxides Sc_2O_3, TiO_2, V_2O_5, and CeO_2 possess noble gas configurations, hence would be expected to have a negative (diamagnetic) lattice susceptibility. However, there appears to be some evidence, especially in the case of V_2O_5, for a contribution due to temperature-independent paramagnetism larger than the negative (diamagnetic) term.[71–74] Freed and Kasper[75] discuss this effect in ions of the type VO_2^{+2}, WO_4^{-2}, MnO_4^-, VO_3^-, and $Cr_2O_7^{-2}$. Bates[76] considers that the feeble paramagnetism believed to exist in Sc_2O_3, TiO_2, and CeO_2 may be caused by the "distortion due to interatomic forces," and adds that it is difficult to determine in a given case whether the effect is due to a negative exchange integral, to electron migration (in conductors), or to ionic deformation.

At least in the case of rutile, the wide range of experimental values reported in the literature, which include both positive and negative values, may result from departures from stoichiometry. The formation of oxygen vacancies (and Ti^{+3} sites) which result when

rutile is prepared at moderately high temperatures in a reducing atmosphere is discussed in Sec. 14. The various values of the magnetic susceptibility of "pure, stoichiometric" rutile, appearing in the literature, are listed in Table V.

9.3.(b) Carrier Susceptibility

Assuming that the carrier electrons behave as a perfect electron gas, and using the appropriate density-of-states effective mass ratio, the following expression for the carrier susceptibility has been derived[69,77]:

$$\chi_c=\left(\frac{\beta^2}{3kT}\right)n_c[3-\langle f_e^2\rangle_{Av}], \tag{9-2}$$

where n_c is the concentration of electrons in the conduction band, β is the Bohr magneton, and $\langle f_e^2\rangle_{Av}$ depends on the curvature of the energy surfaces in k space. This term is related to the effective mass ratio for orbital motion M^M by the relation

$$M^M=(\langle f_e^2\rangle_{Av})^{-\frac{1}{2}}. \tag{9-3}$$

Since M^M is expected to be considerably larger than unity in the case of rutile,[78] Eq. (9-2) may be approximated by the relation

$$\chi_c=\beta^2 n_c/kT, \tag{9-4}$$

which is of the same form as the contribution of unpaired electrons in noninteracting hydrogen-like donors to be discussed in the next paragraph.

9.4.(c) Impurity Contribution

Mooser[79] has discussed (i) the contribution of electrons in noninteracting hydrogen-like impurity sites, and (ii) the case in which the overlapping of the impurity wave functions is sufficiently great for the formation of impurity bands. Considering first the case in which the donor sites are noninteracting and are in s-like ground states, he obtains

$$\chi_{\text{para}}=n_d\beta^2/kT, \tag{9-5}$$

where n_d is the concentration of occupied donors, which is related to N_d, the concentration of donor sites, by the following relation:

$$n_d=N_d/1+\tfrac{1}{2}\exp((E_d-\eta)/kT). \tag{9-6}$$

Here, $E_d-\eta$ is the energy of the donor levels with respect to the Fermi level η.

A diamagnetic term must be added to Eq. (9-5) so that the total contribution of the electrons in isolated, hydrogen-like donor sites is given by the following expression:

$$\chi=n_d(\beta^2/kT-e^2r^2/6m_ec^2) \tag{9-7}$$

in which r is the radius of the electron orbit in cm, e is the electronic charge in esu, c is the velocity of light in cm sec^{-1}, and m_e is the effective mass of the electrons in grams.

If the assumption of a high effective mass M^M, implied in Eq. (9-4) is valid, comparison of this relation with the expression for the paramagnetic contribution of (atomic) hydrogen-like donors shows that they are of the same form. In this case, the paramagnetic susceptibility is independent of the distribution of the unpaired electrons between the donor sites and the conduction band, i.e., the thermal ionization of donor sites does not affect their contribution to the susceptibility. This is in contrast to the case in which the wave functions of the impurity sites overlap sufficiently for the formation of impurity bands. This point is discussed later.

9.4.1. *Electrons in Impurity Bands*

The diamagnetic contribution of electrons in impurity bands is believed to be small and about the same as that of electrons in noninteracting donor sites [the second term in Eq. (9-7)].

Band wide compared with kT.—At low temperatures the paramagnetic contribution is given by the following expression

$$\chi_{\text{para}}=2\beta^2D(\eta) \tag{9-8}$$

in which $D(\eta)$ denotes the density of states in the donor band at the position of the Fermi level. In this temperature range χ should be almost independent of temperature.

Band narrow compared with kT.—At high temperatures, where the band width is much less than kT, the paramagnetic contribution of the electrons in the

[a] After correction for temperature-independent paramagnetic lattice susceptibility ($+6\times10^{-6}$ emu per mole).

impurity band is obtained from the result obtained for the noninteracting donor sites by multiplying by the factor f, which indicates the fraction of the electron spins that are "free" (see Sec. 9.4.2)

$$f=\exp((\bar{E}_d-\eta)/kT)/(1+\exp(\bar{E}_d-\eta)kT), \quad (9\text{-}9)$$

where $\bar{E}_d$ is the energy of the midpoint of the donor band. This factor has the value unity when the Fermi level lies far below the donor band. In the case of principal interest $(\bar{E}_d-\eta)$ is zero or slightly negative, and the multiplying factor is approximately equal to $\frac{1}{2}$. When the Fermi level is more than $3kT$ higher than the donor band f is very small, tending to zero with increased separation.

The numerical value of this factor is therefore highly dependent on the height of the Fermi level. The dependence of the Fermi level on temperature has been discussed in Sec. 5.

Once again it is necessary to draw attention to the high dielectric constant in rutile. It is therefore probable that impurity bands form at lower impurity concentrations than in most other materials. This effect may be offset by the possibly high effective electron mass.

9.4.2. Donor Sites in Nonstoichiometric Rutile

Although the contribution of the Ti^{+4} ions to the magnetic susceptibility is small, and of uncertain sign, the Ti^{+3} ion definitely makes a large contribution to the paramagnetic susceptibility of the crystal. Departures from stoichiometry of rutile are believed to result in the conversion of Ti^{+4} sites to Ti^{+3} sites. These ions of lower valence may in many ways be considered to constitute an "impurity" in the rutile lattice, and in this section the terms "impurity site" and "impurity band" are understood to apply to nonstoichiometric rutile.

Ehrlich[80] has investigated the magnetic susceptibility of solids of the composition TiO_x from $x=0$ to $x=2$. If it is assumed that the formation of an oxygen vacancy results in the formation of two Ti^{+3} sites, each with a magnetic moment of 1.73 Bohr magnetons, one may calculate the resulting paramagnetic susceptibility. For example, Ehrlich estimated that the paramagnetic susceptibility of rutile which had been reduced to the extent of two percent weight loss ($x=1.90$) should be 253×10^{-6} per gram mole at room temperature. Since the experimental value was 119×10^{-6} he concluded that only 47% of the electrons were "free."

Ehrlich's calculations have been extended to his other data, and are summarized in Table VI. As expected, the fraction f of the donor electrons that contribute to the susceptibility (column 7) decreases with increasing donor concentration.

However, we note the higher values of f for the room temperature measurements as compared with the measurements at 90°K.

Now subject to the assumptions of a high effective mass ratio M^M and the applicability of Maxwell-Boltzmann statistics, the raising of electrons from isolated hydrogen atom-like donors to the conduction band should not appreciably alter the paramagnetic susceptibility. We therefore look for an explanation in terms of overlapping of donor wave functions and the formation of a donor band.

A very approximate value for the width of this hypothetical band may be obtained from Ehrlich's low temperature data by the application of Mooser's expression for the susceptibility of electrons in bands wide in comparison with kT. Here, $\chi=2\beta^2D(\eta)$ where $D(\eta)$ represents the density of states at the Fermi level. The total number of levels was taken to be twice the number of oxygen vacancies. The approximation was introduced that the density of states D was uniform throughout the band, whence ΔE was estimated. The results of calculations for TiO_x (where $x=1.90$, 1.95, and 1.97) at 90°K appear in Table VII. The estimated values of ΔE are somewhat larger than kT (which is 0.0077 eV at 90°K), so that the requirement regarding the width of the band is fulfilled.

It is now necessary to account for the observed increase in f with increasing temperature. One may ask whether this increase could reflect a transition from the "wide band" case, at 90°K, to the "narrow band" case. The estimated band widths (last column of Table VII) are about fifty percent greater than kT at 293°K. It is not unreasonable to suppose that the 293° values represent an intermediate case, and that at still higher

[80] P. Ehrlich, Z. Electrochem. 45, 362 (1939).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

temperatures the "narrow band" approximation would be valid. Earlier, it was concluded that the Fermi level would be expected to lie at, or somewhat lower than, the middle of the donor band. In the "narrow band" limit, the expected value of f calculated from Eq. (9-8) is therefore equal to, or greater than, $\frac{1}{2}$. The observed values of f (given in the last column of Table VI) appear to be consistent with this interpretation.

An alternative explanation may be given if two electrons are bound to each oxygen vacancy at sufficiently low temperatures, and these sites are assumed to be noninteracting. One would expect the electron spins to be paired in such a "molecule." Raising of one or both of these electrons to higher states by thermal excitation would uncouple the spins. This conclusion is valid, regardless of the extent of the overlapping of the wave functions of the higher states, provided that the Fermi level lies farther than about $3kT$ below the bottom of any such higher band [see Eq. (9-9)]. If the Fermi level lay closer to this higher band than about $3kT$, the Pauli principle, would have to be invoked, and the value of f would remain below unity.

Ehrlich's results may also be expressed in terms of the Curie-Weiss law (discussed further in the next section), in which case one obtains an effective magnetic moment of 1.5 Bohr magnetons, instead of the expected value of 1.73, and Weiss constants of 700, 72, and 160°K, respectively, for the three compositions $x=1.97$, 1.95, and 1.90.

Gray[81] has reported an investigation of the magnetic susceptibility of "titanium dioxide" during reduction by hydrogen. Simultaneous measurements were made of the decrease in hydrogen pressure, sample weight loss, and paramagnetic susceptibility increase, the temperature being maintained at 560°C. There appears to be an almost linear relation between change in susceptibility and the loss in weight. The sample weight and the method of measurement were not stated and without this information a satisfactory interpretation of the data cannot be made.

9.4.3. *Rutile Containing Impurities*

Representation of the paramagnetic susceptibility arising from donor sites in solids is not often made in terms of the foregoing model invoking donor bands. More commonly the departures from the Curie law are represented empirically by replacement of the T factor in this law by the factor $(T-\Delta)$. This procedure is quite empirical, and may include the effects resulting from the "pairing" of electrons, and the formation of donor bands, discussed in the foregoing.[82,83] Most of the published experimental results are expressed in terms of the magnetic moment of the unpaired electron and the corresponding Weiss constant Δ.

TABLE VII. Width of hypothetical impurity band in TiO_x estimated from Ehrlich's 90°K magnetic susceptibility data.

x	χ_{para} per mole[a]	Number of states per mole (2 per O_a)	Calculated density of states at Fermi level $D(\eta)$ per ev	ΔE estimated width of donor band ev
1.97	104×10^{-6}	3.6×10^{22}	99×10^{22}	0.036
1.95	162	6.0	154	0.039
1.90	216	12.0	206	0.058

[a] After correction for temperature-independent paramagnetic lattice susceptibility ($+6\times10^{-6}$ emu per mole).

Selwood[84] and co-workers have shown the "pure" titanium sesquioxide to be antiferromagnetic, with a critical point near the specific heat anomaly at about 248°K. The Weiss constant was unusually large, and was estimated to be about 2000°K. The corresponding magnetic moment for the Ti^{+3} ion was 1.2 Bohr magnetons, which may be compared with the expected value of 1.73 for the free Ti^{+3} ion with one unpaired electron. These results are contradicted by the later work of Foëx and Wucher,[85] and of Pearson.[86] These workers found a continuous increase in susceptibility as the temperature was increased from −200 to about 360°C, the temperature dependence being most pronounced in the vicinity of 160°C.

When paramagnetic ions are separated by solution in a suitable diamagnetic crystal, their mutual interaction is reduced. An example of this effect appears in the work of Adler and Selwood,[87,88] who have studied a solid solution of 14.3% Ti_2O_3 in the diamagnetic oxide, Al_2O_3. The Ti^{3+} ion was found to have a magnetic moment of 1.1 Bohr magnetons (expected value $\sqrt{3}$ Bohr magnetons), and a value of $\Delta=105$°K was obtained. This value of the Weiss constant Δ may be compared with the value of about 2000° obtained for undiluted Ti_2O_3.

Selwood and co-workers have investigated the incorporation of ions of other transition metals into the rutile crystal lattice. The Weiss constant of the manganese ion tends to zero as expected at infinite dilution, and is almost proportional to the concentration.[89] At a concentration of 19% manganese by weight, Δ is about 315°. The magnetic moment corresponds to a valence state of about 4.1 at zero concentration, falling to

[81] T. J. Gray, *The Defect Solid State* (Interscience Publishers, Inc., New York), p. 287.

[82] Other factors affecting the Weiss constant: the multiplet separations and the effect of inhomogeneous electric crystalline fields are discussed on page 150 of reference 84.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

about 3.9 as the concentration is increased to 19% manganese (by weight).

The valence state of nickel incorporated into the rutile lattice decreases somewhat with increasing concentration.[90] Extrapolation back from the lowest concentration appearing in the curves (about four percent nickel by weight) indicates that the magnetic moment at infinite dilution is probably between 3.8 and 4.0, considerably lower than expected for six (or four unpaired) electrons. However, from the color, and for other reasons, Selwood believes that the oxidation state is indeed +4.

Similar results were obtained for chromium[91] and iron[92] incorporated into the rutile lattice. In the case of iron, Δ fell from 52° at 12.9% iron, to 16° at 1.5% iron (by weight). The corresponding values of the oxidation state were 3.2 and 3.9. The chromium ion in rutile (2.6% by weight) exhibited a magnetic moment of 2.8 Bohr magnetons, and a negative Δ (−27°).

Thus with the possible exception of nickel, these elements assume a valence state of almost four when occupying titanium sites (at sufficient dilution). Selwood has applied the term "induced valence" to this phenomenon.

9.5.(d) Surface Contribution

The magnetic susceptibility will include the contribution of adsorbed gases, in particular physically adsorbed oxygen. The meaning of the term chemisorption when applied to oxygen and metallic oxides is not clear. However, the nature of the space-charge-barrier layer at the surface of a semiconductor (of the order of 10^{-5} cm thick) is influenced by the chemisorption of gases. Any factor which influences the height of the Fermi level in this region will alter the paramagnetic susceptibility. The importance of this effect is expected to increase as the particle size is reduced.

Sandler[93] has used the rate of *ortho-para* conversion of hydrogen on rutile powder as an indication of the surface density of unpaired electrons arising from the paramagnetism due to surface defects. These defects are believed to be due to a stoichiometric deficiency of oxygen. This surface paramagnetism is apparently associated with the blue color of reduced rutile.

A mention of the investigation of the surface paramagnetism of rutile conducted by Reyerson and Honig, and of the effect of reoxidation by NO_2-N_2O_4 will be found in Sec. 12.

10. THERMAL CONDUCTIVITY, SPECIFIC HEAT, AND VARIOUS PHYSICAL PROPERTIES

10.1. Thermal Conductivity

Kingery and McQuarrie[94] have determined the thermal conductivity of a number of pure ceramic oxides, including rutile, in the temperature range 100 to 1800°C. The results were corrected for the porosity of the samples. Values of 0.0119 and 0.0081 (cal sec^{-1} cm^{-2}) (°C cm^{-1}) at 200 and 800°C, respectively, were obtained. Kingery[95] has discussed the variations in thermal conductivity associated with the effect of radiant energy transmission, the ratio of the phonon mean free path to lattice dimension, the value of the Debye temperature, emissivity, and the relation of the electronic conductivity to the thermal conductivity of rutile.

The thermal conductivities of sapphire and rutile single crystals have been measured in the temperature range −50 to 100°C by McCarthy *et al.*[96] The thermal conductivity is greater parallel to the optic axis than in the direction perpendicular to it. Both values decrease with increasing temperature in the temperature range studied, and their ratio is also temperature dependent.

10.2. Thermal Coefficient of Expansion

Day[97] has obtained a value of 80×10^{-7} per °C, for the coefficient of expansion of rutile in the range −130 to 50°C. Mauer and Bolz[98] have determined the thermal expansion coefficient of stoichiometric and reduced rutile from x-ray data. In the temperature range 0 to 200°C the average values of the coefficient of expansion of stoichiometric rutile were 8.0×10^{-6} in the a direction and 9.2×10^{-6} per °C in the c direction. In the temperature range 0 to 1000°C the corresponding average values are 8.4×10^{-6} and 9.2×10^{-6} per °C. In the temperature range 0 to 400°C, the average values for reduced rutile ($TiO_{1.97}$) were 8.4×10^{-6} per °C for the a direction, and 10.5×10^{-6} per °C for the c direction.

10.3. Specific Heat and Debye Temperature

At sufficiently low temperatures, only the low-frequency vibrations are important in determining the internal energy of a solid. In this region the specific heat capacity is expected to be proportional to T^3, and one expects a constant value for the Debye temperature θ. In rutile, this range extends to above 4°K, and Keesom and Pearlman[99] obtained a value of 758°K for the corresponding Debye temperature. In the

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

temperature range 10 to 20°K they found that θ decreases from 650 to 460°K.

Also from specific heat studies, McDonald and Seltz[100] obtained a value of $\theta=670$°K in the temperature range 68 to 298°K.

Basing their calculations on earlier measurements of infrared absorption bands, Breckenridge and Hosler[101] obtained values of $\theta=936$°K and $\theta=1161$°K. However, their interpretation of their Hall mobility data was more consistent with McDonald and Seltz's value of $\theta=670$°K.

After slight reduction in H_2 or Ar, at 1000°C, the heat capacity in the helium region increases greatly.[99] As a tentative explanation, the authors suggested that the additional heat capacity was possibly due to the contribution of the "free" classical electrons. In which band these "free" electrons are to be found, is an open question. From the estimated degeneracy temperature these workers obtained a carrier mass of 350 times the free electron mass.

The heat capacity of rutile powder has been measured in the low temperature region by Shomate.[102] Arthur[103] has made measurements in the range 293 to 1073°K and Naylor[104] in the range 500 to 1800°K. For the heat capacity in calories per mole, valid in the range 500 to 1800°K, Naylor gives the formula:

$$c_p=0.2145+12.3\times10^{-6}T-4380/T^2.$$

Arthur expresses his results in the form

$$c_p=0.1512+0.000245T-0.222\times10^{-7}T^2$$

calories per gram per degree, plus or minus two percent, valid in the range 293 to 1073°K. For purpose of comparison, these formulas yield, respectively, values of 0.217 and 0.333 cal/g/deg, at 800°K.

Dugdale *et al.*[105] expected to find a particle-size effect at low temperatures. Instead, however, they found that the specific heat of rutile was independent of particle size below 50°K. Above this temperature the observed dependence was attributed qualitatively as an effect of the *optical* modes of vibration. Because of the relatively complicated crystal structure of rutile, no attempt was made to make a theoretical calculation of the magnitude of the effect. These workers obtained a value of $C_p=0.115$ cal/mole°K at 20°K and 1.407 cal/mole°K at 50°K.

10.4. Miscellaneous Physical Properties

10.4.1. Density

The density of rutile,[106] calculated from x-ray data is 4.28; the pycnometer density is 4.22 g/cc.[107]

10.4.2. Melting Point

St. Pierre[108] has determined the melting point to be 1840±10°C.

10.4.3. Compressibility

The compressibility of natural rutile single-crystals has been investigated by Bridgman.[109] His results could be expressed up to $p=12\,000$ kg/cm² by the formula

$$\Delta L/L_0=-a_1p+b_1p^2.$$

From 30° to 75°C the value of a_1 for the c direction was found to vary from 1.038 to 1.090×10^{-7}, and in the a direction was found to vary from 1.871 to 1.954×10^{-7}. For all cases investigated, the value of b_1 was 7×10^{-13}.

10.4.4. Hardness

Moore[110] gives a value of 7 to 7½ (Mohs scale) for the hardness of synthetic rutile crystals. This value is slightly higher than that of quartz. Measurements were made on specimens exhibiting various degrees of reduction, but the variation in hardness in these different specimens was about the same as the variation with crystallographic direction.

10.5. Miscellaneous

A list of references for these and other properties of rutile may be found in "Properties of Titanium Compounds and Related Substances," ONR Report ACR-17, October 1956.

11. DIELECTRIC AND OPTICAL PROPERTIES

11.1. Dielectric Constant and Loss Angle

(a) *Stoichiometric rutile.*—The frequency and temperature dependence of the dielectric constant of stoichiometric rutile have been investigated by Eucken and Büchner,[111] Schusterius,[112] Büttner and Engl,[113] Berberich and Bell[114] and by von Hippel and his coworkers.[115] The dielectric constant shows little variation

with frequency until the region of reststrahl vibrations is reached (wavelengths shorter than about 300 μ).

Thus the measurements of Schmidt[116,117] on single crystals, at a frequency of several hundred megacycles per second are the same as the low-frequency values. This worker obtained a value of 173 for the c direction and 89 for the a direction. These results are in agreement with the values calculated from the reflection measurements of Liebisch and Rubens.[118] The value for densely fired ceramics[115] is approximately 100. If care is taken to prevent the loss of oxygen during firing of the ceramic, the dielectric loss is very low; $\tan\delta = 0.0003$ at 1000 cy/sec and 24°C.

At a frequency of 1000 kcps, the measurements of Bunting *et al.*[119] yielded a value of 106 for the dielectric constant of pure rutile ceramic at −60°C and a value of 93 at 85°C. From these results one obtains a value of -11×10^{-4} for the temperature coefficient of the dielectric constant at 85°C and a value of -7.5×10^{-4} at −60°C.

11.2. Static Dielectric Constant and Polarizability

It is usually assumed that the local field F, effective in polarizing ions in certain types of *diagonal cubic* crystals, is given by the relation

$$F_i = E + \gamma_i P/\epsilon_0 \quad \text{(in mks units)}. \tag{11-1}$$

Following Lorentz, γ_i is usually taken to be $\frac{1}{3}$. The static dielectric constant K, and the polarization P, are defined in terms of the electric field E, and the electric displacement D, as follows:

$$D = K\epsilon_0 E = \epsilon_0 E + P. \tag{11-2}$$

The symbols N, V, n_i, F_i, P_i, and α_i are defined as follows. N = the number of unit cells per cubic meter, $V = 1/N$ = the volume of unit cell in m^3, n_i = the number of ions of type i per unit cell, F_i = the local field at ions of type i, P_i = the contribution of ions of type i to the total polarization, and α_i = the polarizability of ions of type i, and is defined by the following equation:

$$P_i = (Nn_i)\alpha_i(\epsilon_0 F_i) \tag{11-3}$$

$$n_i\alpha_i = VP_i/\epsilon_0 F_i. \tag{11-4}$$

The success of the Clausius-Mosotti relation

$$\alpha = \sum n_i\alpha_i \tag{11-5}$$

$$= 3V(K-1)/(K+2) \tag{11-6}$$

is usually taken as evidence for the validity of the Lorentz equation. To the extent that the assumptions used in deriving these results are justified, it may be shown that the polarization P in crystals having "diagonal cubic" symmetry may be expressed in terms of the sum of the polarizabilities; thus

$$P = \sum P_i = \epsilon_0 \sum F_i\alpha_i n_i/V. \tag{11-7}$$

Assuming the same F for all ions, then

$$P = (\epsilon_0 F_i/V)\sum n_i\alpha_i = (\epsilon_0 F_i\alpha/V). \tag{11-8}$$

Making use of the additivity of α implied in Eq. (11-8) Roberts[120] has used the experimental values of α of a number of ionic crystals to prepare a table of the polarizabilities of their constituent ions. The polarizability of oxygen was arbitrarily taken to be 30 A^3, so that the resulting polarizabilities of the halide ions would be nearly proportional to their volumes.

No attempt was made to separate the total polarizabilities into their electronic and ionic components. Nevertheless, it is possible to predict within a few percent the polarizabilities of a large number of ionic cubic crystals using Robert's values of α_i.

(*a*) *Temperature dependence.*—Differentiation of Eq. (11-6) with respect to temperature leads to

$$(1/\alpha)\cdot(d\alpha/dT) = 3\cdot(1/3V)dV/dT + (3K/(K+2)(K-1))\cdot(1/K)dK/dT. \tag{11-9}$$

Thus the temperature coefficient of polarizability is the sum of the temperature coefficient of volume expansion and a term proportional to the temperature coefficient of the dielectric constant. Roberts[120] quotes the values $(1/K)dK/dT = -70\times10^{-5}$, $(1/3V)dV/dT = 0.91\times10^{-5}$ and $K = 114$ at 300°K for rutile ceramic. Substitution of these values in Eq. (11-9) yields the calculated value of $(1/\alpha)d\alpha/dT = 0.90\times10^{-5}$. This result is smaller by a factor of about 30 than the corresponding value for the alkali halides. To the extent that the Clausius-Mosotti equation can be said to apply to rutile, the large negative temperature coefficient of the dielectric constant results from the thermal expansion of rutile and the small temperature coefficient of polarizability.

(*b*) *Defect structure.*—The frequency dependence of the dielectric constant and loss angle is used to investigate the defect structure of dielectric materials. Thus Srivastava[121] has studied the defect structure in slightly impure rutile crystals. The defect structure was enhanced or modified by quenching of the crystals in liquid nitrogen after heating at 820°C for three hours in dry oxygen. The resulting absorption centers were quite anisotropic, and apparently could be observed only with the electric field in the c direction.

Below 10 kc/sec, both the real part of the dielectric constant, K', and the tangent of the loss angle, $\tan\delta$, appeared to be increasing indefinitely with decreasing

frequency, and exceeded the values $K'=700$ and $\tan\delta=0.7$ at 100 cy/sec. Above about 1 mc/sec, K' appeared to be asymptotic to the value for the defect-free material, and $\tan\delta$ fell off to low values.

Relaxation effects occurred in the frequency range 10 kc/sec to several megacycles a second. The frequency f_{max} at which $\tan\delta$ reached a maximum value (of approximately 0.75) increased from about 8000 cy/sec at 27°C, to about 800 kcps at 278°C. These effects could be annealed out by heating in atmospheric air at moderate temperatures (about 150°C). Measurements made below about 40°C indicated that f_{max} was an exponential function of reciprocal temperature, and the data were used to yield an estimated value of 0.18 ev for the activation energy involved.

These effects were associated with the presence of traces of silver and copper (about 0.01%), and were absent in crystals free from these impurities.

Similar phenomena have been observed by Freymann,[122] who ascribed the effect to "reorientation of positive and negative lattice defects."

(*c*) *Effect of other impurities.*—Skanavi[123,124] has found that small additions of Group II oxides to rutile cause a large increase in the dielectric constant, of the order of 3×10^4. Zerfoss and co-workers[125] believed that this might be due to the formation of an "irregular sandwich of a conducting surface region and a dielectric interior with indefinite boundaries," which would produce a large space charge polarization.

The phenomenon may be explained by the overlapping of wave functions of the more closely spaced of the impurity sites. Regions of closer than average impurity separation, would be expected to occur at random. In these regions there would be produced chains of atoms which would produce high conductivity paths of limited length. Such a mechanism would constitute a slight extension of the hypothesis of Zerfoss.

Nicolini[126] has prepared a form of ceramic "rutile" with unusual dielectric properties. The material was prepared by heating "pure' titanium dioxide to 1400°C. The dielectric constant, which has a value exceeding 10 000 at 10 cy/sec, drops to its normal value of about 100 at approximately 10^5 cy/sec. $\tan\delta$ has a maximum value of 3.2 at 20 000 cy/sec.

11.3. Optical Absorption

At 4°K, "pure" rutile is transparent in the visible region at wavelengths longer than the sharp absorption edge at 4100 A. (See Figs. 10 and 11.) This edge becomes less sharp at higher temperatures, and extends to slightly longer wavelengths. The absorption coefficient rises rapidly at wavelengths longer than 5 μ.[127,128]

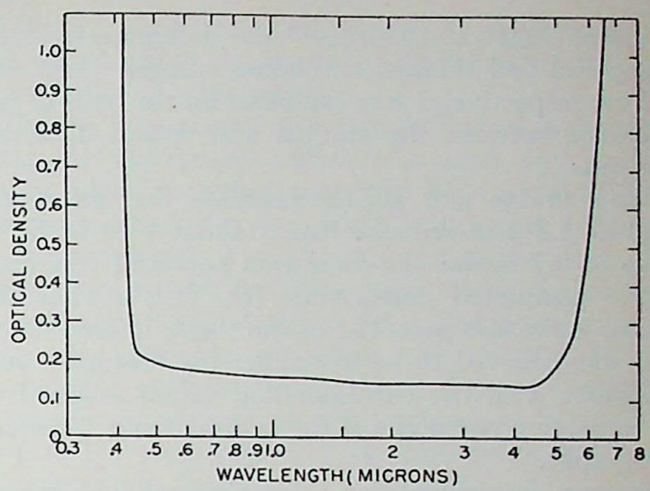

FIG. 10. Optical density of clear rutile (after Breckenridge and Hosler[138]).

After heating in hydrogen for 2.5 min at 600°C there is an increase in optical density, with a very broad maximum centered at 1.2 μ.[128]

In the far infrared, Parodi[129] found transmission lines at 30.5, 41, and 50 μ.

Breckenridge and Hosler[128] attempt to interpret the 4100-A optical edge (3.02 ev) in terms of the transition of an electron from a helium-like, neutral oxygen vacancy $(O_v\cdot 2Ti^{+3})^0$ or from a $(O_v\cdot Ti^{+3})^+$ center to the Ti^{+4} conduction band. Their assignment of the energy levels is based on evidence obtained from thermodynamics and other grounds. At higher temperatures some of these vacancies and their associated electrons are in excited states. As a result, the activation energy is supposed to be reduced and rendered less sharp.

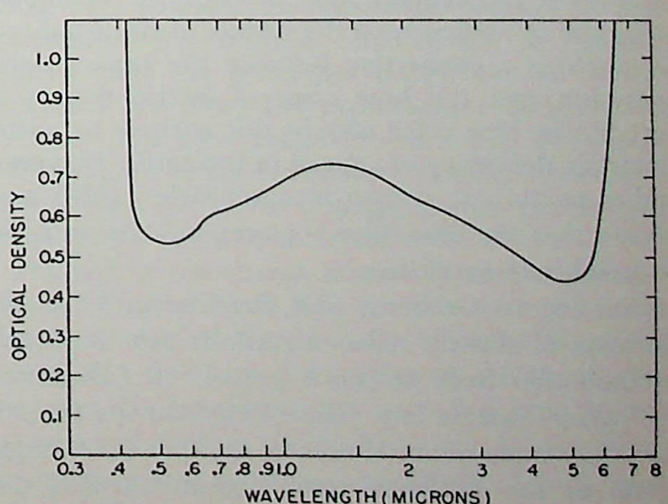

FIG. 11. Optical density of slightly reduced rutile (after Breckenridge and Hosler[138]).

Following Mott and Gurney[130] the difference between the optical and thermal activation energies (3.02 and 0.62 ev, respectively) was explained on the basis of the difference between the statical and optical dielectric constants.

Breckenridge and Hosler associate the absorption band at 1.2 μ in reduced rutile (about 1 ev with the value of 0.2 ev for the ionization potential (thermal) of the postulated donor sites $(O_v \cdot Ti^{+3})^+$. Thus the optical ionization potential of the singly ionized donor sites was believed to be five times the thermal value, consistent with the corresponding values assigned to the ionization potentials of the neutral donor (previous paragraph).

Support is claimed for this assignment of energy levels by experiments on the bleaching of colored rutile on cooling to liquid air temperatures mentioned briefly in the same paper.

11.4 Color

Weyl and Forland[131] have discussed (i) the color changes introduced by traces of ions such as Nb^{+5}, Ta^{+5}, Sb^{+5}, W^{+6}, which are usually considered colorless, and by very small traces of Fe^{+3} in rutile; (ii) the phototropy of rutile (reversible darkening when exposed to light) which may be obtained by incorporating certain impurities into rutile, as for example, a combination of the oxides of iron and niobium; and (iii) the oxidizing effect which titanium dioxide may exert on other materials when it is irradiated by ultraviolet light.

The presence of the Fe^{+3} ion introduces a rose color, that of the Nb^{+5} ion a blue-gray color into rutile. The blue-gray color is also present in reduced rutile, but unlike the effect of the Nb^{+5}, the discoloration of reduced rutile may be bleached by reoxidation.

Sandler's experiments on the rate of *ortho-para* conversion of hydrogen on the surface of rutile indicate that there is a connection between the surface paramagnetism and the blue color of lattice defects in rutile.[132] The blue color may be due entirely to a stoichiometric deficiency of oxygen in the rutile. However, Sandler points out certain inconsistencies which may indicate that the blue color is associated also with the the presence of impurities.

According to Gebhardt and Herrington,[133] the discoloration of slightly reduced rutile is due to organic contamination from stopcock grease, etc. Degassing of a "clean" sample in a "clean" vacuum system produced no discoloration. However, if either the vacuum system or the specimen were contaminated, a discoloration resulted. At temperatures of 300 to 550°C the loss of oxygen was estimated to be about 10^{-8} mole/g of TiO_2.

When heated in air to high temperatures, powdered rutile becomes lemon-yellow but returns to its original whiteness on cooling again to room temperature.[134] At 900°C there is a maximum in the emission spectrum at about 4700 A.

11.5 Refractive Indices

Measurements of the index of refraction (normal ray) in the visible region, were made by Bärwald[135] and Schroeder.[136] Cronemeyer[127] has obtained good agreement with the earlier work, and has given the result of his measurements together with values calculated from reflection measurements (Liebisch and Rubens[118]) and from transmission measurements.

Using prisms cut from single crystals, DeVore[137] has measured the refractive indices of rutile in the wavelength range 4250 to 15 000 A. DeVore has expressed his results by means of the formulas

$$n^2 = 7.197 + 3.322 \times 10^7/(\lambda^2 - 0.843 \times 10^7)$$

for the extraordinary ray and

$$n^2 = 5.913 + 2.441 \times 10^7/(\lambda^2 - 0.803 \times 10^7)$$

for the ordinary ray. The results are said to be in good agreement with those of Bärwald.[135]

Radhakrishnan[138] has used the method of Bragg to calculate the refractive indices of rutile. This worker has also used the measurements of Schroeder[136] to derive the values of the constants a, b, c, and λ_0 in the dispersion formula for rutile

$$n^2 - 1 = a - c\lambda_0^2 - b\lambda^2/(\lambda^2 - \lambda_0^2)$$

in which n is the index of refraction at wavelength λ. Values calculated using this relation agreed with observation within the experimental error.

11.6 Reflection Coefficient

The reflection coefficient of natural rutile crystals has been measured by Liebisch and Rubens[118] in the range 1.4 to 300 μ. Their results appear in Fig. 12.

12. ADSORPTION AND SURFACE LAYERS

In this section no reference is made to the extensive literature concerning adsorption of various gases and vapors on rutile powder, with the exception of certain experiments which yield direct information concerning the defect structure of the surface of rutile.

From the measured rate of *ortho-para* conversion of hydrogen at the surface of rutile (discussed also in

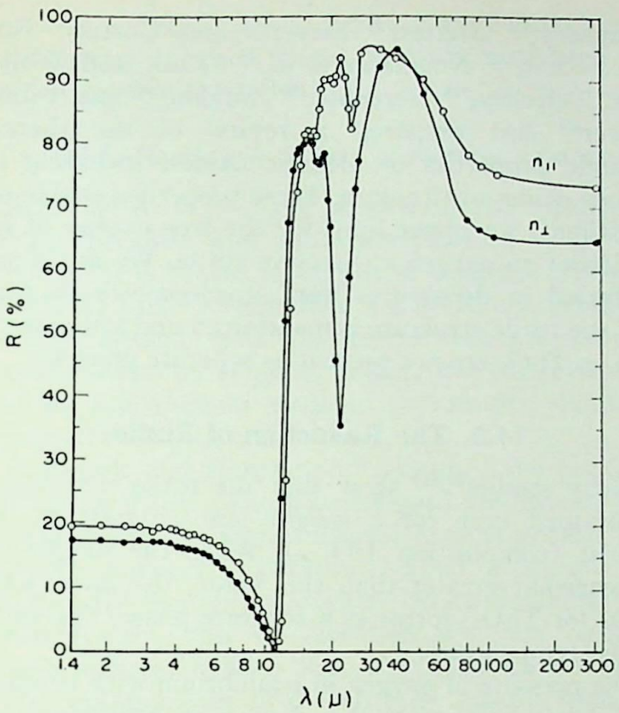

FIG. 12. Reflection coefficient in percent for natural single crystals of rutile (after Liebisch and Rubens[118]).

Sec. 11.4), Sandler[139] has obtained information concerning the state of adsorbed oxygen. The oxygen adsorbed on rutile at 90°K is apparently in molecular form, and the correspondingly high conversion rate is ascribed to the paramagnetism of this form of oxygen. On heating the specimen to room temperature, dissociation of some of the oxygen evidently occurred, leading to re-oxidation of the surface and a disappearance of the blue color. Reyerson and Honig[140] have investigated the diamagnetic susceptibility of NO_2-N_2O_4 adsorbed on rutile. To obtain a constant value for the gram susceptibility of the absorbate these workers found it necessary to assume that the (positive) susceptibility of the rutile decreased during adsorption. Thus it seemed reasonable to suppose that the rutile was initially partially reduced, but became re-oxidized by the NO_2-N_2O_4. The true value (after re-oxidation) of the susceptibility of rutile estimated in this way was 0.061×10^{-6} cgs units per gram. This interpretation is strengthened by the observed permanent increase in weight of the specimen, and by spectroscopic analysis of the equilibrium gases.

12.1. Photoconductivity in Surface Layers

The curves of spectral distribution of photoconductivity of most semiconductors exhibit a sharp rise in the vicinity of the absorption edge. As the wavelength of the incident light decreases, the response reaches a maximum value, and begins to decrease while the absorption coefficient is still rising. At small intensities the photocurrent is usually proportional to the light intensity at all wavelengths.

On the long wavelength side of the response maximum, the absorption coefficient is small, and much of the incident radiation traverses the crystal without being absorbed. On the short wavelength side, the penetration depth is small, and most of the absorption takes place in the surface region, where the electron recombination velocity†† is high. The wavelength of maximum response is determined by the relative importance of these mechanisms. Thus the response maximum will depend on the thickness of the crystal, and on the temperature, if the absorption coefficient is temperature-dependent.

Cronemeyer[127] has measured the photocurrent of thin crystals of rutile as a function of the wavelength of the incident radiation. The response increased rapidly with the energy of the incident photons in the region of 2.9 ev (4300 A). The edge of the photoconductivity curve is shifted to slightly lower energies as the temperature is increased from 103 to 295°K. Because of the high absorption coefficient above 3 ev (4100 A), and because of the important role of surface effect in this region, the interpretation of the results is difficult for higher photon energies.

At 1.2 μ, the response is smaller than the maximum response by a factor of 10^6.

13. BAND STRUCTURE OF RUTILE—CONCLUSIONS

Estimates of the width of the energy gap from measurements of electrical conductivity in the intrinsic range involve an assumption that the density-of-states effective masses of the valence and conduction bands are identical.

The measurements of electrical conductivity made in the high temperature range (700 to 1100°C) where presumably the intrinsic conductivity is measured, indicate that the forbidden energy gap of rutile is between 3 and 4 ev. The experimental value obtained by Earle (3.4 ev), Hauffe (3.9 ev), and Cronemeyer (3.06 ev) are discussed in another section. Cronemeyer's investigation of optical absorption and photoconductivity yield a value of about 2.8 to 3.1 ev.

The sign of the charge carriers in semiconductors is usually obtained from Hall or thermopower measurements. Because of the difficulty of measuring the potential at a point on the surface of a high resistance specimen, Hall measurements have not been made on specimens of rutile in the intrinsic range. Measurements of thermopower on rutile specimens of high purity indicate that the charge carriers are probably electrons.

The measurements of Breckenridge and Hosler

[139] Y. L. Sandler, J. Phys. Chem. 58, 54 (1954).
[140] L. H. Reyerson and J. M. Honig, J. Am. Chem. Soc. 75, 3920 (1953).

†† The surface recombination velocity is defined as "the rate at which electrons disappear from the interior across the surface, divided by the density of electrons in excess of equilibrium in the interior."

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

indicate that the mobility of reduced specimens is about 0.1 cm^2 $volt^{-1}$ sec^{-1} at 500°K. The value for intrinsic rutile may be approximately the same. By combining this value of mobility with the electrical conductivity measurements of Cronemeyer, one obtains an effective electron mass ratio of the order of 1000. However, values of the electron concentration evaluated from the combined Hall and conductivity data of Breckenridge and Hosler (see Sec. 8) yield effective mass ratios of the order of unity.

An attempt has also been made to discuss the band structure of reduced rutile with the inclusion of a donor band. The measurements of the magnetic susceptibility of rutile containing a stoichiometric deficiency of oxygen made by Ehrlich could be explained by the presence of such a donor band approximately 0.04 ev in width. Assuming the existence of this band (in which the mobility is expected to be low, and the effective electron mass high), then the donor band is probably 0.05 to 0.20 ev below a "conduction band" (in which the effective mass is considerably lower). The values of the energy separation of these bands calculated from the conductivity, Hall effect, and thermopower measurements discussed in earlier sections are given after the author's names. Electrical conductivity of reduced rutile: Kataoka and Suzuki (0.12 to 0.15 ev). Thermopower: Kataoka and Suzuki (0 to 0.13 ev). Hall data: Breckenridge and Hosler (0.025 to 0.05 ev). Optical absorption: An absorption band characteristic of reduced rutile was observed by Cronemeyer in the range 1 to 3 μ (0.4 to 1.2 ev). In order to compare these energies with the other data, they may have to be reduced by a factor of about 5.1 to allow for the difference between the optical and statical dielectric constants, as discussed in Sec. 11.3. This correction would place the donor band about 0.08 to 0.24 ev below the conduction band.

The evidence for the presence of a donor band is not conclusive. Consequently, the data have also been discussed below in terms of noninteracting sites. On the basis of the simple model and the assumption of noninteracting donor sites, the electrical conductivity measurements lead to the values of donor ionization potentials: Kataoka and Suzuki (0.29 to 0.35 ev), Boltaks (less than 0.2 ev). Thermopower: Kataoka and Suzuki (0.02 to 0.13 ev); Henisch (0.09 ev). Hall measurements: Breckenridge and Hosler (0.10 to 0.15 ev).

14. THERMODYNAMIC PROPERTIES AND REDUCTION

14.1. Thermodynamic Properties

The thermodynamic properties, free energy of formation, etc., of the various oxides (and many other compounds of titanium) are fully listed in the publication: The Properties of Titanium Compounds and Related Substances, ONR Report ACR-17 (October, 1956). These tables were prepared from the results of Humphrey,[141] Mixter,[142] Sieverts and Gotta,[143] Roth and Becker,[144] Neumann *et al.*,[145] Roth and Wolf,[146] Foëx,[147] Kelley,[148] Shomate,[149] Naylor,[150] and others. Brewer[151] has prepared a review of the thermodynamic properties of metallic oxides, including the various oxides of titanium. These properties enable one to estimate an upper limit for the free energy of formation of an oxygen vacancy in rutile. We are chiefly interested in departures from stoichiometry so small that the rutile structure is maintained and lower oxides such as Ti_3O_5 are not present as separate phases.

14.2. The Reduction of Rutile

X-ray studies[80,152] show that the rutile structure is maintained even for a weight loss as great as two percent (composition $TiO_{1.90}$). When the weight loss is somewhat greater than this value, the lower oxide Ti_3O_5 (or Ti_2O_3) forms as a separate phase, depending on the temperature.

The pressure of oxygen in equilibrium with titanium oxide decreases with the degree of reduction, the decrease being most rapid when the composition is close to the relative oxygen content represented by the formulas Ti_2O_3, Ti_3O_5, and TiO_2. For values of weight loss up to two percent, the degree of reduction may apparently be controlled[163] by heating the specimen of rutile in oxygen at reduced pressure, in a vacuum system free from contamination by stopcock grease. For high degrees of reduction, the equilibrium oxygen pressure is inconveniently low for the use of this simple method, and it becomes necessary to reduce the specimen by chemical means.

The oxygen pressure may be established at the desired low value by heating the specimen in a mixture of hydrogen and water vapor of known composition. The equilibrium constant of this reaction is known with accuracy,[153] and the equilibrium oxygen pressure may be calculated from the following equation:

$$\log K_p = \log p_{O_2} (p_{H_2}/p_{H_2O})^2 = 5.9 - 25\,900/T.$$

Alternatively, the CO-CO_2 reaction may be used to establish the desired oxygen pressure around the specimen.[152] A third method involves the heating of the titanium oxide in a sealed container with some

pieces of a metal which forms a very stable oxide. Experiments in which these methods have been used are discussed in the following.

14.2.1. Heating in Oxygen at Reduced Pressure

Assayag *et al.*[152] have measured the equilibrium oxygen pressure and the corresponding weight loss when rutile is heated in oxygen to temperatures above 1000°C.‡‡ Little information was given concerning the vacuum system used. Because of the possibility of contamination by stopcock grease, and the presence of CO in the vacuum system, the results should be accepted with caution.

Gebhardt and Herrington[154] obtained the usual discoloration when rutile was degassed for sixteen hours at 400 to 600°C in a conventional vacuum system, using greased stopcocks. However, when a sample was cleaned by heating in oxygen before degassing in a clean system, this discoloration was not obtained. These workers believe that the discoloration results from contamination of the rutile by organic impurities originating in the stopcock grease. The "clean" vacuum system made use of a mercury diffusion pump and mercury cutoffs instead of stopcocks. The conclusions were substantiated by mass spectrometric analysis and the detection of CO and CO_2 in the vacuum system.

14.2.2. Use of the CO-CO_2 *Equilibrium*

Assayag *et al.*[152] have used the equilibrium between CO and CO_2 to control the degree of reduction of rutile corresponding to compositions in the range $TiO_{1.908}$ to $TiO_{1.977}$ (i.e., 0.4% to 2% loss in weight). They have also shown by x-ray methods that this material retained the rutile structure.

14.2.3. Use of the Hydrogen-Water Vapor Equilibrium

Nasu[155–157] has used the hydrogen-water vapor equilibrium in the reduction of rutile in the temperature range 1022 to 1282°K. A specimen of powdered rutile was placed in a platinum crucible and suspended in an iron reaction chamber at the end of a quartz spring. The approach to equilibrium could be determined by the change in weight. A mixture of hydrogen and water vapor of unstated composition was introduced to the specimen. Later the composition of a sample of the equilibrium mixture was determined by measuring its pressure with a McLeod gauge both before and after the removal of the water vapor by condensation with liquid nitrogen, and the ratio of the partial pressures in the equilibrium mixture was then calculated.

Nasu[155–157] found that the equilibrium oxygen pressure remained constant from one percent to about 9.7% reduction, at which point its value fell abruptly. The absence of variation in the equilibrium constant in this range of reduction seems to indicate that the lower oxide existed as a separate phase, and the value of 9.7% corresponds closely to the loss in weight corresponding to the formation of Ti_2O_3. These results seem to set an upper limit of one percent to the weight loss which rutile can sustain at these temperatures without leading to the presence of aggregates of a different phase, i.e., when speaking of slightly reduced rutile, a weight loss of less than one percent is implied.

Unfortunately, the equilibrium ratios calculated from more recent calorimetric and free energy data are considerably higher than Nasu's values. Moreover, as Kelley has pointed out, Nasu's high-temperature data correspond exactly to the p_{H_2O}/P_{H_2} ratio for the FeO-Fe system, which fact may be related to Nasu's use of an iron reaction chamber.

14.2.4. Use of the Alkaline Earth Metals

Kubaschewski and Dench[158] have investigated the partial free energy of the titanium-oxygen system at 1000 and 1200°C between the limits of zero and 38% oxygen by weight. A quantity of barium, calcium, or magnesium was mixed with a quantity of one or other of the oxides of titanium. The mixture was sealed in a steel container and fired at the desired temperature. After cooling, the alkaline earth oxide was dissolved with hydrochloric acid and the remaining powder was analyzed for O; N, H, Fe, Ba, Ca, or Mg, and Ti. The equilibrium oxygen pressure was assumed to be that of the alkaline earth oxide at the temperature of the reaction. From these data a plot was made of partial free energy against composition of the oxide. In this paper, the effect of the formation of alkaline earth titanate was not discussed. The pressure of oxygen in equilibrium with a quantity of alkaline earth titanate is probably lower than that in equilibrium with the alkaline earth oxide.

14.2.5. Other Methods

Ehrlich[80] prepared specimens of TiO_x with x greater than 1.97 by heating appropriate mixtures of rutile and titanium metal or TiO to 1500–1600°C. Wyss[159] investigated the reduction of rutile by hydrogen and reported that at 1575°K, Ti_3O_5 is formed. The absence of further reduction under these conditions seems to indicate, as pointed out by Brewer,[151] that Ti_2O_3 is

‡‡ In the temperature range $T=1318$ to 1531°K, and $p=10^{-2}$ to 10^{-4} atmos, the results of these workers may be expressed very roughly by the following expression for the fractional weight loss f.

$$\log f = -\tfrac{1}{3}\log p_{O_2} - 5000/T - 0.10.$$

more stable relative to Ti_3O_5 than Humphrey's data appear to indicate.[141]

Kelley has investigated the reduction of rutile in an atmosphere of hydrogen-water vapor, but his results have not been published. As reported by Brewer,[151] the equilibrium pressure ratio p_{H_2O}/p_{H_2} changes abruptly at the composition Ti_3O_5. On the other hand, Welch[160] found no evidence for Ti_3O_5 when rutile is reduced by hydrogen at 1400°K. At 1700°K, Ti_3O_5 can be formed, in confirmation of Humphrey's conclusion that Ti_3O_5 is stable only at high temperatures.

Russian workers have investigated the reduction of metal oxides by hydrogen, and by alcohols.[161] Freundlich and Bichara[162] have used CaH_2 to reduce rutile. In his paper "Reduction of metallic oxides by carbon in boric oxide and borax melts," Khundkar[163] reports that rutile is not reduced by active carbon at 1000°C.

Comparison of the Debye θ Determined from Elastic Constants and Calorimetry

G. A. Alers and J. R. Neighbours

Scientific Laboratory, Ford Motor Company, Dearborn, Michigan

INTRODUCTION

As the temperature of a solid approaches 0°K the simple Debye continuum model should be applicable and the lattice specific heat calculated from the elastic constants using this model should agree with that measured by calorimetric techniques. Now that accurate low-temperature specific heat and elastic constant data are available, it is possible to compare critically the values of the Debye characteristic temperature θ, which these two methods yield. Usually, the calorimetrically determined θ is obtained from the slope of the straight line in a plot of C/T *versus* T^2 where C is the measured specific heat and T the absolute temperature. Such a plot separates the contribution of the electrons and is a straight line only if the lattice specific heat varies with T^3 as predicted by the Debye model. To determine θ from the elastic constants requires the calculation of the three sound wave velocities as a function of direction in the crystal lattice and then the averaging of the reciprocal of each velocity cubed over all directions. It is possible to do this by hand for hexagonal materials, but cubic materials require a long and elaborate calculation which is reasonable only if an electronic computer is available. Without a computer the tables prepared by de Launay[1] or the approximate methods developed by Quimby and Sutton,[2] and by Betts *et al.*[3] may be used.

Various models have been proposed to determine the lattice specific heat in the temperature range where the Debye model is expected to become inapplicable. These models consider a discrete lattice rather than a continuum and use measured elastic constants to define the effective force constants which act upon any given lattice point. With these force constants, the dynamics of the entire lattice can be worked out and the specific heat calculated.

This paper evaluates the different methods of calculating θ from the elastic constants and compares the resulting values with the results of calorimetric measurements.

DETERMINATION OF θ_0

The necessary data for calculating the value of Debye θ at 0°K, hereafter denoted by θ_0, are shown in Table I. In this table, the low-temperature elastic constants of copper,[4] silver,[5] gold,[5] zinc,[6] magnesium,[7] and lithium fluoride[8] are extrapolated from measurements performed at 4.2°K while those of aluminum,[9] lithium,[10] sodium chloride,[11] and potassium bromide[12] are extrapolated from measurements near 77°K. The 0°K atomic volumes and densities are calculated from the lattice constants appearing in the ASTM card catalog and the following thermal expansion measurements: Nix and McNair[13] for the noble metals and aluminum, Pearson[14] for lithium, Grüneisen and Goens[15] for zinc, and Henglein[16] for potassium bromide and sodium chloride. The data for magnesium and lithium fluoride are taken from the papers cited.

Table II lists values of θ_0 as calculated from the data in Table I by various methods along with the results of calorimetric measurements. The first column shows the θ_0 obtained from de Launay's tables[1] using case 2 and the Sterling central difference interpolation formula[17] in two dimensions. A graphical interpolation may cause the results to differ by about 0.3%. These tables are

Table I. Constants of certain materials extrapolated to absolute zero. The elastic constants are in units of 10^{12} dyne/cm². Ω is the atomic volume and ρ the density at 0°K.

based on a computer calculation and the values calculated should be exact except for errors introduced by interpolation between the tabulated values. Since the published tables apply only to cubic materials with $(C_{11}-C_{12})<2C_{44}$ there are no entries for potassium bromide and sodium chloride nor for the hexagonal metals. The second column gives the results obtained from approximating the velocity function with a six-term power series[2] and the third column shows the results obtained if a six-term expansion in cubic harmonics[3] is used. The latter expansion technique has been applied to hexagonal materials by using spherical harmonics[18] and was used to complete column three for zinc and magnesium.

The IBM 650 digital computer of the Ford Motor Company Research Department was programed to find the average velocity function using 120 points spread uniformly over the unit triangle for cubic materials and using a one degree interval for the single angle variable in hexagonal materials. The resulting values of θ_0 are given in the column headed "Numerical integration." The two entries for zinc are calculated from the two available sets of 4.2°K elastic constants[6] in Table I. Increasing the number of points considered in the unit triangle to 933 increased the value of θ_0 for copper by 0.17°K or 0.06% and decreased the θ_0 value for lithium by 0.49°K or 0.15%. Since the values from a 120-point calculation differ so slightly from the results of the longer calculation, and since these differences are much less than the errors expected from errors in the elastic constants, it is felt that the 120-point calculation with its consequent saving in computer time is sufficiently accurate.

Table II shows that all the foregoing methods for calculating θ_0 from elastic constants are essentially in agreement. In every case the differences are less than one percent. The columns headed "de Launay" and "Numerical integration" are results of essentially the same calculation and should agree closely, as they do. The differences between these columns are indicative of the errors introduced by interpolation and by the method of numerical integration. The large difference apparent for aluminum is presumably due to our slight extrapolation of de Launay's tables to cover the particular values of elastic constants for this metal. For lithium, the large difference (1.3°K) is not due to the inadequacy of the 120-point division of the unit triangle, but to some other unknown cause.

Roughly the ease of calculation of θ_0 by any one method is in the same order as the columns in Table II. If one uses graphical interpolation, the method of de Launay is outstanding in its simplicity. Although the two series methods are about equally involved, it is our experience that the value of θ_0 resulting from the method of Betts and co-workers is apt to be more nearly mistake-free, probably because the individual steps can be checked separately.

Since some cubic materials and all hexagonal materials fall outside the range of de Launay's published tables and since the series methods are probably poorer approximations, we take the column headed "Numerical integration" to be the best values of θ_0 calculated from elastic constants.

The uncertainty of these values is determined by the absolute accuracy of the elastic constants. With the computer program setup it is a simple matter to determine how sensitive the final θ_0 value is to errors in each individual constant. Table III shows the values of θ_0 for aluminum (low anisotropy) and for gold (average

TABLE III. Changes in Debye temperature with changes in elastic constants.

anisotropy) which are obtained by numerical integration if only one elastic constant is increased by 0.5%. A 0.5% change in elastic constants causes θ_0 to change by less than 1%. Also listed is the θ_0 value obtained for zinc when the elastic constant C_{13} is increased by 1%. This particular constant is difficult to measure accurately so it is encouraging to observe that θ_0 is not very sensitive to its uncertainties. From pulsed ultrasonic measurements, the absolute values of the measured elastic constants are estimated to be in error by about one-half percent. Since the errors in θ_0 are about the same size as the errors in the elastic constants, the calculated Debye temperature may be expected to be accurate to about one percent. This conclusion is supported by the fact that the θ_0's calculated from the two sets of low-temperature elastic constant data available on zinc differ by only 0.7%.

COMPARISON OF θ_0 WITH CALORIMETRIC RESULTS

The last column in Table II gives the values of θ_0 determined from specific heat measurements[19–27] in the 1 to 4°K temperature range. Included are several as yet unpublished results[28,29] as well as a new calculation,[30] using the 1955 temperature scale, of data already in the literature.[19] These values have been obtained by fitting the data on a C/T *versus* T^2 plot with a straight line by the method of least squares. The slope of this line defines the calorimetric θ_0. Small differences in the numerical value of the calorimetric and elastic θ_0's may arise simply because the elastic constant line is not the best least squares fit to the data. Thus the best way to compare the two results is to plot the calorimetric data and superimpose on it the line defined by the elastic constants. Since only the slope of the line is defined, it must be forced to pass through the calorimetric data at some point and disagreement is then apparent if the line and the data diverge.

Rather than plot a separate C/T *versus* T^2 graph for each material listed in Table II, the calorimetric data have been normalized to allow several sets of data to be presented in one graph. This is shown in Figs. 1 and 2 where $C\theta/T$ is plotted against $(T/\theta)^2$. On such a plot vertical lines are lines of constant T/θ. If the specific heat data are described by the sum of a linear and a cubic temperature term then, in a plot like Fig. 1, the data will define a straight line with an intercept of $\gamma\theta$ (where γ is the coefficient of the linear term) and a slope determined by the ratio of the normalizing θ to the θ which best fits the data. In constructing these figures, the values of normalizing θ were taken from the numerical integration column of Table II. The lines are drawn with the slope predicted by the Debye theory and so as to fit best the lower end of the data. We have chosen not to plot data in which there are good reasons for the large and clear differences between the calorimetric and elastic θ_0's. These are sodium chloride,[27] aluminum,[23,24] lithium,[25] and potassium bromide.[26] For sodium chloride and aluminum the specific heat data are quite scattered and can easily be described with the elastic θ_0. For lithium the lines defined by the elastic data and the calorimetric data diverge completely, but this is probably owing to the presence of a crystal structure change[31] between 77°K where the elastic constants were measured and 4°K where the specific heat was measured. In the case of potassium bromide the calorimetric measurements extend only to temperatures of the order of $\theta/50$ which is not low enough for a valid comparison.

Figure 1 shows the plot of $C\theta/T$ *versus* $(T/\theta)^2$ for the specific heat measurements of the noble metals[19] and lithium fluoride.[20] It is apparent that the elastic θ_0 defines a straight line which describes the calorimetric data for copper, silver, and lithium fluoride to within

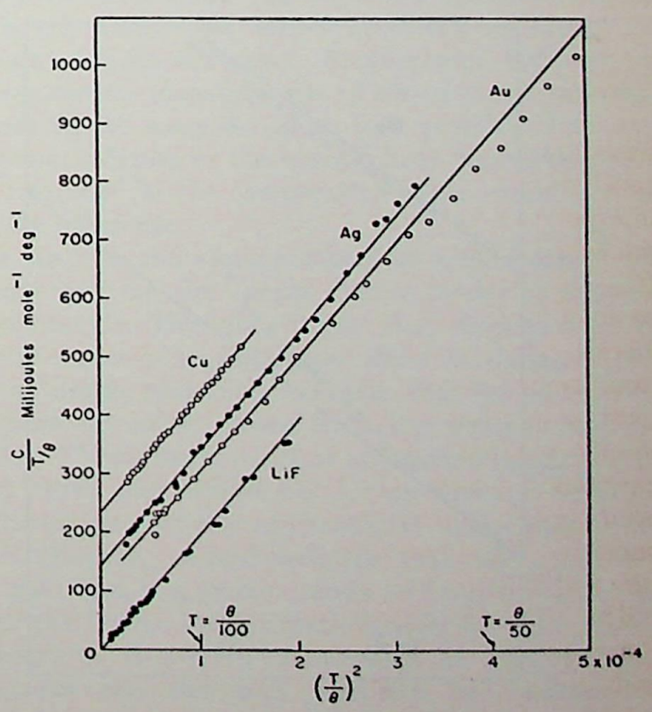

FIG. 1. Comparison of the specific heat calculated from Debye theory (solid lines) with the measured specific heats of cubic materials.

the experimental scatter of the data. For gold, the elastic line is clearly not the best straight line fit to the data. This difference is just outside the experimental errors arising from elastic constant errors. It may be that simple Debye theory is not appropriate over the whole temperature range given in the figure in which case the elastic constant line should fit the data only below a certain temperature. From this point of view, it may be concluded that the elastic θ_0 and Debye theory successfully describe the calorimetric data below temperatures of approximately $\theta/60$.

The disagreement between calorimetric and elastic θ_0's is more explicit for the hexagonal metals since both cases examined show large deviations. Figure 2 shows a $C\theta/T$ *versus* $(T/\theta)^2$ plot of the specific heat measurements on magnesium[28] and zinc.[22] Superimposed on these data are the straight lines predicted by the elastic constant measurements with the lines chosen to pass through the data at the low-temperature end. It is obvious that the line based on elastic data is not the best straight-line fit to the data and that a good description of the data occurs only below temperatures of about $\theta/150$ where we have required it to fit. In these cases, the elastic constants would have to be in error by about 4% in order to account for the difference in results. Such a difference is far outside experimental error for all the constants except C_{13}. Table III shows that if this one constant is changed by 1%, the value of θ is only changed by 0.1% which makes it unlikely that the inaccuracy of C_{13} could account for the discrepancy in θ values. It may be argued that the true Debye region has not been reached for these hexagonal metals even though the temperature is below $\theta/100$. However, the magnesium specific heat data does fall on a straight line which indicates that it can be well described with a T^3 dependence. The zinc data deviate slightly from a T^3 law and Seidel[22] has made a least squares fit to his heat capacity data assuming a temperature dependent θ. From this he extrapolates to $T=0°K$ to obtain a value of $\theta_0=309°K$ which is still 5% below the elastic constant value.

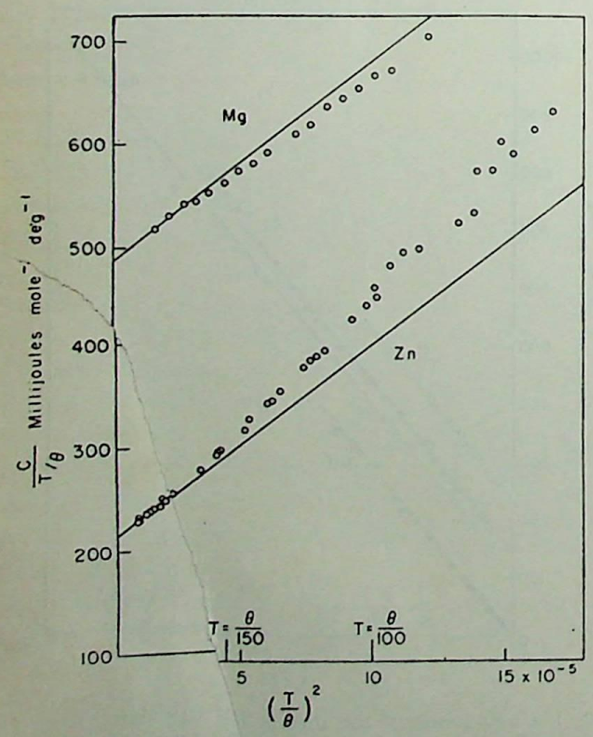

FIG. 2. Comparison of the specific heat calculated from Debye theory (solid line) with the measured specific heats of hexagonal metals.

TEMPERATURE DEPENDENCE OF θ

The previous section has shown the degree to which Debye theory describes experimental specific heat measurements near absolute zero. In order to calculate the lattice specific heat above $T=0$ using elastic constant data, it is necessary to modify Debye theory to include effects which arise because the solid is not a continuum but a lattice of discrete atoms. This requires considering a model in which the solid consists of mass points held in equilibrium by forces which are expressable in terms of the elastic constants. For convenience, the results of these modifications are usually expressed in terms of an effective θ which can be compared with the Debye θ. This modified θ is expected to vary with temperature and its temperature dependence can be calculated assuming a particular force constant model. From this, the lattice specific heat can be determined and compared to the calorimetric measurements in order to judge the validity of the model chosen. It is also possible to calculate a calorimetric θ from specific heat measurements and compare it with the modified θ predicted by the lattice theory. But unless very precise calorimetric measurements are used, the resulting values of θ may show considerable scatter and make a judgment of the theoretical model very difficult. We have chosen to compare the specific heat values themselves since these are of more technical interest and since it is then obvious how much error can be expected from using elastic constant models to estimate lattice specific heats.

Figure 3 shows the experimental data for copper,[32] silver,[33] and gold[34] plotted as C/T *versus* T^2. The solid curves labeled D show the variation of the specific heat predicted by the unmodified Debye theory which has the constant value of $\theta=\theta_0$. Gold, which shows deviations from the elastic constant θ_0 at temperatures of $\theta/60$, follows this theory to remarkably high temperatures ($T\sim\theta/7$) even though silver and copper deviate considerably from it at temperatures of the order of $\theta/20$. The curves marked L are based on the model of de Launay[1] who assumes a central force connecting nearest and next-nearest neighbor atoms

and a third force arising from the compressibility of the electron gas. This model does not describe the lattice specific heat for gold and copper over the temperature range in which data are available but seems to describe the silver data up to temperatures of approximately $\theta/10$.

The curves marked *H* are the predictions of the model of Horton and Schiff[35] which are based on assuming a three-force constant noncentral interaction between nearest neighbor atoms only. This model is in better agreement with the measurements for copper and gold, but not enough to be significant. None of the models gives a really satisfactory description of the specific heat in the range where measurements are available. However, this apparent failure may not be serious since these theories are expected to apply only up to temperatures of $\theta/20$ and the available data do not cover this range. A critical evaluation of the models must wait for accurate specific heat data between 4 and 15°K.

A model applicable to hexagonal metals has been calculated by Garland and Slutsky.[36] Using central forces between the first three nearest neighbors and a force due to the compressibility of the electron gas they find that θ decreases with increasing temperature but not as rapidly as is observed. They also find that zinc with its high c/a ratio cannot be described well with their model and do not attempt a comparison with the specific heat values.

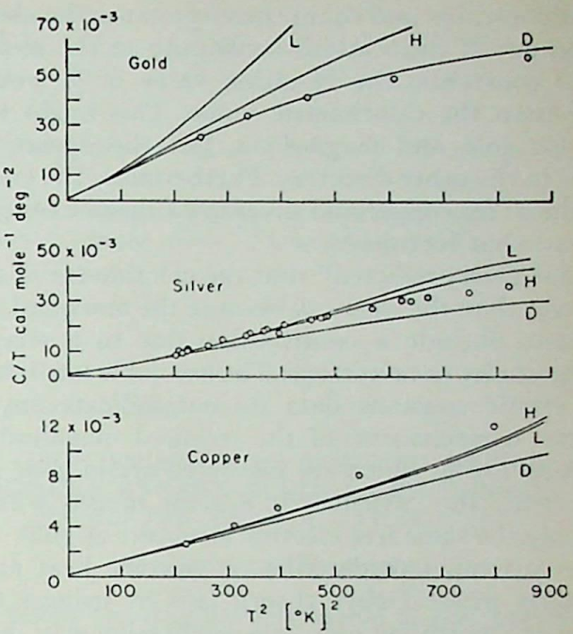

FIG. 3. Comparison of the specific heat calculated from several different models with the measurements in the 15 to 30°K range. The curves marked *D* are based on Debye's continuum model while those marked *L* and *H* refer to the lattice models proposed by de Launay and by Horton and Schiff, respectively.

CONCLUSIONS

For the cubic materials considered, the value of θ_0 calculated from elastic constants measured at 4°K by direct numerical integration is in very good agreement (except possibly for gold) with the low-temperature specific heat measurements. The tables of de Launay yield results which agree with the integration to within the accuracy of reading the table and is by far the easiest to apply. The two expansion methods of Betts *et al.* and of Quimby and Sutton appear to give θ_0 accurately to 1% even for the most anisotropic case but the method of Quimby and Sutton seems laborious and more susceptible to mistakes. Considering the differences in the results of the series approximation, and the errors in interpolation and extending de Launay's tables, we advance the values listed under the Numerical integration column in Table II to be the best available values calculated from elastic constants.

Since the lattice specific heat predicted by Debye theory from elastic constants is consistent with the calorimetric measurements to the extent shown in Fig. 1, it seems possible to conclude that the simple Debye model of lattice heat capacity is a very good approximation at low temperatures in cubic substances. In materials where the lattice specific heat cannot clearly be separated from other contributions (i.e., when there are large electronic specific heats, low-temperature phase transitions, or magnetic interactions) the elastic constants can be used to define the lattice contribution without introducing appreciable error.

For the hexagonal metals and gold there seems to be a definite difference between the calorimetric θ_0 and the elastic constant value. The reason for this is not certain. It is not likely that errors in elastic constants will account for the difference. Furthermore, for zinc two independently measured sets of elastic constants result in nearly the same θ_0 value. It is possible that small systematic errors in the specific heat measurements or uncertainties in the temperature scale would account for the difference.

It may be that temperatures of $\theta/60$ are not sufficiently low for the simple Debye model to apply to these metals. This may imply that dispersion of the elastic waves is an important effect at these temperatures. Simple reasoning indicates that for an isotropic medium deviations down from the straight line in a C/T *vs* T^2 plot are a result of an upward bending of the $\omega(k)$ curve and conversely for an upward deviation. Although not strictly applicable to anisotropic media, such reasoning would indicate that the $\omega(k)$ curve for gold and magnesium tends to bend upward away from the Debye approximation while for zinc it bends downward. However, examination of Figs. 1 and 2 indicates that the data need not be considered as "curving away" from the theoretical straight line since it can be fitted by a straight line of different slope. Thus the dispersion must be of a rather special nature.

There may be effects which modify the measured

elastic constants and could therefore cause the observed differences. If dislocations contribute to the measured elastic constants, the resulting value of θ_0 would be lower than the calorimetric value. This might be the case for gold and magnesium, but the deviation for zinc is in the other direction. Furthermore, the excellent agreement for copper and silver must then be considered as somewhat fortuitous.

It has been predicted[37] that the calorimetric θ_0 should be larger than the elastic θ_0 because the measured elastic constants include a contribution due to a relaxation mechanism of the electrons. The available low-temperature elastic constant data do not indicate any such relaxation mechanism of the required magnitude and the values of θ_0 which are predicted are in good agreement with the calorimetric θ_0's for metals with presumably the same free electron structure as gold.

The attempts to describe the specific heat at temperatures where Debye theory fails by using a lattice model are satisfying only in a qualitative way, but are unsatisfactory in predicting the detailed temperature dependence of θ. However, before a critical comparison can be attempted, accurate specific heat measurements must be made in the 4° to 20°K range.

ACKNOWLEDGMENTS

The authors are grateful to Dr. J. Zimmerman, Dr. A. Arrott, and Mr. J. Skalyo of this Laboratory, Dr. J. Rayne of the Westinghouse Research Laboratory, Mr. G. Seidel of Purdue University, Dr. C. W. Garland of MIT, and Dr. G. K. Horton and Dr. H. Schiff of the University of Alberta for communicating their results prior to publication. We also wish to thank Mr. M. T. MacNeil for his help in preparing the calculation program for the computer, and Dr. P. M. Sutton of the Corning Glass Works for calculating the values listed under his name in Table II.

ADDENDUM

Since submitting this article, more elastic constant and calorimetric data have become available. Calorimetric measurements by Phillips[38] down to $\theta/1000$ (0.3°K) gives $\theta_0=426°$ for aluminum which compares favorably with the calculated value of $\theta_0=428.2$ shown in Table II. New calorimetric measurement on LiF[39] down to $\theta/80$ give $\theta_0=722$°K which is in disagreement with the calculated value in Table II. However, these latter calorimetric data are somewhat scattered and, in fact, can be reasonably well described by a line corresponding to $\theta_0=734.1$°K.

Other new data are shown in the added tables. Additions to Table I shows the recent elastic constant data. The values of atomic volume and density are taken from the reference cited. Additions to Table II shows the resulting calculated values of θ_0.

As before, the calculated values of θ_0 are in good agreement with each other. The results of calorimetric measurements are also listed. For thorium, although the calorimetric θ_0 seems to be in disagreement, the calorimetric data up to $\theta/50$ is well described by choosing $\theta_0=164.2$°K. The calorimetric and elastic constant values for nickel are apparently in disagreement but the calorimetric data are quite scattered so that critical comparison is not possible.

For the two alkali halides listed, the calculated and calorimetric values are in apparent agreement. However, on a plot like Fig. 1 the elastic constant line through the origin does not fit the calorimetric data, which extends down to almost $\theta/100$. Dispersion effects can explain this failure as shown by Barron, Berg, and Morrison[40] who obtained the values of θ_0 listed above by extrapolating calorimetric data to $T=0$. This result indicates that deviations from the Debye approximation occur at relatively lower reduced temperatures for the alkali halides than for the cubic metals. If dispersion is to account for the discrepancies in the hexagonal metals, it must be concluded that the Debye approximation is inapplicable at reduced temperatures much lower than those which are suitable even for the alkali halides.

Masers*

J. WEBER

University of Maryland, College Park, Maryland

"It is strange that practical electronics remained untouched by these fundamental facts (electron spin) and could get along with the notion of the charged mass point or the minute charged sphere." [Arnold Sommerfeld, *Electrodynamics* (Academic Press, Inc., New York, 1948)].

I. INTRODUCTION

THE development of electronics during the first half of this century was based almost completely on the quantum states of translational energy of the free electron. Only recently did physicists recognize the fact that the spin states and the bound states of electrons in atoms and molecules could be employed for amplification. We give here an account of these technological advances together with a summary of the physics which made them possible.

The physical principles and experimental techniques required for development of paramagnetic amplifiers and molecular amplifiers were well established in the period 1945–1950. Such microwave amplifiers have much lower noise than those employing thermionic vacuum tubes. This low noise property has been the principal motivation for the large amount of work in this field.

The earliest work on molecular amplification started independently at three different laboratories.[1–3] It had a different motivation, namely, the hope that millimeter wave oscillators and amplifiers would result.

The word "maser" was coined by the Columbia group[2] as an acronym for "microwave amplification by the stimulated emission of radiation." This word appears in Webster's dictionary with the spellings "mazer" and "maser" and has the meaning "a large drinking cup, originally of a hard wood." The free electron vacuum tube amplifier may also be regarded as operating thfough the mechanism of the stimulated emission of radiation. In what follows, however, the word maser is taken to mean either a molecular amplifier or a paramagnetic solid state amplifier.

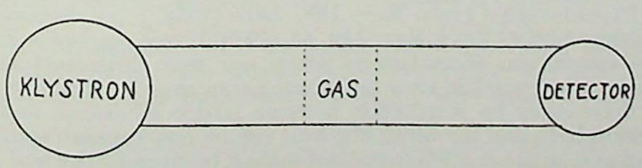

FIG. 1. Absorption of microwaves by a gas.

II. AMPLIFICATION BY SYSTEMS HAVING A HIGHER ENERGY STATE MORE DENSELY POPULATED THAN A LOWER STATE

A. General Principles

We follow the original[1] discussion of this principle of maser type amplification. In the experimental arrangement of Fig. 1, there is a microwave system which consists of a wave guide with gas inside, in thermal equilibrium. Such a gas may absorb microwaves, and this absorption can be described in the following terms.

Suppose the gas has a pair of energy levels (Fig. 2) with values E_1 and E_2, with $E_2 > E_1$. Let n_1 and n_2 be the numbers of particles with energies E_1 and E_2. Let the absolute temperature be denoted by T and Boltzmann's constant by k. Then we can write

$$n_2 = n_1 e^{-(E_2-E_1)/kT}. \quad (1)$$

We suppose that electromagnetic radiation is present with frequency ν given by

$$\nu = (E_2-E_1)/h. \quad (2)$$

The power absorbed by the gas can be written

$$P_A = W_{12} n_1 h\nu. \quad (3)$$

Here W_{12} is the transition probability for transitions from state 1 to 2 induced by radiation. Similarly the power emitted by the gas due to the stimulated emission of radiation is given by

$$P_E = W_{21} n_2 h\nu. \quad (4)$$

Neglecting spontaneous emission for the moment we can write $W_{21} = W_{12}$ and for the *net* power absorbed

$$P = W_{12}(n_1-n_2)h\nu. \quad (5)$$

P will be positive and the gas will absorb power, if n_1 exceeds n_2. This will be the case in consequence of expression (1), if the gas is in thermal equilibrium. How-

ever, the net power absorbed can be made negative, and amplification will result, if $n_2 > n_1$. For the present we consider amplification by a one-quantum process, resulting from the nonequilibrium situation $n_2 > n_1$. The same considerations which lead to coherent absorption for $n_1 > n_2$ suggest that for[4] $n_2 > n_1$ the amplified signal will be coherent with the driving signal. The energy levels which are employed may be bound states of molecules, or spin states in a magnetic field. The low-temperature solid state masers use paramagnetic ions in an externally applied magnetic field.

B. Three-Level Method

Many methods have been proposed for obtaining a higher population density in an upper energy level than in a lower one. Most of these are not generally useful, but may nonetheless have special applications. A fairly complete survey is given in Sec. IV. First we present a summary of the three-level method, first proposed by Prokhorov,[3] and developed independently by Bloembergen,[5] and also by Javan; this appears to be by far the most generally useful one. We follow Bloembergen's treatment.

In a system with three energy levels, E_1, E_2, and E_3 (Fig. 3), let the selection rules be such that transitions are allowed between each level and either of the other two. In thermal equilibrium, the numbers of particles in the different states satisfy the relations,

$$n_1 > n_2 > n_3. \tag{6}$$

The frequencies ν_{32}, ν_{21}, ν_{31} are defined by the relations

$$\nu_{mn} = (E_m - E_n)/h. \tag{7}$$

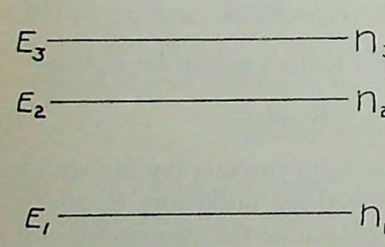

FIG. 3.

An intense rf field of frequency ν_{31} will induce transitions between states 1 and 3. Since initially there are more particles in state 1, the particles will initially leave state 1 at a greater rate than return to it from state 3.

Saturation phenomena will result in which $n_3 \to n_1$. Under these nonequilibrium conditions we may expect either that $n_2 > n_1$ or $n_3 > n_2$. In the first case amplification is possible at frequency ν_{21} and in the second case at ν_{32}. In order to arrive at quantitative values relaxation[6]

[4] The term negative temperature [E. M. Purcell and R. V. Pound, Phys. Rev. 81, 279 (1951)] is often used to describe a system in which higher energy levels are more densely populated than lower ones. This is consistent with expression (1). The idea of a negative temperature implies that while part of a system is not in equilibrium with its environment, it is sufficiently isolated from its positive temperature bath that it can be considered as a separate thermodynamic system described by a temperature. The concept of spin temperature has been carefully considered by A. Abragam and W. G. Proctor [Phys. Rev. 109, 1441 (1958)]. Negative temperature is only possible for a system whose energy levels have an upper bound. Thus when such a system is heated from 0°K to a temperature $+\infty$ the levels become equally populated. If it is heated further the temperature changes discontinuously to $-\infty$, and on further heating it eventually tends to minus 0°K at which point all particles are in the state of highest energy. As Bloembergen has remarked, negative temperature is hotter than hot. It has been suggested by Ramsey that the discontinuity at $+\infty$ could have been avoided if the reciprocal of temperature had been used. At negative temperatures resistances become negative and amplification is then possible.

[5] N. Bloembergen, Phys. Rev. 104, 324 (1956).

[6] An important issue in the operation of a paramagnetic ion low-temperature maser is the mechanism of paramagnetic relaxation. We discuss briefly some pertinent aspects of this problem. It appears more complex than the corresponding nuclear magnetic resonance problem. One experimental fact is that it is possible to couple the saturation radiation to one set of spin levels and simultaneously saturate a second pair of levels at approximately the same spacing which is weakly coupled to the radiation field [Strandberg, Davis, Faughnan, Kyhl, and Wolga, Phys. Rev. 109, 1988 (1958)]. Strandberg [Phys. Rev. 110, 65 (1958)] has interpreted these results as evidence for the idea that there are anomalies in the phonon excitation, with the lattice modes with frequency near the spin resonance in equilibrium with the high-temperature saturated spin system. He considers this to be in part a consequence of the fact that the specific heat of the lattice vibrations at 4°K (calculated from say the Debye model) is several orders smaller than that of the paramagnetic spin system. Giordmaine, Alsop, Nash, and Townes [Phys. Rev. 109, 302 (1958)] have described a series of experiments using paramagnetic resonance at 9000 Mc, at 1–4°K; $Gd_2Mg_3(NO_3)_{12}\cdot 24H_2O$), $K_3Cr(CN)_6$, and $Cu(NH_4)_2(SO_4)_2\cdot 6H_2O$) were used. They found that it was not possible to "burn a hole" in their resonances by saturation, indicating that their lines were homogeneously broadened. In the case of Cu, saturation of one line immediately saturated seven neighboring resonances. They were not able to observe the spin reversal by adiabatic rapid passage. No difference in absorption was noted in times as short as one msec after adiabatic rapid passage. They also observed that excitation due to a rapid sweep through a single resonance decayed very rapidly while that due to a slower sweep decayed at the normal rate, $T_1 \to 10$ sec. They interpreted these results as evidence for the idea that for some salts at low temperatures it is the lattice bath relaxation which limits the total relaxation rate. [Gorter, Van der Marel, and Bölger, Physica 21, 103 (1955)]. They also remarked that for these salts the spin lattice relaxation time is several orders smaller than the observed values of T_1, and is of order 10^{-5} sec for Gd and 10^{-4} sec for Cu. In addition, they concluded that the breadth of the lattice modes is much larger than the width of the resonances in the diluted crystals (several hundred Mc for 1% paramagnetic concentration of the Cu salt), that the relaxation time T_1 is dependent on crystal size, and that the breadth of the lattice modes increases with increasing concentration of paramagnetic centers. They also suggested that for those salts described by the foregoing conditions, operation of an adiabatic rapid passage two-level maser would be impractical while three-level maser operation would be possible with reduced band width.

Bloembergen [Phys. Rev. 109, 2209 (1958)] and Strandberg independently [Phys. Rev. 110, 65 (1958)] have reached a different conclusion. Bloembergen points out that three-level maser iction is not possible for a salt whose paramagnetic relaxation rate is determined by interaction between lattice vibrations and the helium bath and for which the heat conduction between spin system and lattice is 1000 times better than between lattice and heat bath. Let ν_{31} be the saturation frequency and ν_{32} the amplification frequency and let these frequencies be widely spaced, with no overlapping of phonon bands. Then we have a negative spin temperature corresponding to levels 2 and 3. If the thermal contact with the phonons is very good then a band centered at frequency ν_{32} will start to gain energy, in order to attempt to reach equilibrium with the negative temperature spin system. Since the lattice vibration levels are those of harmonic oscillators, they have no upper bound. They cannot be saturated [R. Karplus and J. Schwinger Phys. Rev. 73, 1020 (1948)] and the temperature associated with the ν_{32} band can never become negative. The steady state (nonequilibrium) situation would be one in which the spins of levels 2 and 3 are at a very high negative temperature and those

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

effects must be included. Let w_{12} be the heat bath induced transition probability from state 1 to state 2, with corresponding meanings for w_{21}, w_{32}, w_{23}, w_{13}, and w_{31}. First suppose the system is in thermal equilibrium with no microwave fields applied. The number of particles leaving the state E_1 per sec must equal the number returning to it, so

$$n_1w_{12}=n_2w_{21}, \quad n_1w_{13}=n_3w_{31}. \tag{8}$$

Employing the Boltzmann factor enables us to write

$$w_{12}/w_{21}=n_2/n_1=e^{-h\nu_{21}/kT}. \tag{9}$$

The w's are the reciprocals of the spin lattice relaxation times. Now suppose that a strong microwave field of frequency ν_{31}, and a weak microwave signal of frequency ν_{32} are present. Let W_{31} and W_{32} be the transition probabilities induced by these rf fields. The numbers of particles n_1, n_2, and n_3 occupying the three levels satisfy the relation,

$$n_1+n_2+n_3=N. \tag{10}$$

For $(h\nu_{32})/(kT)\ll 1$, the populations satisfy the equations

$$\frac{dn_3}{dt}=w_{13}\left(n_1-n_3-\frac{Nh\nu_{31}}{3kT}\right)+w_{23}\left(n_2-n_3-\frac{Nh\nu_{32}}{3kT}\right)$$
$$+W_{31}(n_1-n_3)+W_{32}(n_2-n_3),$$

$$\frac{dn_2}{dt}=w_{23}\left(n_3-n_2+\frac{Nh\nu_{32}}{3kT}\right)$$
$$+w_{21}\left(n_1-n_2-\frac{Nh\nu_{21}}{3kT}\right)+W_{32}(n_3-n_2), \tag{11}$$

$$\frac{dn_1}{dt}=w_{13}\left(n_3-n_1+\frac{Nh\nu_{31}}{3kT}\right)$$
$$+w_{21}\left(n_2-n_1+\frac{Nh\nu_{21}}{3kT}\right)-W_{31}(n_1-n_3).$$

These equations have the following approximate steady-state solution for the case in mind, $W_{31}\gg W_{32}$.

$$n_1-n_2=n_3-n_2=\frac{hN}{3kT}\left[\frac{-w_{23}\nu_{32}+w_{21}\nu_{21}}{w_{23}+w_{21}+W_{32}}\right]. \tag{12}$$

In case the numerator of (12) is positive, amplification is possible at frequency ν_{32}. In case it is negative, amplification is possible at the frequency ν_{21} and the W_{32} in the denominator of (12) must be replaced by W_{21}. The signal power emitted by the material is obtained by multiplying (12) by the signal induced transition probability W_{32} and the energy of one quantum.

$$P=\frac{Nh^2\nu_{32}(w_{21}\nu_{21}-w_{32}\nu_{32})W_{32}}{3kT(w_{23}+w_{21}+W_{32})}. \tag{13}$$

The situation described by (12) and (13) is qualitatively the same, but more complex, if $(h\nu/kT)$ is not small compared to 1. The procedures for calculating the transition probability W_{32} require a knowledge of the matrix elements of the interaction with the Maxwell field, and appropriate relaxation times. For the remainder of the section we consider a paramagnetic ion type of solid state amplifier. In this case the signal induced transition probability is given by

$$W_{32}=\left(\frac{2\pi}{h}\right)^2|\langle 2|M_x|3\rangle|^2\langle H_s^2(\nu_{32})\rangle_{Av}T_2. \tag{14}$$

Here M_x is the (x component) magnetic dipole operator, $\langle H_s^2(\nu_{32})\rangle_{Av}$ is the volume average squared magnetic field at the signal microwave frequency ν_{32}, and T_2 is the spin-spin relaxation time.

Expression (13) shows that the temperature T of the heat bath must be low. The three-level solid state masers which have so far been successfully operated have employed liquid helium cooling with temperatures in the range 1.25–4°K. In addition to increasing the amplification, the low temperatures partially improve the noise performance.

The power which is absorbed from the saturation†

lattice vibrations with which the spins are on "speaking terms" will be at a very high positive temperature. A high negative temperature means that the level populations associated with states 2 and 3 are almost equal, and therefore the maser would not operate in the observed manner. Bloembergen has solved the problem of three-level maser and phonon steady states in terms of the spin populations n_1, n_2, n_3 and the average lattice oscillator excitation quantum numbers in the three phonon bands, $n_{ph}(\nu_{32})$, $n_{ph}(\nu_{21})$, $n_{ph}(\nu_{31})$. His solution confirms that n_3-n_2 is too small for maser operation if the contact between spins and phonons is better than between phonons and heat bath.

A possibility which has briefly been explored by the author is that the temperature associated with all three maser spin levels is positive, amplification occurring as a result of a two-quantum process involving absorption of a saturation frequency photon and emission of an amplification frequency photon. This is a kind of Raman process in which energy is conserved in both transitions. Direct calculation shows that this effect is too small, and that a low negative spin temperature needs to be assumed, in conjunction with single photon processes, in order to explain the operation of a maser.

It can be concluded that the paramagnetic relaxation mechanisms suggested by Giordmaine, Nash, and Townes do not apply to those salts which have been successfully used in a three-level maser.

Shapiro, Bloembergen, and Artman [Bull. Am. Phys. Soc. Ser. II, 3, 317 (1958)] have reported additional indirect saturation experiments which they interpret as caused by higher order spin-spin interactions rather than by "hot phonons." This appears very reasonable because it is difficult to see how the lattice vibration modes could be tightly coupled to the saturated spin system without being similarly coupled to the negative temperature spin system. Further work by Bloembergen, Shapiro, Pershan, and Artman (Cruft Laboratory Technical Report No. 285, Harvard University, Cambridge, Massachusetts, October 15, 1958) has increased the evidence that the indirect saturation phenomena are indeed due to spin spin interactions. This follows the mechanism proposed by R. Kronig and C. J. Bouwkamp, Physica 5, 521 (1938) and Physica 6, 290 (1939).

† *Note added in proof.*—An interesting discussion of masers as heat engines has been given by H. E. D. Scovil and E. O. Schulz-

field of frequency ν_{31} is given by that needed to balance the tendency of collisions to restore equilibrium, and is

$$P_s=(h\nu_{31})^2 n_1/2T_1kT. \quad (15)$$

Here T_1 is the spin-lattice relaxation time.

Expressions (13), (14), and (15) lead to the following general criteria for selection of materials for a paramagnetic ion three-level maser. If the heat bath transition probabilities w_{21} and w_{23} are nearly equal, the frequencies ν_{21} and ν_{32} should be very unequal. However, if the frequencies ν_{21} and ν_{32} are approximately equal, then w_{21} and w_{23} should be very unequal. If ν_{21} is exactly equal to ν_{32} the device cannot operate since the same signal which induces transitions between states 2 and 1 will be effective in inducing transitions between 3 and 2. Amplification between one pair of states would be annulled by absorption associated with the other pair since (12) requires that $n_1-n_2\approx n_3-n_2$. In order to obtain large gain the temperature T has to be small. The spin should be at least 1, but preferably not more than $\frac{3}{2}$, otherwise the particles will be distributed among too many states. (Gd with a spin of $\frac{7}{2}$ is a notable exception.) It is also desirable that the nuclear spin be zero. Expression (15) requires that for small T, the spin-lattice relaxation time T_1 be as large as possible, otherwise excessive saturation power will be needed with consequent difficulty in maintaining low temperatures. Expressions (13) and (14) show that the product of total number of spins, N, and the spin-spin relaxation time T_2 should be as large as possible. Inasmuch as an increase in concentration of spins tends, in general, to decrease T_2 it is necessary to attain an optimum value of the product NT_2 by suitably diluting the paramagnetic ions. The zero field splitting ought to be of the same order of magnitude as the energy level difference associated with the signal frequency. This follows because mixing of the spin states is essential in order to have transitions allowed between all three levels. This is most favorable when the Zeeman and crystalline field terms are comparable.

It is possible, and in some cases desirable, to use a four-level system. A particularly elegant solution of the problem of four-level maser design employing ruby has been given by Kikuchi,[7] Makhov, Lambe, and Terhune with $E_4-E_2=E_3-E_1$. In the latter case a pumping frequency $\nu_{42}=\nu_{31}$ populates the third level and simultaneously depopulates the second level.

A generalization of (13), given by Kikuchi, is

$$P=\frac{Nh^2}{4kT}\left[\frac{w_{21}\nu_{21}-w_{32}\nu_{32}+w_{41}\nu_{41}+w_{43}\nu_{43}}{w_{21}+w_{23}+w_{14}+w_{34}+W_{32}}\right]W_{32}\nu_{32}. \quad (16)$$

The active material of a maser can be placed in a wave-guide transmission system or in a resonant cavity. In the former case we have a traveling wave amplifier with power output given by

$$P=P_oe^{\beta l}, \quad (17)$$

where l is the distance along the amplifier.

Differentiating this with respect to l leads to the gain coefficient β given by

$$\beta=dP/Pdl. \quad (18)$$

Here (dP/dl) is the power emitted per unit length and P is the power at the point where (dP/dl) is calculated, in accordance with expressions (13) or (16). Employing (14), this can be written

$$\beta=\frac{32\pi^3(n_3-n_2)\,|M_{32}|^2T_2\nu f}{hv_g}, \quad (19)$$

where f is a filling factor which may approach 1 and v_g is the group velocity.

Here the power P has been set equal to the energy density times the group velocity v_g. This equation shows that a slow wave structure (small group velocity) is a desirable method of obtaining a higher gain-band-width product. Slow wave structures proposed thus far are a ruby rod with a helix wrapped around it, considered by W. W. Anderson of Stanford University, and a rectangular wave guide with conducting fingers giving circular polarization, considered by DeGrasse, Schulz-DuBois,

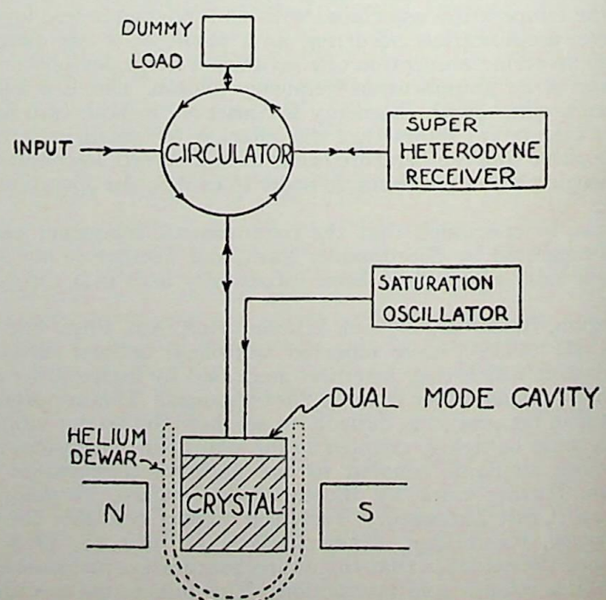

FIG. 4. Reflection cavity maser.

DuBois [Phys. Rev. Letters 2, 262 (1959)]. They consider a hot reservoir with temperature T_1 and filter allowing a band of frequencies in the vicinity of ν_{31} to pass, in thermal contact with a maser. Levels 2 and 3 are in thermal contact with a cold reservoir at temperature T_0, and coupled through a filter with pass band centered about ν_{32}. The signal frequency is ν_{21}. Ignoring relaxation processes within the maser, using the Boltzmann distribution law and requiring $n_2>n_1$ leads to the result that the maser efficiency ν_{21}/ν_{31} is that of the Carnot engine, $(T_1-T_0)/T_1$. They note the important result that instead of using a coherent microwave pump at ν_{31}, thermal excitation by two reservoirs as described above should make it possible to generate microwaves.

and Seidel of the Bell Telephone Laboratories. These structures could be employed either as transmission or reflection devices. Means must be provided to prevent output power from being fed back to the input, causing the amplifier to oscillate, and for preventing noise from the load from getting to the maser and being amplified. Transmission devices utilizing nonreciprocity would accomplish this.

The reflection cavity type of maser has undergone most development and appears capable of giving enough gain-band-width product for most purposes. A block diagram is sketched in Fig. 4. Here a nonreciprocal device, the microwave circulator,[8] prevents power from being fed back and causing oscillation, and keeps noise from the load out of the maser. Resonant cavity expressions for gain and noise performance are usually expressed in terms of the Q's (quality factors) of a cavity. The Q is defined by

$$Q=2\pi\nu E/P_a, \tag{20}$$

where E is the energy in the principal cavity mode and P_a is the rate of absorption of energy. The unloaded Q, usually denoted by Q_o, is defined by

$$Q_o=2\pi\nu E/P_{aw}, \tag{21}$$

where P_{aw} is the part of the absorbed power that is absorbed in the cavity walls. The magnetic Q, denoted by Q_m, is defined by

$$Q_m=-\frac{2\pi\nu E}{P_e}=\frac{-\nu\langle H^2(\nu)\rangle V_c}{4P_e}, \tag{22}$$

where P_e is the net power emitted by the active material.

Here V_c is the volume of the cavity and ν is the frequency being amplified. The denominator is given by expressions (13) or (16). The external Q, denoted by Q_e, is defined by

$$Q_e=2\pi\nu E/P_{en}, \tag{23}$$

where P_{en} is the net power output.

The cavity mode may be represented by the equivalent circuit in Fig. 5. G_m, G_o, and G_e are conductances associated with the spin system, the walls of the cavity, and the output load, respectively. From Fig. 5, a loaded Q may be defined as

$$Q_l^{-1}=Q_m^{-1}+Q_o^{-1}+Q_e^{-1}. \tag{24}$$

The voltage standing wave ratio in the transmission system which drives the cavity, B, is given in terms of

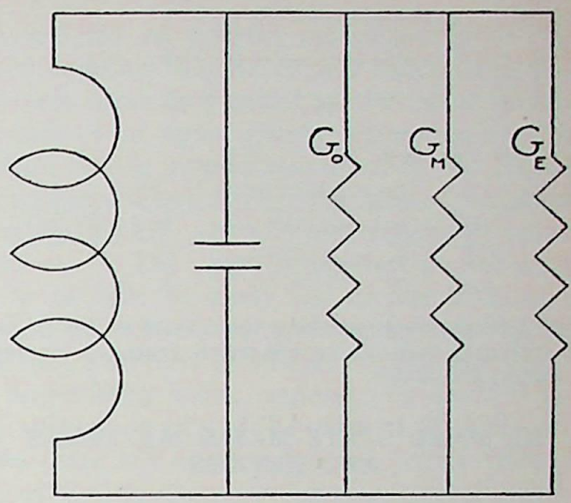

FIG. 5. Cavity equivalent circuit.

the incident voltage V_i and the reflected voltage V_r, as

$$B=\frac{|V_i|+|V_r|}{|V_i|-|V_r|}=\frac{1+g}{1-g}. \tag{25}$$

Here g is the "voltage" gain defined by $g=|V_r/V_i|$. The power gain is g^2.

After solving (25) for g^2, we obtain

$$g^2=[(1-B)/(1+B)]^2. \tag{26}$$

The maser will oscillate if $-Q_m^{-1}>Q_o^{-1}+Q_e^{-1}$, and will amplify if $Q_o^{-1}+Q_e^{-1}>-Q_m^{-1}>Q_o^{-1}$. Let us consider some characteristics of an amplifier.

From transmission line theory, the voltage standing wave ratio B (at resonance), in terms of the conductances shown in Fig. 5, is

$$B=(G_m+G_o)/G_e=Q_e[Q_o^{-1}+Q_m^{-1}]. \tag{27}$$

This assumes that the input transmission line is matched to a conductance (G_m+G_o).

Use of (26) gives for the power gain,

$$g^2=\left[\frac{Q_e^{-1}-(Q_o^{-1}+Q_m^{-1})}{Q_e^{-1}+(Q_o^{-1}+Q_m^{-1})}\right]^2. \tag{28}$$

In terms of the loaded Q this takes the form

$$g^2=[2Q_lQ_e^{-1}-1]^2. \tag{29}$$

The band width is obtained by dividing the operating frequency by the loaded Q. For a low-temperature maser Q_o is so large that it may be neglected in (28). The product of the square root of power gain and band width is

$$g\Delta\nu=\frac{\nu[Q_e+|Q_m|]}{Q_e|Q_m|}. \tag{30}$$

For a high-gain device it is customary to adjust Q_e so that it equals the magnitude Q_m. Under these conditions (30) is approximately a constant, given by

$$g\Delta\nu\approx 2\nu/|Q_m|. \tag{31}$$

[8] Microwave circulators are not available below about 1400 mc/sec. Autler has proposed an ingenious arrangement [Lincoln Laboratory, MIT, Rept. M 37-27; Proc. Inst. Radio. Engrs. 46, 1880 (1958)] using two masers in a "balanced" arrangement, which does not require use of a circulator. The two masers are at opposite ends of a coaxial or wave-guide "magic" tee. One of the maser arms is a quarter wavelength longer than the other. The antenna and receiver are connected to the other two arms. Thus the two maser outputs combine at the load. Noise from the load is amplified by the masers but is then radiated back out through the antenna.

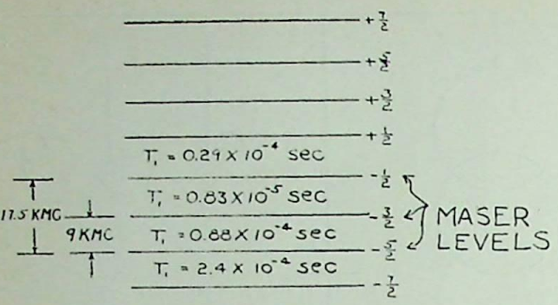

FIG. 6. Energy levels of the ground state of Gd^{+++} in ethyl sulfate, including spin-lattice relaxation times, as employed by Scovil, Feher, and Seidel.

III. SOLID STATE MASER MATERIALS AND DEVICES

The materials which have so far been successfully employed in three-level masers are[9,10] gadolinium ethyl sulfate, potassium chromicyanide,[11,12] and ruby.[7] We use the roman type g for the magnitude of the Zeeman tensor. This should not be confused with the italic g used for voltage gain.

Gadolinium ethyl sulfate was used in the first successful solid state maser.[10] The gadolinium ion is in an ^8S ground state having 7 electrons in a half-filled $4f$ shell. There is fine structure splitting into 7 lines with spacing which varies approximately as $3\cos^2\theta - 1$, where θ is the angle between the constant magnetic field, H_o, and the crystalline field axis. If the steady magnetic field is normal to the crystalline symmetry axis, the spin Hamiltonian may be written[11] approximately as

$$\mathcal{H} = g\beta_m H_o \cdot S_z - \tfrac{1}{2}D[S_z^2 - \tfrac{1}{3}S(S+1)] + \tfrac{1}{2}D[S_x^2 - S_y^2], \quad (32)$$

where β_m is the Bohr magneton, S is the spin operator, $g = 1.99$, $D = .02$ cm^{-1}, and the axis of quantization is parallel to that of the constant magnetic field, H_o. The first term of (32) represents the interaction with the field H_o which brings the transition to the required frequency. The second term makes the level spacings unequal, and the third term mixes the states, giving rise to transitions with $\Delta S_z = \pm 2$. The angle between H_o and the microwave magnetic field should be zero for the $\Delta S_z = \pm 2$ transitions and 90° for the $\Delta S_z = \pm 1$ transitions. Scovil, Feher, and Seidel used an angle of 45°. The energy levels and relaxation times of the ground state of Gd^{+++} in ethyl sulfate are shown in Fig. 6. Because the energy level separations are almost equal,

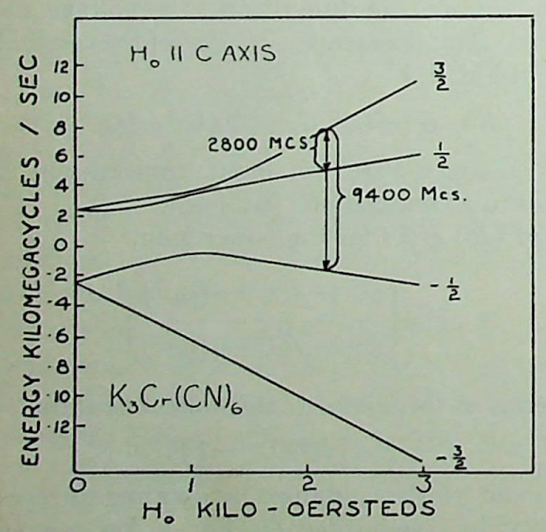

FIG. 7. Energy levels of $K_3Cr(CN)_6$ in $K_3Co(CN)_6$ *vs* applied magnetic field, for $H_o \parallel$ to the c axis.

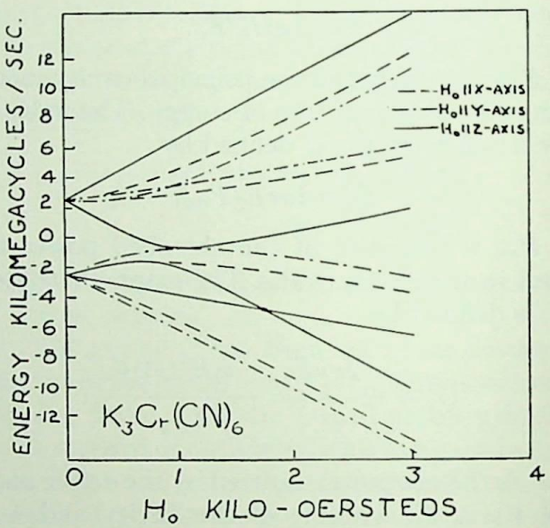

FIG. 8. Energy levels of $K_3Cr(CN)_6$ in $K_3Co(CN)_6$ *vs* applied magnetic field for H_o parallel to x, y, and z axes.

expression (13) requires that the spin-lattice relaxation times w_{21}^{-1} and w_{32}^{-1} be very unequal. A value for w_{32} ten times that of w_{21} is accomplished by introduction of cerium[9] into the crystal. An optimum value of NT_2 was obtained by employing a 90-mg (8% of the resonant cavity effective volume was filled) lanthanum ethyl sulfate crystal containing 0.5% Gd^{+++} and 0.2% Ce^{+++}. The device was operated at 1.2°K with a saturation frequency of 17.5 kmc/sec. Oscillations were obtained at 9 kmc/sec.

The second material to be successfully used[12] in a solid state maser was potassium chromicyanide diluted in a cobalticyanide crystal [$K_3Co(CN)_6$]. In this case 0.5% Cr was used as the paramagnetic salt. This material appears to have the long spin-lattice relaxation time of 0.2 sec, at 1.25°K. The paramagnetic resonance spectrum of $K_3Cr(CN)_6$ arises from two differently oriented complexes per unit cell. The spin Hamiltonian is

$$\mathcal{H} = \beta_m \mathbf{H} \cdot \mathbf{g} \cdot \mathbf{S} + D[S_z^2 - \tfrac{1}{3}S(S+1)] + E[S_x^2 - S_y^2]. \quad (33)$$

For cobalt as the diluent $D=0.083$ cm^{-1}, $E=0.011$ cm^{-1}, and the Zeeman tensor $\mathbf{g}$ is approximately isotropic and equal to 1.99. The direction cosines between the magnetic axes (x, y, and z) and the pseudo-orthorhombic crystalline axes (a, b, and c) are

	x	y	z
a	0.104	0	0.994
b	$\pm$0.994	0	$\mp$0.104
c	0	1	0

Energy level diagrams computed by McWhorter and Meyer are shown in Figs. 7 and 8. They used a dual mode coaxial cavity one half wavelength long at 2800 mc/sec operating in the TEM mode. For pumping, the cavity operated in the TE_{113} mode. The constant magnetic field H_o was applied, approximately parallel to the crystalline c axis, with operating conditions shown in Fig. 7. The upper two levels, labeled $+\frac{3}{2}$ and $+\frac{1}{2}$ were used for amplification and the second and fourth levels

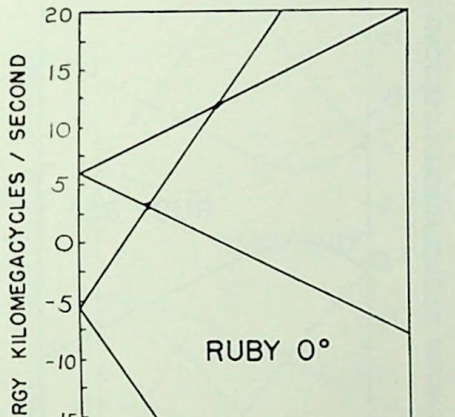

FIG. 9. Energy levels of Cr^{+++} in ruby *vs* applied magnetic field for H_o parallel to c axis of the crystal.

(labeled $+\frac{3}{2}$ and $-\frac{1}{2}$) were saturated by the rf field. Figure 7 shows that the energy level separation of the first and second levels (labeled $-\frac{3}{2}$ and $-\frac{1}{2}$) is approximately the same as that of the second and fourth levels. It has been shown[13] that for the Meyer-McWhorter arrangement (constant magnetic field parallel to the c axis and rf magnetic field parallel to the a axis) the transition probability for the first- to second-level transition is in fact 100 times greater than for the desired second and fourth levels. This is because the matrix elements are 4 times greater and the saturation radio-frequency magnetic field normal to the constant magnetic field favors the $\Delta m=1$ transitions. This implies that indirect saturation was accomplished by McWhorter and Meyer. They coupled strongly to levels 1 and 2 and succeeded in saturating levels 2 and 4 also. This possibility of indirect saturation of one pair of levels by coupling to another pair which have the same energy separation is a useful aid in maser design. The total number of spins in the upper quartet of the chromium ion is approximately 10^{19}. A 10% filling factor was used. The calculated gain-band-width product $g\Delta\nu$, was 2.6×10^6 sec^{-1}. The measured value was 1.8×10^6 sec^{-1}. The small filling factor was chosen in order to be able to study the device without undue distortion of the cavity electromagnetic mode configurations. Practical amplifiers would therefore use a much larger filling factor, approaching unity. This gives a large increase in $g\Delta\nu$, of the order of 50. This is partly because there are more spins and partly because the increased dielectric constant enables a smaller cavity to be used.

The third material to be successfully used was ruby. Paramagnetic resonance in this material was investigated in the Soviet Union in 1955 and 1956,[14] and in the United States by Geusic.[15]

Again the Cr^{+++} ion is used, but the host crystal is Al_2O_3. The four nonequivalent sites are indistinguishable since the spin is less than two, and the crystal has trigonal symmetry. Maser action in ruby was first demonstrated by Makhov, Kikuchi, Lambe, and Terhune at the University of Michigan.[7] The spin Hamiltonian for Cr^{+++} in the Al_2O_3 lattice is given by

$$\mathcal{H}=\beta_m\mathbf{S}\cdot\mathbf{g}\cdot\mathbf{H}+D[S_z^2-\tfrac{1}{3}S(S+1)]. \qquad (34)$$

$\mathbf{g}$ is the Zeeman tensor with components $g_{zz}=g_{\parallel}$, $g_{xx}=g_{yy}=g_{\perp}$. This Hamiltonian leads to the eigenvalue equation[7]

$$(\epsilon^2-1)^2-\tfrac{5}{2}x^2\epsilon^2+\tfrac{9}{16}x^4-\frac{x^2(5g_{\parallel}^2\cos^2\theta-g_{\perp}^2\sin^2\theta)}{2g^2}$$
$$+\frac{2\epsilon\lambda x^2(g_{\perp}^2\sin^2\theta-2g_{\parallel}^2\cos^2\theta)}{g^2}=0. \qquad (35)$$

Here

$$\epsilon=\frac{\text{Energy}}{|D|},\quad x=g\frac{\beta_m H}{|D|},$$

$$D=-0.1913\text{ cm}^{-1}=3.798\times10^{-17}\text{ ergs},$$

$$\lambda=\frac{D}{|D|},\quad g=1.986,\quad g^2=g_{\parallel}^2\cos^2\theta+g_{\perp}^2\sin^2\theta.$$

This equation is readily solved for the situations $\theta=0$, $\theta=\pi/2$, $g_{\perp}^2\sin^2\theta=2g_{\parallel}^2\cos^2\theta$. In the latter case, $\theta=\cos^{-1}(1/\sqrt{3})$ gives (assuming isotropic $\mathbf{g}$)

$$\epsilon(\pm\tfrac{3}{2})=\pm[1+(5/4)x^2+x(3+x^2)^{\frac{1}{2}}]^{\frac{1}{2}},$$
$$\epsilon(\pm\tfrac{1}{2})=\pm[1+(5/4)x^2-x(3+x^2)^{\frac{1}{2}}]^{\frac{1}{2}}.$$

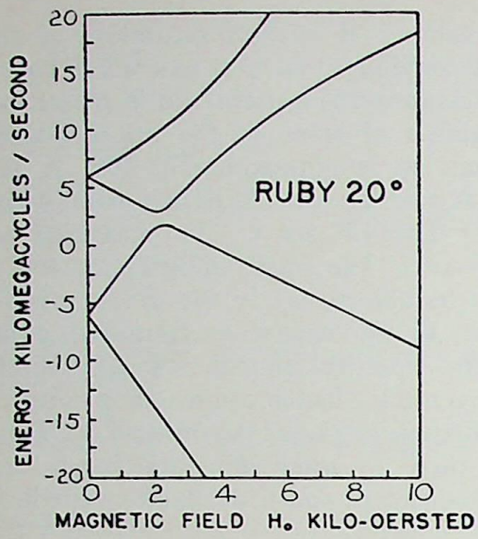

FIG. 10. Energy levels of Cr^{+++} in ruby *vs* applied magnetic field for H_o at 20° to c axis of the crystal.

Curves of energy levels as calculated with assistance of Dr. Schulz-DuBois are shown in Figs. 9–13. The four-level device using ruby has already been discussed. We are indebted to Professor Townes for the name "push-pull maser" for the four-level device of Makhov, Kikuchi, Lambe, and Terhune.‡

B. Characteristics of Some Ruby Masers

A ruby three-level maser has been developed by Alsop, Giordmaine, and Townes.[16] A large filling factor, approaching 0.9, is used. The "voltage gain" band-width product approaches 100 Mc, and the band width is approximately 5 Mc. The magnetic Q is about 400. The volume of the active material is about $\frac{1}{3}$ cm³. A rectangular cavity is used, operating in the TE_{011} mode for the signal frequency and the TE_{012} mode for the saturation microwave field. The small cavity volume results from the high dielectric constant of ruby. About 30 mw of pumping power are required. The pump power is coupled to the wave guide by a remotely gear-controlled probe, and the signal power is coupled in by means of an iris. Liquid helium cooling with helium maintained at low pressure provided a bath temperature of 1.4°K.

Morris, Kyhl, and Strandberg[17] have described the ruby maser illustrated in Fig. 14. All four levels are employed. The chromium concentration is about 0.01%. Levels 1–3 and 2–4 are saturated at 23 kMc/sec. Levels 2–3 are employed for amplification. The device is tunable over the range 8400–9700 Mc/sec, and has the new feature that cavity resonance is not needed at the saturation frequency if a saturation power of 100 mw is employed. The fringing fields near the coupling hole allow enough coupling to saturate the crystal at 23 kMc/sec.

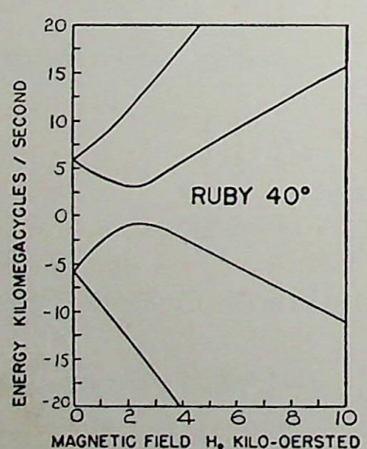

FIG. 11. Energy levels of Cr^{+++} in ruby *vs* applied magnetic field for H_o making an angle of 40° with the c axis of the crystal.

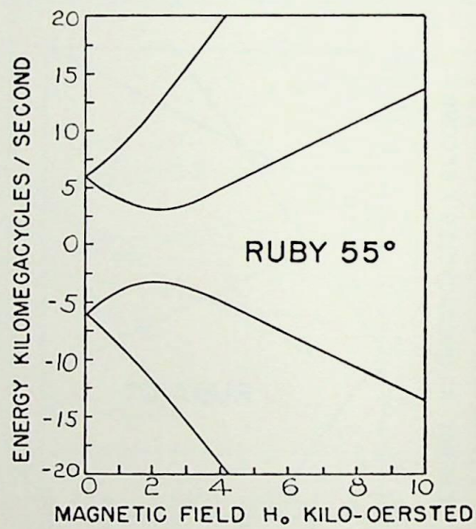

FIG. 12. Energy levels of Cr^{+++} in ruby *vs* applied magnetic field for H_o making an angle of 55° with the c axis of the crystal.

Design of masers is facilitated by the extensive tables of energy levels and transition probabilities now being prepared by W. S. Chang and A. E. Siegman of the Stanford Electronics Laboratories.[18]

IV. SUMMARY OF OTHER METHODS FOR OBTAINING MASER ACTION

Bloch[19] showed, in 1946, that inversion of level populations can be obtained by "adiabatic rapid pas-

sage" through resonance. We have again a system of spins in a "constant" magnetic field H_o. If a microwave magnetic field is applied at right angles to the "constant" magnetic field the spin system will precess about H_o. Suppose that H_o is smaller than the value required for resonance at the microwave angular frequency ω. If H_o is steady for a long time, and is then suddenly increased through resonance and beyond, the spin system is turned over. The magnetization vector will be antiparallel to H_o until equilibrium is restored by the spin-lattice relaxation mechanism. The passage through resonance must be adiabatic, but rapid enough so that the sweep occurs in a time short compared with the spin-lattice relaxation time. While the magnetization is antiparallel to the field there are more moments antiparallel than parallel. This means more particles in excited states than in the ground state. Such a system will therefore amplify.

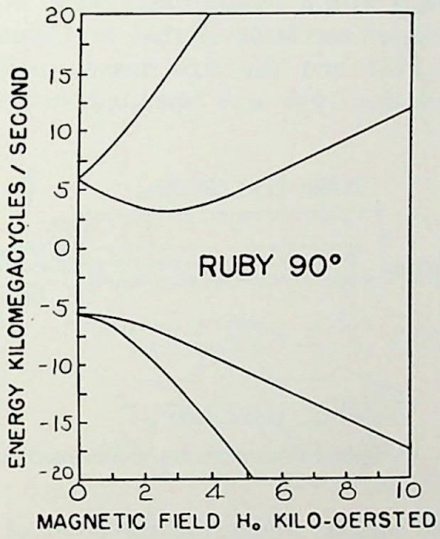

FIG. 13. Energy levels of Cr^{+++} in ruby *vs* applied magnetic field for H_o making an angle of 90° with the c axis of the crystal.

We assume the magnetic field H_o to be in the z direction. It is simpler to discuss the case where a circularly polarized rf field is applied, with its magnetic field in the x–y plane. The rf field is given by

$$H_x = H_1 \cos\omega t, \quad H_y = \mp H_1 \sin\omega t. \tag{36}$$

The $-$ sign refers to a positive gyromagnetic ratio and the $+$ sign to a negative one. The magnetization vector then satisfies the following equations.

$$\dot{M}_x - \gamma(M_y H_z - M_z H_y) + (M_x/T_2) = 0, \tag{37}$$

$$\dot{M}_y - \gamma(M_z H_x - M_x H_z) + (M_y/T_2) = 0, \tag{38}$$

$$\dot{M}_z - \gamma(M_x H_y - M_y H_x) + (M_z/T_1) = M_o/T_1. \tag{39}$$

γ is the gyromagnetic ratio, T_1 is the longitudinal (spin-lattice) relaxation time, T_2 is the transverse (spin-spin) relaxation time, and M_o is the value of the magnetization in the absence of a radio-frequency field.

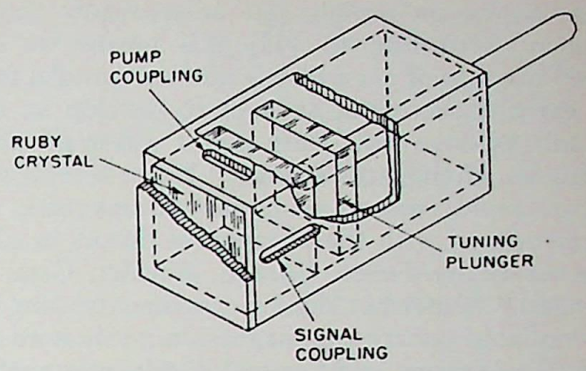

FIG. 14. Ruby maser of Morris, Kyhl, and Strandberg.

A quantity $\delta(t)$ is defined by the relation

$$\delta(t) = \frac{H_o(t) - (\omega/|\gamma|)}{H_1}. \tag{40}$$

$\delta(t)$ is zero at the resonant field $H_o = \omega/|\gamma|$. The magnetic field H_o is assumed to vary at a slow enough rate so that

$$|d\delta/dt| \ll |\gamma H_1|. \tag{41}$$

This is a statement of the adiabatic criterion. Subject to this condition Bloch gives the following solution of (37), (38), and (39):

$$M_x = \frac{M\cos\omega t}{(1+\delta^2)^{\frac{1}{2}}}, \tag{42}$$

$$M_y = \mp\frac{M\sin\omega t}{(1+\delta^2)^{\frac{1}{2}}}, \tag{43}$$

$$M_z = M\delta/(1+\delta^2)^{\frac{1}{2}}, \tag{44}$$

$$M(t) = \frac{1}{T_1}\int_{-\infty}^{t} \frac{\delta(t')e^{-[\theta(t)-\theta(t')]}M_o(t')}{[1+\delta^2(t')]^{\frac{1}{2}}}dt', \tag{45}$$

$$\theta(t) - \theta(t') = \frac{1}{T_1}\int_{t'}^{t}\left[\frac{\delta^2(t'') + (T_1/T_2)}{1+\delta^2(t'')}\right]dt''. \tag{46}$$

In order to discuss adiabatic rapid passage we assume that $\delta^2(t'')$ has been constant for a long time and then at time t_o is quickly increased through resonance, without violating (41). We have, for $\delta^2 \gg T_1/T_2$,

$$\theta(t) - \theta(t') = (t-t')/T_1. \tag{47}$$

The part of (45) resulting from the rapid change of δ is negligible. For the rest, since δ is large we have, from (45)

$$M(t) = \pm M(t_o). \tag{48}$$

Here the $+$ sign refers to the situation where δ was positive up to t_o (H_o larger than the resonant value, initially), and the $-$ sign refers to the situation where δ was negative up to t_o (H_o smaller than the resonant value, initially, then increased through resonance). Thus the sign of $M(t)$ does not change, but the sign of δ

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

changes as we go rapidly but adiabatically through resonance. According to (44) this means we have changed the sign of M_z which is now antiparallel to H_o.

An early unsuccessful attempt to develop an adiabatic fast passage solid-state maser was reported by Combrisson, Honig, and Townes.[20] Maser action due to adiabatic rapid passage using the paramagnetic electrons associated with the phosphorus donors in silicon was observed by Feher, Gordon, Buehler, Gere, and Thurmond.[21] Somewhat similar experiments using neutron irradiated quartz and magnesium oxide were done by Chester, Wagner, and Castle.[22] With a quartz sample containing $\sim 10^{18}$ spins the inverted state persisted for 2 msec at 4.2°K. A value of 5×10^6 sec^{-1} was obtained for the "voltage" gain-band-width product for gains between 8 and 21 db. This work was done at 9 kMc/sec with microwave powers for inversion of about 0.5 w, in 50–100 μsec pulses. A modulation structure of the pulsed power emitted from the cavity as the magnetic field is swept through resonance is observed. Senitzky[23] has suggested that this amplitude modulation of the power from the resonant cavity is due to the periodic transfer of energy between the cavity electromagnetic field and the spin system.

Purcell and Pound[24] were able to obtain inverted level populations in a magnetic resonance experiment using a single crystal of LiF which had a very long relaxation time. They removed their crystal from the strong field and inverted its spin system by means of other rapidly varying magnetic fields. When the crystal was reinserted in the strong field they were able to observe the return of the magnetization to its equilibrium value, from its "negative-temperature" state.

Weber studied the following method[1] in 1951. Consider a symmetric top molecule in an externally applied electrostatic field. The Stark effect has linear and quadratic terms. The linear effect is the dominant one if the field is not too strong. The energy levels are given by the formula

$$E_{JKM_j}^{(1)}=\frac{-\boldsymbol{\mu}\cdot\mathbf{E}KM_j}{J(J+1)}. \tag{49}$$

$\boldsymbol{\mu}$ is the electric dipole moment, $\mathbf{E}$ is the Stark field, J, K, and M_j are the quantum numbers associated with the symmetrical top. If the electrostatic (Stark) field is applied normal to the microwave electric field the $\Delta M=\pm 1$ transition will be allowed, and the frequency for such a transition will be

$$\nu=\boldsymbol{\mu}\cdot\mathbf{E}K/J(J+1)h. \tag{50}$$

If the gas is in equilibrium it will absorb microwaves at this frequency. There are more electric dipole moments parallel to the field than antiparallel to it. If the electrostatic field is suddenly reversed we have a negative temperature, and more dipole moments antiparallel than parallel to the field, and the device will amplify during roughly one relaxation time. A pulsed oscillator may be constructed as shown in Fig. 15. Here we have a resonant cavity with Stark electrode. If a square wave is applied there will be a microwave pulse emitted each time the field reverses and the TE_{10} mode (microwave electric field *parallel* to the Stark electrode) will be excited.

No experiments of this type were done because calculations showed that it would be difficult to achieve a useful gain-band width product in any gas-type maser amplifier, and the use of a solid was suggested.

A maser oscillator using a gas is, however, a very useful frequency standard, and compares favorably in many respects with a cesium beam clock. Work on an ammonia maser oscillator started at Columbia University in 1951 and the first maser oscillator and amplifier of this type was operated successfully by

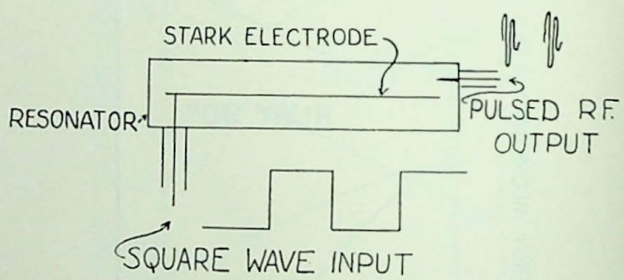

FIG. 15. Pulsed symmetric top maser oscillator.

Gordon and Zeiger[2] under the direction of Professor C. H. Townes in 1954. Similar work was done independently[3] by Basov and Prokhorov at the Lebedev Institute at about the same time. In addition to providing an exceptionally stable oscillator, the ammonia maser can also be employed as a very high resolution spectrometer. A sketch of the focuser and beam and cavity details is given in Fig. 16. The maser action is accomplished in the following way. The nitrogen atom in ammonia is in a potential which is symmetric on either side of the plane of the hydrogen atoms. In this kind of potential each harmonic oscillator level is split, and the ground state splitting provides microwave absorption lines of different frequencies for different rotational levels. In a Stark field the energy of the upper doublet level increases and that of the lower level decreases. The focuser of Fig. 16, provides an electric field with intensity approximately proportional to the displacement from the axis. If a molecular beam is now sent through the focuser the molecules in the lower doublet state drift outward to regions of lower energy and increasing field, and are removed. The center of the beam contains mostly higher energy particles. These

enter the resonant cavity and undergo stimulated emission. In this case, then, a higher population in excited states is achieved by the simple expedient of removing ground state particles from the beam.

The condition for sustained oscillation of a resonant cavity with volume V which contains n excited atoms or molecules may be obtained by setting the emitted power equal to the power lost in the cavity walls.

$$nW_{21}h\nu \geq P_w.$$

W_{21} is the transition probability. We write W_{21} in terms of the appropriate squared matrix elements $|\mu|^2$ and the line width $\Delta\nu$, and P_w in terms of the quality factor Q to obtain (Gordon, Zeiger, and Townes, see reference 2)

$$n \gtrsim hV\Delta\nu/4\pi|\mu|^2Q.$$

The frequency range over which appreciable energy is distributed in a maser oscillator is given in terms of the

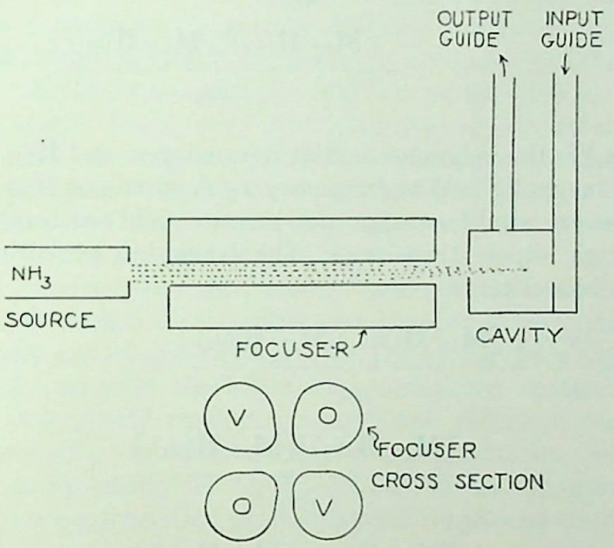

FIG. 16. Columbia ammonia maser.

total power output P, Boltzmann's constant, and the cavity wall temperature T as

$$\delta\nu = 4\pi kT(\Delta\nu)^2/P.$$

An upper state population ten times that of the lower state may be achieved in practice. The power output is approximately 10^{-9} w. An ammonia maser oscillator has been reported to have frequency stability over periods of one hour of the order of 1 part in 10^{10}. The stability is associated with the low noise property.

Another method of achieving inverted level populations in ammonia gas has been proposed by Dicke.[25] This uses a "hot grid" cell and again the quadratic Stark effect. A maser using this method of population inversion is being constructed by Dr. J. P. Wittke at RCA Laboratories.

Level population inversion can also be achieved by means of intense pulses of microwaves. For simplicity,

[25] J. P. Wittke, Proc. Inst. Radio Engrs. 45, 291 (1957).

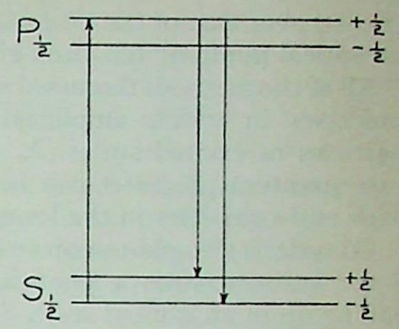

FIG. 17. Optical pumping.

consider, a two-level system with "permanent" electric dipole moment μ, driven at resonance[26] by a microwave field $E=E_o\sin(\omega t-\delta)$. The Hamiltonian is

$$\mathcal{H}=\mathcal{H}_o+\mathfrak{u}\cdot\mathbf{E}_o\sin(\omega t-\delta). \quad (51)$$

Let the wave functions with $E_o=0$ be ψ_1 and ψ_2.

If we use this in the time-dependent Schroedinger equation and neglect sum frequency terms, an exact solution of the resulting equations gives for the wave function,

$$\Psi=\left[\cos\left(\frac{|\mathfrak{u}_{12}\cdot\mathbf{E}_o|t}{2\hbar}\right)\right]\psi_1 e^{-i(E_1t/\hbar)} + \left[\sin\left(\frac{|\mathfrak{u}_{12}\cdot\mathbf{E}_o|t}{2\hbar}\right)\right]\psi_2 e^{-iE_2t/\hbar}. \quad (52)$$

Here $\mathfrak{u}_{12}$ is the dipole matrix element connecting the states 1 and 2. From this it follows that if the system is in the state ψ_1 at $t=0$, then at $t=(\pi\hbar)/(|\mathfrak{u}_{12}\cdot\mathbf{E}_o|$, the microwave pulse has driven the system into state 2. This treatment is valid only for times short compared with the relaxation time since the effect of collisions is ignored.

Thus if we have thermal equilibrium at $t=0$ and apply a strong rf pulse of the correct length we can obtain inversion of level populations. This effect has been demonstrated by Dicke and Romer,[26] and by Kyhl, Standberg, Collins, and Park.[27]

The methods of optical pumping can also be employed[28] to achieve maser action. In Fig. 17 we have a system with a $^2S_{\frac{1}{2}}$ ground state and a $^2P_{\frac{1}{2}}$ excited state, in a magnetic field. In equilibrium almost all of the particles will be in the split S state. The $m=-\frac{1}{2}S$ state will have slightly more particles in it than the $m=+\frac{1}{2}$ state. Right circularly polarized optical resonance radiation will induce transitions with the selection rule $\Delta m=+1$. The excited particles can now spontaneously emit, either with $\Delta m=-1$, or 0. However this process only removes particles from the $m=-\frac{1}{2}S$ state and returns them to *both* the $m=-\frac{1}{2}$ and $m=+\frac{1}{2}$ states. Therefore the population of the $^2S_{+\frac{1}{2}}$ state will be in-

creased over that of the $^2S_{-\frac{1}{2}}$ state. A review of the work on optical pumping has been given by Kastler.[29]

All of the methods discussed so far use single quantum processes in which amplification results from more particles in excited states. A. Javan[30] has shown that two quantum processes can be used for amplification, with more particles in the lower state (Fig. 18).

Consider a two photon process in which a particle in a lower state absorbs a photon, then emits a photon, ending up in an excited state. Suppose the frequency of absorption corresponds to that of an intense (pump) oscillator and the emission is stimulated by a signal which it is desired to amplify. In this case we are obtaining emission in a particle transition from a state of lower energy to a state of higher energy. If all particles are in the ground state, amplification will result. Let the transition probability be W_{12} and let n_1 particles be in the ground state. The emitted power is $W_{12}n_1h\nu$. If the excited state has n_2 particles the reverse process may occur in which a photon of amplification frequency ν is absorbed and a pump frequency photon is emitted. The net power emitted will be $W_{12}h\nu(n_1-n_2)$, which is positive at positive temperatures.

For a *one* quantum process W_{12} may be written as

$$W_{12}=4\pi^2\tau|H_{12}'|^2/h^2. \tag{53}$$

Here τ is the relaxation time and H' is the interaction matrix element. For a two quantum process H' is replaced by

$$\sum_i H_{1i}'H_{i2}'/(E_1-E_i). \tag{54}$$

The summation is over all intermediate states of the particle and the quantized electromagnetic field. In Raman spectroscopy the intermediate states are usually quantum states which are different from the initial and final states, because the diagonal interaction matrix elements ordinarily vanish. If the diagonal matrix elements do not vanish in either the initial or final state, no intermediate state is necessary. For example we may have a diagonal magnetic dipole matrix element in a product of the following type

$$\langle-\tfrac{1}{2},N_1,N_2|H'|-\tfrac{1}{2},N_1+1,N_2\rangle \times\langle-\tfrac{1}{2},N_1+1,N_2|H'|N_2-1,N_1+1,+\tfrac{1}{2}\rangle. \tag{55}$$

Here we use the nomenclature of quantum electrodynamics. The first bracket involves a matrix element between states in which the particle spin is $-\frac{1}{2}$, and the electromagnetic field oscillators of frequency ν_1 and ν_2 have N_1 and N_2 quanta, respectively, to a state with particle spin unchanged, N_1+1 quanta for the oscillator with frequency ν_1, and N_2 quanta for the oscillator with frequency ν_2. The second bracket then involves a final state in which the spin becomes $+\frac{1}{2}$ and the field oscillator of frequency ν_2 has lost a quantum. Three additional matrix elements, similar to (55) may be written. One of these corresponds to an intermediate state of the particle the same as the initial state but an absorption first of frequency ν_2 followed by emission of frequency ν_1. The other two matrix elements involve an intermediate state of the particle which is the same as the final state, with both possibilities for the order of absorption and emission. Some of these matrix elements may be small in comparison with the others, depending on circumstances of the experimental arrangement. The summation (54) may be written in terms of the (magnetic) dipole matrix elements M_{11} and M_{12} as

$$-\frac{[\mathbf{M}_{11}\cdot\mathbf{H}(\nu_1)][\mathbf{M}_{12}\cdot\mathbf{H}(\nu_2)]}{h\nu_1} +\frac{[\mathbf{M}_{12}\cdot\mathbf{H}(\nu_2)][\mathbf{M}_{22}\cdot\mathbf{H}(\nu_1)]}{h\nu_1} +\frac{[\mathbf{M}_{11}\cdot\mathbf{H}(\nu_2)][\mathbf{M}_{12}\cdot\mathbf{H}(\nu_1)]}{h\nu_2} -\frac{[\mathbf{M}_{12}\cdot\mathbf{H}(\nu_1)][\mathbf{M}_{22}\cdot\mathbf{H}(\nu_2)]}{h\nu_2}. \tag{56}$$

$\mathbf{H}(\nu_1)$ is the magnetic field at frequency ν_1 and $\mathbf{H}(\nu_2)$ is the magnetic field at frequency ν_2. A corresponding expression would contain the electric field vectors for electric dipole transitions. The transition probability can be written as

$$W=\frac{4\pi^2\tau}{h^2}\left|-\frac{[\mathbf{M}_{11}\cdot\mathbf{H}(\nu_1)][\mathbf{M}_{12}\cdot\mathbf{H}(\nu_2)]}{h\nu_1} +\frac{[\mathbf{M}_{12}\cdot\mathbf{H}(\nu_2)][\mathbf{M}_{22}\cdot\mathbf{H}(\nu_1)]}{h\nu_1} +\frac{[\mathbf{M}_{11}\cdot\mathbf{H}(\nu_2)][\mathbf{M}_{12}\cdot\mathbf{H}(\nu_1)]}{h\nu_2} -\frac{[\mathbf{M}_{12}\cdot\mathbf{H}(\nu_1)][\mathbf{M}_{22}\cdot\mathbf{H}(\nu_2)]}{h\nu_2}\right|^2. \tag{57}$$

The net power emitted by a two-level system which has n_1 particles in the lower state and n_2 particles in the upper state may then be written as

$$P=\frac{4\pi^2(n_1-n_2)\tau\nu_1}{h}\left|-\frac{[\mathbf{M}_{11}\cdot\mathbf{H}(\nu_1)][\mathbf{M}_{12}\cdot\mathbf{H}(\nu_2)]}{h\nu_1} +\frac{[\mathbf{M}_{12}\cdot\mathbf{H}(\nu_2)][\mathbf{M}_{22}\cdot\mathbf{H}(\nu_1)]}{h\nu_1} +\frac{[\mathbf{M}_{11}\cdot\mathbf{H}(\nu_2)][\mathbf{M}_{12}\cdot\mathbf{H}(\nu_1)]}{h\nu_2} -\frac{[\mathbf{M}_{12}\cdot\mathbf{H}(\nu_1)][\mathbf{M}_{22}\cdot\mathbf{H}(\nu_2)]}{h\nu_2}\right|^2. \tag{58}$$

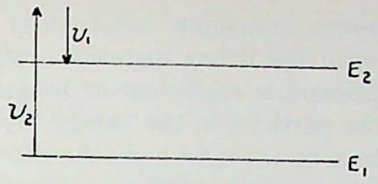

FIG. 18. Raman maser.

V. NOISE PERFORMANCE

Prior to 1950, methods had been developed for generation, amplification, and detection of signals in the electromagnetic spectrum from zero frequency to the mm wave region. At frequencies below 10 mc/sec the noise performance is already better than is ordinarily required for communications in the presence of atmospheric and other external noise. Indeed, a well designed vacuum tube amplifier in the vicinity of 1 mc/sec is capable of noise performance corresponding to an internal temperature of about 25°K. Microwave amplifiers, on the other hand, did not have good low-noise performance, mainly because of electron stream fluctuations originating at a hot cathode. Inasmuch as this type of noise must be absent in a maser, it was suggested that molecular beam maser type amplifiers would have very little noise.[31] It was very gratifying that the important sources of low-temperature solid state maser noise which were understood in 1956, are sufficiently small to make possible sensitivities which may approach detection of single microwave photons.

We consider first the inherent spontaneous emission noise of a maser, disregarding circuit noise, at spin temperature approaching minus 0°K. The earlier discussion did not consider the effect of spontaneous emission. This is a purely random process[32] and therefore contributes noise. In an ensemble of charged particles, each having two energy levels, those which are in the upper state have a transition probability for transitions to the lower state of the form

$$W_{21}=f(\nu,\mu^2\cdots)[N+1], \tag{59}$$

in consequence of the interaction with the electromagnetic field.§

Here f is a function of frequency and squared matrix elements and N is the number of quanta per radiation oscillator. The one which adds to N gives the effect of spontaneous emission. Let us calculate an equivalent temperature for spontaneous emission. In thermal equilibrium at temperature T, according to the Bose-Einstein statistics, N would be

$$\frac{1}{e^{h\nu/kT}-1}. \tag{60}$$

The positive temperature which black surroundings would need, to emit input noise equivalent to the spontaneous emission, will be denoted by T_E. From (59) we see that this (equivalent) T_E corresponds to an equivalent $N=1$.

Expressions (60) and (59) allow us to write

$$1=e^{h\nu/kT_E}-1, \tag{61}$$

giving

$$T_E=h\nu/k\,\ln_e 2. \tag{62}$$

Suppose we ask the question: how many microwave photons will double the randomly fluctuating output of a maser whose spin temperature approaches -0°K. Let the averaging time of the receiver be τ and let the equivalent input noise energy during this interval be U_n. This is given by the product of the Nyquist formula noise power for T_E and the averaging time τ.

$$U_n=\left[\frac{h\nu}{e^{h\nu/kT_E}-1}\right]\Delta\nu\tau. \tag{63}$$

Here $\Delta\nu$ is the band width. $\Delta\nu\tau\approx 1$. Employing expression (61) gives

$$U_n=h\nu. \tag{64}$$

The equivalent input (noise) energy over the averaging time is that of one photon. If one microwave photon is incident during this interval it will double the average noise output and therefore we are justified in saying that a maser with no circuit noise and spin temperature approaching -0°K may detect single microwave photons, and a flux of $\Delta\nu$ photons per sec, with reasonably large probability.

The foregoing analysis gives exactly what would be predicted by the Nyquist formula for *any* resistance at a temperature -0°K. The Nyquist formula noise energy (delivered to a "matched" load) over the averaging time τ is given by

$$U_n=\frac{h\nu\Delta\nu\tau}{|e^{h\nu/kT}-1|}. \tag{63a}$$

In the limit as $T\rightarrow -0°$ (63a) becomes

$$U_n=h\nu\Delta\nu\tau\approx h\nu, \tag{64a}$$

in agreement with (64). This makes it clear that the residual noise in a low-temperature maser is of the same type as discussed by Johnson and Nyquist[33] long ago.

If the spin temperature is not close to minus 0°K (64a) becomes

$$U_n=\frac{h\nu\Delta\nu\tau}{|e^{h\nu/kT_{\text{spin}}}-1|}. \tag{64b}$$

[31] The Columbia work (Gordon, Zeiger, and Townes, reference 2) showed that good noise performance could be obtained with a molecular beam maser. Spontaneous emission from the molecules was not discussed. For a room temperature device this is small compared with input noise.

[32] It has been shown [J. Weber, Phys. Rev. 94, 215 (1954)] that this type of noise is also present in conventional free electron amplifiers.

§ *Note added in proof.*—Expression (59) is given in Chapter V, *The Quantum Theory of Radiation*, by W. Heitler (Oxford University Press, London, 1954), third edition. It follows from the quantization of the Maxwell field. Each degree of freedom is like a harmonic oscillator and the $N+1$ arises from the squared harmonic oscillator matrix elements for downward transitions.

[33] J. B. Johnson, Phys. Rev. 32, 47 (1928); H. Nyquist, Phys. Rev. 32, 110 (1928).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

For the case $(h\nu)/(kT)\ll 1$, the number of photons required to double the output is therefore

$$|kT_{\text{spin}}/h\nu|. \tag{65}$$

Javan has remarked that the noise performance of a Raman type maser will be essentially the same as that of devices which employ greater populations of particles in excited states. This follows because the photon of frequency ν_1 (Fig. 18) can be spontaneously emitted in the absence of a signal, provided that intense "pump" radiation of frequency ν_2 is present.

A complete system will also have noise due to emission from circuit elements and the transmission system. A quantity which has been used to describe the performance of radio receivers is the noise figure, denoted by the symbol F. F is defined as the ratio of the total noise power output of the receiver to that part of the noise power output due to the source at the input of the receiver. An equivalent definition is that it is the quotient of the signal to noise power ratio at the input divided by the signal to noise power ratio at the output.

We now calculate the noise figure of a complete maser receiving system, considering first a traveling wave maser. Our approach is similar to that employed by Strandberg,[34] for two-level systems.[35] We consider three-level systems, taking effects of saturation[36] into account. Let $R_\nu d\nu$ be the number of modes per unit volume in a range $d\nu$ which can propagate, A be the cross-sectional area, and V_G the group velocity. The number of particles per unit volume in the states with energies E_1, E_2, and E_3 will be denoted by n_1, n_2, and n_3. Let β be the power gain per unit length. A quantity K is defined by the following relation

$$\beta = K(n_2 - n_1). \tag{66}$$

Let N be the average number of quanta per mode in the vicinity of the operating frequency ν_{21} and let p_ν be the energy per mode. The change in power as a consequence of energy exchanged in a differential length leads to

$$\begin{aligned} &V_G A R_\nu d\nu (dp_\nu/dx) \\ &\quad = V_G A R_\nu d\nu [Kn_2 h\nu(N+1) - Kn_1 h\nu N - \alpha_c N h\nu \\ &\qquad + \alpha_c p_\nu(T_c) - \alpha_{13} N h\nu + \alpha_{13} p_\nu(T_{13})]. \end{aligned} \tag{67}$$

In expression (67) $p_\nu(T_c)$ is the average energy per mode in equilibrium at the temperature of the waveguide walls T_c, and from statistical mechanics $p_\nu(T) = h\nu[e^{h\nu/kT}-1]^{-1}$, $p_\nu(T_{13})$ is the average energy per mode at the temperature T_{13} associated with particles in the energy levels with energies E_1 and E_3, α_c is the power absorption coefficient of the transmission system when the maser material is absent and $\alpha_{13}(\nu_{21})$ is the absorption coefficient at frequency ν_{21} associated with the particles in the energy levels E_1 and E_3. The first term on the right gives the effect of both stimulated and spontaneous emission in inducing transitions out of the state with energy E_2, the second term gives the absorption by particles in the ground state, the third term gives the effect of absorption by conducting walls or loss other than the active solid, the fourth term gives the emission from the walls, the fifth and sixth terms represent the effects of absorption and emission from particles undergoing transitions between the first and third states. We define the temperatures T_{12} and T_{13} by

$$n_1/n_2 = e^{h\nu_{21}/kT_{12}}, \quad n_1/n_3 = e^{h\nu_{31}/kT_{13}}. \tag{68}$$

Integrating expression (67) gives

$$(p_\nu)_{\text{out}} = (p_\nu)_{\text{in}} g^2 + \left[\frac{\beta p_\nu(T_{12}) - \alpha_c p_\nu(T_c) - \alpha_{13} p_\nu(T_{13})}{\beta - \alpha_c - \alpha_{13}}\right] \times (1-g^2). \tag{69}$$

Here g^2 is the power gain defined earlier. This tells us that the temperature of the environment of the maser enters in a subtle way, through the quantity $\alpha_c p_\nu(T_c)$. If the absorption coefficient of the environment, α_c, is small, then little noise is contributed even if T_c is not close to absolute zero. This is a consequence of Kirchhoff's law. Let the source temperature be T_s, the load temperature be T_L, and let the transmission line to the maser have a power loss factor t and a temperature T_t. Thermodynamic considerations enable us to express the output noise emission of the transmission line per cycle in terms of the input noise emission (per cycle) of the source, as

$$(p_\nu)_{\text{line}} = t p_\nu(T_s) + (1-t) p_\nu(T_t). \tag{70}$$

Expression (70) is $(p_\nu)_{\text{in}}$ for the maser.

We can now use (69), (70), and the previous definition of noise figure to write

$$\begin{aligned} F &= \frac{(p_\nu)_{\text{out}} + p_\nu(T_L)}{g^2 t p_\nu(T_s)} \\ &= 1 + \frac{1}{t p_\nu(T_s)} \left\{ (1-t) p_\nu(T_t) + (1-g^{-2}) \right. \\ &\quad \left. \times \left[\frac{\alpha_c p_\nu(T_c) + \alpha_{13} p_\nu(T_{13}) - \beta p_\nu(T_{12})}{\beta - \alpha_c - \alpha_{13}}\right] + \frac{p_\nu(T_L)}{g^2} \right\}. \end{aligned} \tag{71}$$

It was once thought that the saturation field would make a significant contribution to the noise because the temperature T_{13} associated with the (saturated) 1-3 system tends towards infinity. This is not the case; only a negligible contribution results, in the following way.[36]

[34] M. W. P. Strandberg, Phys. Rev. **106**, 617 (1957).

[35] Noise in maser type amplifiers has been discussed by Muller [Phys. Rev. **106**, 8 (1957)], Pound [Ann. Phys. **1**, 24 (1957)] and Shimoda, Takahasi, and Townes [J. Phys. Soc. Japan **12**, 686 (1957)]. The role of spontaneous emission was emphasized by R. H. Dicke at the Symposium on Amplification by Atomic and Molecular Resonance, Asbury Park, New Jersey (March 1, 1956).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

The quantity $\alpha_{13}(\nu_{21})$ may be written

$$\alpha_{13}(\nu_{21})=\frac{\chi n_1|\mu_{13}|^2}{kT_{13}}\left[\frac{\tau_{13}^{-1}}{4\pi^2(\nu_{21}-\nu_{31})^2+\tau_{13}^{-2}}\right], \quad (72)$$

where χ is a constant, and τ_{13} is the appropriate relaxation time.

β may be written in terms of χ and the 1–2 system relaxation time τ_{12}, as

$$\beta=\frac{\chi n_2|\mu_{12}|^2\tau_{12}}{|p_\nu(T_{12})|}. \quad (73)$$

The ratio of the terms involving α_{13} and β in the noise figure formula (71) is

$$\frac{\alpha_{13}p_\nu(T_{13})}{|\beta p_\nu(T_{12})|}=\frac{n_1|\mu_{13}|^2}{n_2|\mu_{12}|^2}\left[\frac{(\tau_{13}\tau_{12})^{-1}}{4\pi^2(\nu_{21}-\nu_{31})^2+\tau_{13}^{-2}}\right]. \quad (74)$$

For a typical amplifier in the microwave region, this gives a number of order 10^{-3}. Physically this is because a high-saturation temperature means a small absorption coefficient for the 1–3 system, consequently small noise emission.

In order to extend the previous results to a cavity type of maser we note that we have one mode with effective power width $(\pi/2)\Delta\nu$. $\Delta\nu$ is the band width over which the power exceeds one half of the maximum (exact resonance) power. The $\pi/2$ takes account of those parts of the response outside of the region where the power exceeds half the power at resonance. In order to calculate the noise we again employ detailed balancing on a power per cycle basis, making use of the definitions of the various Q's employed earlier. The noise power output per cycle is

$$P_{\text{noise}}=(g+1)^2\Big[lp_\nu(T_s)+(1-l)p_\nu(T_l)+\frac{Q_e}{Q_o}\Big\{p_\nu(T_c)-\frac{1}{1+\gamma}(p_\nu(T_{12})+\gamma p_\nu(T_{13}))\Big\}-\frac{g-1}{g+1}\Big(\frac{p_\nu(T_{12})+\gamma p_\nu(T_{13})}{\gamma+1}\Big)\Big]. \quad (75)$$

The noise figure is then given by

$$F=\frac{(g+1)^2}{g^2lp_\nu(T_s)}\Big[(1-l)p_\nu(T_l)+lp_\nu(T_s)+\frac{Q_e}{Q_o}\Big\{p_\nu(T_c)-\frac{1}{1+\gamma}(p_\nu(T_{12})+\gamma p_\nu(T_{13}))\Big\}-\frac{(g-1)}{(g+1)}\Big(\frac{p_\nu(T_{12})+\gamma p_\nu(T_{13})}{1+\gamma}\Big)\Big]+\frac{g^{-2}p_\nu(T_L)}{lp_\nu(T_s)}. \quad (76)$$

Here the quantity γ is defined by

$$\gamma=\frac{Q_m}{Q_{13}}=\frac{-\alpha_{13}(\nu_{21},T_{13})}{\beta}, \quad (77)$$

with Q_{13} the Q associated with energy absorption by the 1–3 system. The somewhat unusual appearance of (77) with the factor $(1+g)^2$ results from the fact that g^2 is the power gain at resonance. Different parts of the cavity response contribute noise, but with different effective gain.

The term noise temperature is often used, rather than noise figure. This may be defined in terms of the noise figure as

$$\left.\begin{aligned}&[e^{h\nu/kT_n}-1]^{-1}=(F-1)[e^{h\nu/kT_s}-1]^{-1}\\ &T_n\approx(F-1)T_s, \quad \text{for} \quad \frac{h\nu}{kT}\ll 1\end{aligned}\right\}. \quad (78)$$

Here T_n is the noise temperature, and T_s is the source temperature.

McWhorter and Arams[37] have measured the noise temperature of a complete solid state maser system and found it to be $20\pm5°$K.

The use of the concept of noise figure or noise temperature was very meaningful for the older type of microwave amplifiers. We propose a method of describing the noise performance which seems better for very quiet amplifiers. The number of photons received over the receiver averaging time which will double the noise output can be employed as a "noise number" to specify the performance of a low noise receiver. We showed earlier that the minimum noise number of a maser is one. The connection between noise number N_n and noise temperature T_n is

$$N_n=[e^{h\nu/kT_n}-1]^{-1}+[e^{h\nu/kT_s}-1]^{-1}. \quad (79)$$

VI. MICROWAVE PHOTON COUNTERS

The maser makes use of stimulated emission. If *all* of the particles were in the upper state of a two-level maser, it could amplify without absorbing any of the incident photons. However, under these conditions the noise number is one, so that at least one incident photon is necessary in order that its randomly fluctuating output be doubled over the receiver averaging time. The incidence of one photon could be interpreted as a spontaneous fluctuation. In an earlier paper[36] we remarked that a maser is a voltage amplifier, not a power amplifier, and that all voltage amplifiers have spontaneous emission noise. Detectors such as nuclear counters must absorb energy in order to operate. However, unlike a maser, the internal fluctuations of a counter or power amplifier can be made arbitrarily

small. Such a device has essentially zero output until it detects a photon. It was proposed[36] that power amplifiers and detectors be developed which employ particles initially in their ground states. Methods for doing this are now being studied here. Consider a three-level system, in which the frequency ν_{21} (Fig. 19) for transitions from the first to the second state, is in the optical region. A lamp illuminates with intense light of frequency ν_{21} which can be linearly polarized. Then transitions from state 1 to state 2 are allowed, since $\Delta m=0$. Excited particles in state 2 can spontaneously emit only linearly polarized light. We employ a detector which counts circularly polarized optical frequency photons, which can be emitted only in certain directions. In order to detect microwave photons we arrange to have them circularly polarized. Then a microwave photon can be absorbed in a transition to state 3 or 4, since $\Delta m=1$. Excited particles in states 3 or 4 can now spontaneously emit circularly polarized photons which will be counted. Thus if no microwave photons are present we have particles in states 1 and 2 and only linearly polarized photons. The device has no output. As soon as a microwave (or infrared) photon is absorbed we have a particle in state 3 or 4, and when this particle emits, we have a circularly polarized photon, which is counted. This method is similar to that which has been employed in optical pumping experiments. The transition probability for this type of third-order process can be calculated in the following way. Let the wave function for atom and electromagnetic field be $\Phi(t)$.

$$\Phi(t)=\sum a_i(t)\Psi_i.$$

The Ψ_i are unperturbed wave functions of particle and electromagnetic field. Let the ground state be denoted by the subscript M. Let $a_M=1$ at $t=0$, and $a_j=0$ for $j\neq M$, at $t=0$. Let H' be the interaction part of the Hamiltonian. We quantize the electromagnetic field, H' is then not time dependent. Our process is one involving three photons. One is absorbed from the lamp, one is absorbed from the microwave field, and one is then spontaneously emitted. The third-order probability amplitude coefficient is given by

$$a_L^{(3)}=\frac{h^{-3}H_{LK'}H_{KN'}H_{NM'}}{\nu_{NM}}\times\left[\frac{1}{\nu_{KM}}\left\{\frac{e^{i2\pi\nu_{LM}t}-1}{i\nu_{LM}}-\frac{e^{i2\pi\nu_{LK}t}-1}{i\nu_{LK}}\right\}-\frac{1}{\nu_{KN}}\left\{\frac{e^{i2\pi\nu_{LN}t}-1}{i\nu_{LN}}-\frac{e^{i2\pi\nu_{LK}t}-1}{i\nu_{LK}}\right\}\right].$$

The intermediate states are denoted by the subscripts N and K. We are interested in three photon transitions of the type in which energy is conserved or nearly conserved in all three steps. The subscript N refers to the state in which a particular oscillator excited by the lamp has lost one photon. The subscript K refers to the state in which a particular microwave field oscillator has lost a photon. In order to calculate the probability that the particle has returned to the ground state with emission of a circularly polarized photon we must square the probability amplitude and integrate over all lamp photons, microwave photons, and emitted circularly polarized photons. We denote by $\rho(N)$, $\rho(K)$, and $\rho(L)$ the density of intermediate and final states. The transition probability is then

$$W=\frac{1}{h^6t}\int\left|\frac{H_{LK'}H_{KN'}H_{NM'}}{\nu_{NM}}\right|^2\times\left[\frac{1}{\nu_{KM}}\left\{\frac{e^{i2\pi\nu_{LM}t}-1}{\nu_{LM}}-\frac{e^{i2\pi\nu_{LK}t}-1}{\nu_{LK}}\right\}-\frac{1}{\nu_{KN}}\left\{\frac{e^{i2\pi\nu_{LN}t}-1}{\nu_{KN}}-\frac{e^{i2\pi\nu_{LK}t}-1}{\nu_{LK}}\right\}\right]^2\times\rho(E_L)\rho(E_K)\rho(E_N)dE_LdE_KdE_N.$$

We need to evaluate this expression, under conditions such that energy is conserved or nearly conserved in all steps. All denominators may vanish. An approximate solution can be obtained in the following way. When integrating over dE_N, we are integrating over all lamp photons which can be absorbed. Let the lamp have intensity which is zero except for a range $\Delta\nu_1$ on each side of that required for resonance. Let the lamp intensity be assumed constant over the range $2\Delta\nu_1$. A study of the integrand shows that it is not singular in the range where all denominators vanish. The integral over E_N is along the real frequency axis from $-\Delta\nu_1$ to $+\Delta\nu_1$. We can equally well integrate along a semicircle in the lower half complex frequency plane from $-\Delta\nu_1$ on the real axis to $+\Delta\nu_1$ on the real axis. The second pair of terms which have the factor $1/(\nu_{KN})$ may then be neglected in comparison with the pair of terms which have the factor $1/(\nu_{KM})$. This integration along the semicircle is now readily performed. The integration over E_K can be performed in the same way if the relaxation time for interaction with other particles is much smaller than the spontaneous emission lifetime. This leaves one integration which may then be handled in the same way as for one photon processes. The result

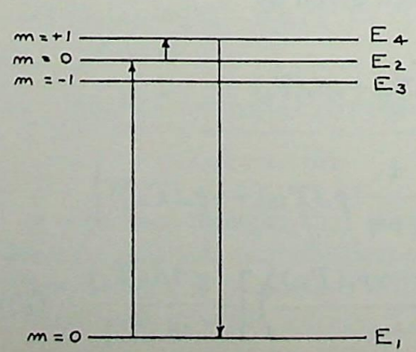

FIG. 19. Energy levels for quantum mechanical amplifier without spontaneous emission noise.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

then gives the transition probability

$$W=\frac{16\pi^2\rho(E_N)\rho(E_K)\rho(E_L)|H_{LK}'H_{KN}'H_{NM}'|^2}{h^3\Delta\nu_{NM}\Delta\nu_{KM}}.$$

All quantities are evaluated at resonance. This predicts modified absorption (or emission) at one frequency due to intense radiation at a different frequency, for single particles. $\rho(N)$ is calculated from the average number of field oscillators excited by the lamp. It is reasonable to suppose that each lamp excited field oscillator is unlikely to have more than one photon. The remaining quantities require, for calculation, a detailed knowledge of the transitions and the experimental arrangements. The excited states of the rare earth salts may be suitable for such counters and are now being investigated by Mr. U. E. Hochuli.

At a meeting held at the National Academy of Sciences in April, 1958, Bloembergen independently proposed a microwave (or infrared) photon counter which operates on similar principles (Fig. 20).

Consider a solid with at least three low-lying levels and one or more optical levels. The solid, such as a salt of the rare earth elements, is cooled to such a low temperature that only the ground state is occupied. $kT\ll E_2-E_1$. Strong optical illumination takes place at the frequency $h^{-1}(E_4-E_2)$. This light is normally not absorbed because the level E_2 is empty, unless it is excited by an incident quantum E_2-E_1. Then the system gets raised to level E_4. The spontaneous emission from level E_4 to E_3 can be detected by a photomultiplier tube. Again, discrimination from the strong incident background can be made by directional, frequency, or polarization filters.

VII. MASERS AT LOW FREQUENCIES AND IN THE INFRARED

There has not been a great deal of motivation for development of masers at low frequencies. The theory previously given would appear to be applicable. Nuclear spin energy levels and the levels associated with nuclear quadrupole spectra are available in this part of the spectrum. The small nuclear moment gives a weaker interaction with radiation, but this tends to be compensated by longer transverse relaxation times. As noted by Braunstein[38] a nucleus of spin $I>2$ which possesses an electric quadrupole moment will yield at least three unequally spaced levels in a crystal of lower than cubic symmetry. If the crystalline field has large deviations from axial symmetry the $\Delta m=2$ transitions (necessary for saturation) begin to have significantly large transition probabilities.

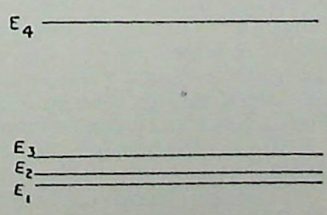

FIG. 20. Energy levels for quantum mechanical amplifier without spontaneous emission noise.

Allais[39] obtained maser action in nuclear resonance experiments in the megacycle region. This followed the work of Abragam, Combrisson, and Solomon[39] in the kilocycle region.

In the infrared and optical parts of the spectrum the sensitivity of a maser will be expected to be less than that of photon counting devices. At 8000 A the spontaneous emission equivalent temperature is 18 000°K. Achievement of coherent amplification would be desirable. This is a useful concept only when large numbers of photons are involved so that the phase can be well defined.[40] The availability of highly monochromatic sources would extend the resolution of spectroscopy in these regions. One problem is to provide a device at infrared and optical frequencies which has the energy storage capacity ordinarily provided by an electromagnetic cavity resonator, with wide mode separations. Dicke has proposed[41] a number of arrangements which employ a standing wave system between parallel planes. Similar proposals have been made by Schawlow and Townes.[42] They suggest that a multimode cavity could be employed. Single modes might be selected by reducing the cavity to partially transparent end plates, with open sides. The great directivity associated with diffraction from sources which are many wavelengths on a side may make it possible to select particular modes and suppress unwanted ones. They carry out calculations for a system using potassium vapor.

VIII. PARAMETRIC AMPLIFIERS

During the past few years another type of microwave amplifier has been developed, which has promise of low noise performance approaching that of a maser. We describe it in classical terms because nothing seems to be gained by a quantum mechanical description. In Fig. 21 two oscillators are coupled by a time-dependent capacitor. Let the natural frequencies of the oscillators be ν_1 and ν_2, and let the capacity C_3 have the time dependence

$$C_3=C_o+C_t\sin[2\pi(\nu_1+\nu_2)t].$$

It has been known since at least the time of Lord Rayleigh that two harmonic oscillators with natural frequencies ν_1 and ν_2, with this kind of time-dependent coupling may be unstable.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

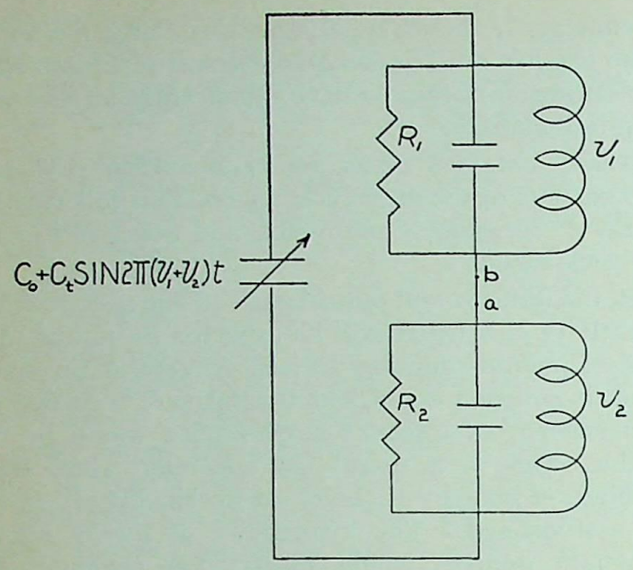

FIG. 21. Parametric amplifier.

Consider first a capacity alone with

$$C=C_t \sin[2\pi(\nu_1+\nu_2)t]$$

driven by a voltage $V=V_1 \sin(2\pi\nu_1 t)+V_2 \sin(2\pi\nu_2 t)$. The principal part[43] of the current is

$$i=-\pi\nu_1 C_t V_2 \sin(2\pi\nu_1 t)-\pi\nu_2 C_t V_1 \sin(2\pi\nu_2 t).$$

If, in the circuit of Fig. 21, a voltage $V_G \sin 2\pi\nu_1 t$ is applied between terminals a and b, the output voltage of frequency ν_1 can be shown to have increased amplitude

$$V_1=V_G\left[1-i2\pi C_o R_1\nu_1-\frac{\pi^2\nu_1\nu_2 C_t^2 R_1 R_2}{1-i2\pi\nu_2 C_o R_2}\right]^{-1}.$$

In deducing this we assume that the oscillator of frequency ν_1 has impedance R_1 at ν_1 and zero impedance at all other frequencies. A corresponding assumption is made concerning the oscillator of frequency ν_2. The time-dependent capacitor or inductance need have very little random fluctuations. The low noise properties of this type of amplifier were pointed out unequivocally by van der Ziel[44] in 1948. This pioneering theoretical work appears to represent the earliest solution to the problem of low noise microwave amplification. Experimental verification of the low noise properties was accomplished by Salzberg and Sard.[45] The noise figure of a parametric amplifier has been given as[43]

$$F=1+\frac{G_1}{G_g}+\frac{\nu_1}{\nu_2}\frac{G_{T1}}{G_g}+F_S+F_G,$$

where G_1 = effective conductance of unloaded amplifying resonant circuit, G_g = effective conductance coupled into the amplifying resonant circuit by the generator, G_{T1} = effective conductance of the loaded amplifying resonant circuit, ν_1 = amplifying frequency, ν_2 = idling frequency, F_S = shot noise, and F_G = gain fluctuation noise.

The revival of interest in this type of amplifier appears to have started with the work of Suhl[46] and Weiss[47] on the ferromagnetic amplifier. Low noise "up frequency conversion" is also possible with parametric devices.[48] Room temperature operation is possible, with moderately good noise performance.

IX. APPLICATIONS OF MASERS TO EXPERIMENTAL PHYSICS AND RADIO ASTRONOMY

The very low noise, coupled with adequate gain-bandwith product, make the low-temperature solid state maser an obvious tool for radio astronomy and radar.‖ A modified Dicke-type radiometer in which a maser is used for pre-amplification has been described.[49] The ruby maser of Alsop, Giordmaine, and Townes, which was described earlier, was mounted near the focus of the Naval Research Laboratory 50-ft reflector in order to minimize transmission line losses. Liquid helium cooling was provided by a stainless steel Dewar with 3 l capacity which was maintained under partial vacuum. This allowed about 15 hr of observation before recharging was needed. The complete radiometer installation made it possible to observe with an rms output fluctuation of 0.03°K for an output time constant of 5 sec. The intermediate frequency amplifiers had a band width of 5 Mc.

The great stability of oscillators such as the cesium beam clock and the molecular beam masers make possible certain experimental tests of both special and general relativity. These possibilities have been discussed by Moller.[50] A molecular beam maser has been employed to repeat the Michelson-Morley experiment.[51] If there is a fixed ether a difference in frequency would

[43] We are following the treatment of H. Heffner and G. Wade, Meeting of Institute of Radio Engineers Professional Group on Electron Devices, Washington, D. C. (October, 1957).

[48] Herrmann, Uenohara, and Uhlir, Proc. Inst. Radio Engrs. **46**, 1301(L) (1958).

‖ *Note added in proof.*—Operation of a ruby maser at 60°K was reported by C. R. Ditchfield and P. A. Forrester [Phys. Rev. Letters **1**, 448 (1958)], and independently by T. H. Maiman (Hughes Aircraft Company Report). A maser employing a slow wave structure with band width of 67 mc per sec and gain of 13 decibels was described by R. W. DeGrasse (Bell Telephone Laboratories Report entitled "Slow Wave Structures for Unilateral Solid State Maser Amplifiers"). Amplifiers employing ruby which have wide tunability were reported by G. K. Wessel [380–450 mc, Proc. Inst. Radio Engrs. **47**, 590 (1959)], and by F. R. Arams and S. Okwit [850–2000 mc, Proc. Inst. Radio Engrs. **47**, 992 (1959)]. A proposal for generating higher frequencies than the pump frequency was made by A. E. Siegman and R. J. Morris [Phys. Rev. Letters **2**, 302 (1959)]. They suggest a staircase scheme in which say the spin populations of the lowest pair of states are reversed by adiabatic rapid passage, followed by adiabatic rapid passage reversal of the populations of levels 2 and 3. Then levels 3 and 1 can be employed for power generation.

be expected between two molecular beam type masers with beam velocities parallel and antiparallel to the earth's orbital motion. Let u be the velocity of the molecules relative to the cavity which is assumed to be moving with velocity v with respect to the fixed ether (u is parallel to v). It is assumed that the photons radiated by the molecules move with a velocity **c** relative to the fixed ether. The photon velocity relative to the cavity must be normal to u. This requires that **c** be tilted forward of the normal to u by an angle $\phi \approx (v/c)$. The expected doppler shift would be $vu\phi/c = uv v/c^2$. For a thermal velocity of 0.6 kMs/sec and for the earth's orbital velocity the difference in frequency between two *oppositely* directed beams is $2uvv/c^2$, which is ~ 10 cps if $\nu = 23\,870$ Mc/sec. The experiment was done by mounting two maser oscillators on a rack which could be rotated about a vertical axis. The oscillators were adjusted so that their frequencies differed by a small amount. This difference was recorded and the apparatus was then rotated through 180°. A slight change of about 1/50 cps was observed under the best conditions of operation. This is smaller by a factor of 1000 than what would be expected on the basis of a fixed ether. Inasmuch as the special theory of relativity is one of the most securely established of all physical theories, such experiments may be regarded as a search for other effects such as perhaps an anisotropy of space in this part of our galaxy. The use of stable oscillators to test the gravitational red shift has also been considered.[50,52] This is perhaps more a test of whether or not these devices are natural clocks (whose intervals are invariants) than a test of the fundamental postulates of the general theory of relativity.

A series of experiments is being planned by the author to search for gravitational radiation. The theory of an antenna for such radiation has been discussed.[53] Two masses which are separated will have forces exerted upon them by a gravitational wave. The phase difference at the two masses results in one being driven relative to the other. Also strains can be set up in a material by a gravitational wave. Under some conditions it is desirable to make use of acoustical resonance, under other conditions where acoustic phase reversal is troublesome, it is better not to employ acoustical resonance. The gravitational wave interacts both with the mass of the piezoelectric crystal and the conducting masses shown. Very low-frequency search is planned. The output voltages are amplified as shown in Fig. 22. Liquid helium temperatures and low noise receivers may make it possible to observe correlation in the outputs, in the presence of electrical noise.

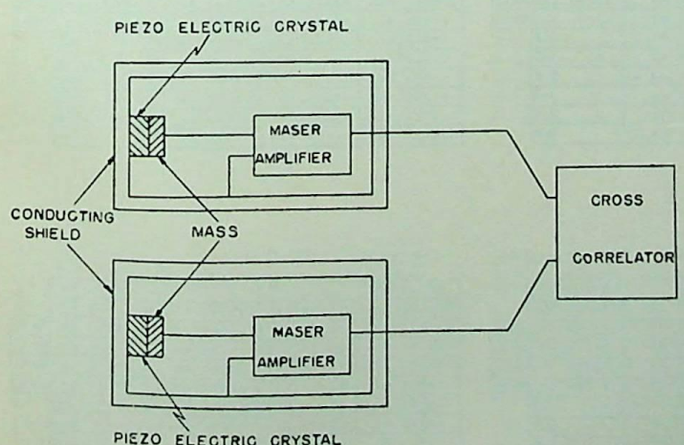

FIG. 22. Masers for detection of gravitational radiation at radio-frequencies.

X. CONCLUSION

The new microwave amplifiers are the result of electronics research to develop millimeter wave techniques, magnetic resonance research, and research in microwave spectroscopy. Maser amplifiers bring to the microwave region a detection sensitivity of the order of a few microwave photons. Most of these amplifiers employ the magnetic moment of the electron, and therefore fill in the gap in modern electronics pointed out by Sommerfeld. We may look forward to important advances in radio astronomy, spectroscopy and solid state physics, in consequence of improved ability to distinguish weak signals.

ACKNOWLEDGMENTS

We thank Professor Bloembergen, Professor Strandberg, and Professor Townes for helpful criticism and a profitable correspondence. Suggestions for improving the manuscript were also made by Dr. L. S. Nergaard and Dr. E. O. Schulz-DuBois. We acknowledge stimulating discussions with Dr. R. K. Wangsness and Professor R. A. Ferrell.

APPENDIX. MACHINE CALCULATIONS OF MATRIX ELEMENTS AND ENERGY LEVELS FOR RUBY¶

The following data are entirely the work of W. S. Chang and A. E. Siegman of the Stanford University Electronics Laboratories. We thank them for their kindness and cooperation in allowing this work to be published here.

The spin Hamiltonian used was

$$\mathcal{H} = g\beta_M \mathbf{H}_{dc} \cdot \mathbf{S} + D(S_z^2 - 5/4),$$

with $g = 1.99$ and $2D = +11.46$ kmc/s. The small anisotropy in the g tensor was ignored.

FIG. 23. Format of each sub-block in tables for ruby.

The energy eigenvectors $|j\rangle$ and the energy eigenvalues E_j are defined by the equations

$$\mathcal{H}|j\rangle = E_j|j\rangle$$

and

$$|j\rangle = a_j|\tfrac{3}{2}\rangle + b_j|\tfrac{1}{2}\rangle + c_j|-\tfrac{1}{2}\rangle + d_j|-\tfrac{3}{2}\rangle,$$

where $j=1$ through 4 denotes the four energy levels.

The axes were chosen so that the c axis of the ruby crystal is the z axis, the dc magnetic field H_{dc} lies in the x–z plane at an angle θ from the z axis, and the y axis is perpendicular to the plane containing H_{dc} and the c axis.

The transition probability matrix elements between levels k and l are given by

$$\frac{(\bar{H}')_{kl}}{\beta_M H_{rf}} = \frac{1}{\beta_M H_{rf}}\langle k|2\beta_M \mathbf{H}_{rf}\cdot\mathbf{S}|l\rangle$$

$$= (\alpha\phi_1 + \gamma\phi_3) + j\beta\phi_2,$$

where H_{rf} is the peak amplitude of the linearly-polarized rf magnetic field, and ϕ_1, ϕ_2, ϕ_3 are the direction cosines of $\mathbf{H}_{rf}$ with respect to the x, y, z axes.

For each operating point, characterized by H_{dc} and θ, the four energy eigenvalues E_j in units of kmc/s, the eigenvector expansion coefficients $a_j \cdots d_j$ for each level j, and the values of α, β, γ for each possible transition are presented in tabular form in Tables I(a) through I(i). The tables cover $\theta=10°$ to $\theta=90°$ in 10° increments, with H_{dc} increasing from 500 gauss to 7500 gauss by 500 gauss increments in each table.

The format of each subblock in the tables is shown in Fig. 23. The numbers in the blocks are expressed in

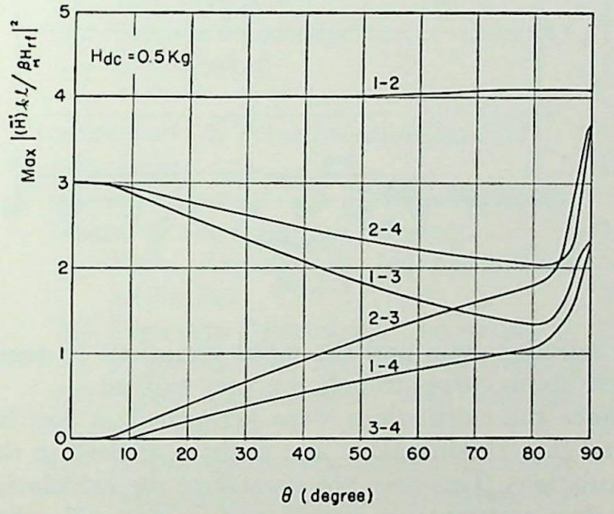

FIG. 24.

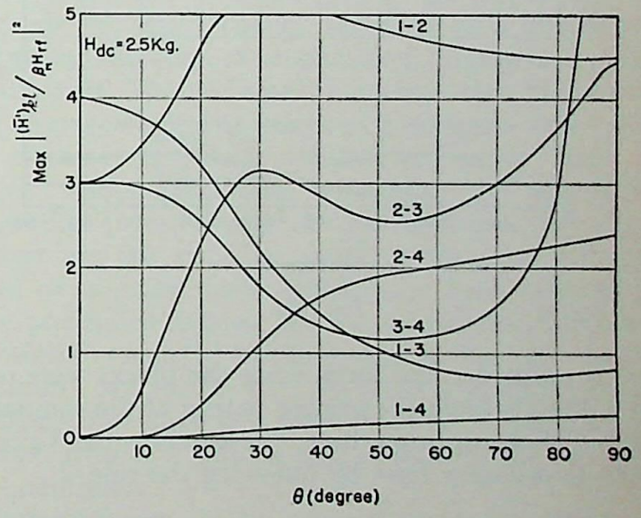

FIG. 26.

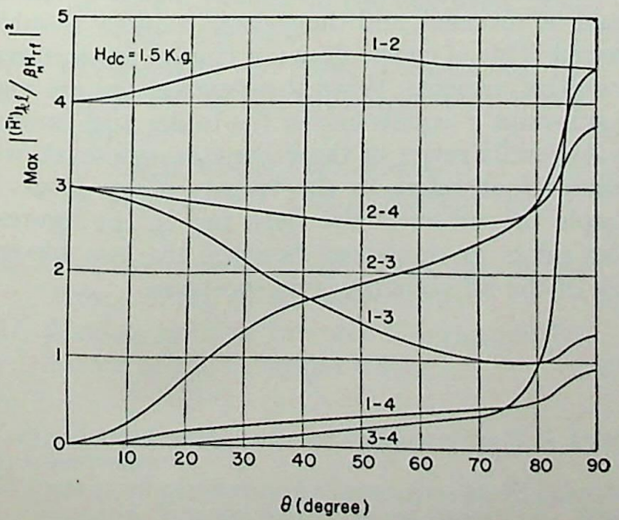

FIG. 25.

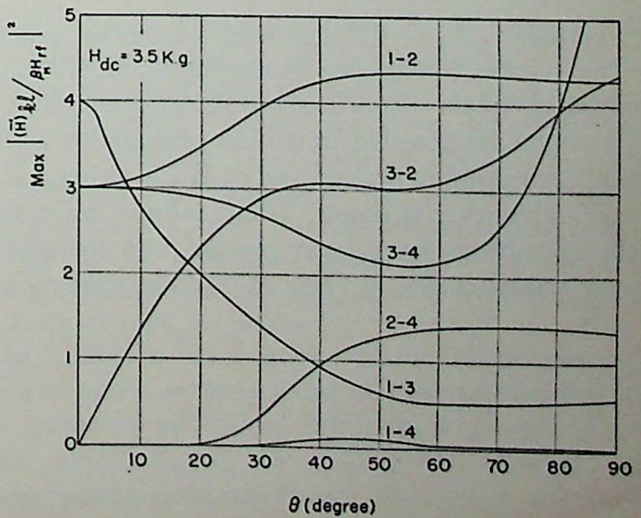

FIG. 27.

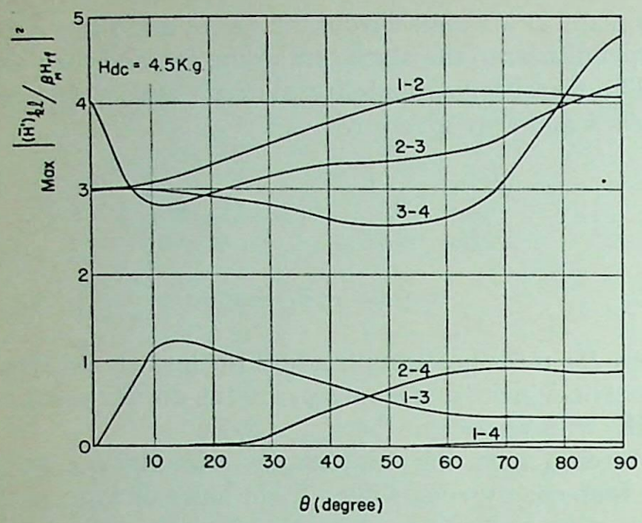

FIG. 28.

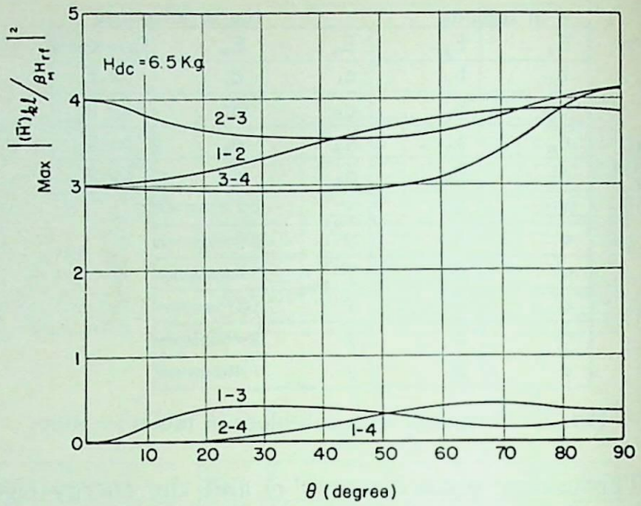

FIG. 30.

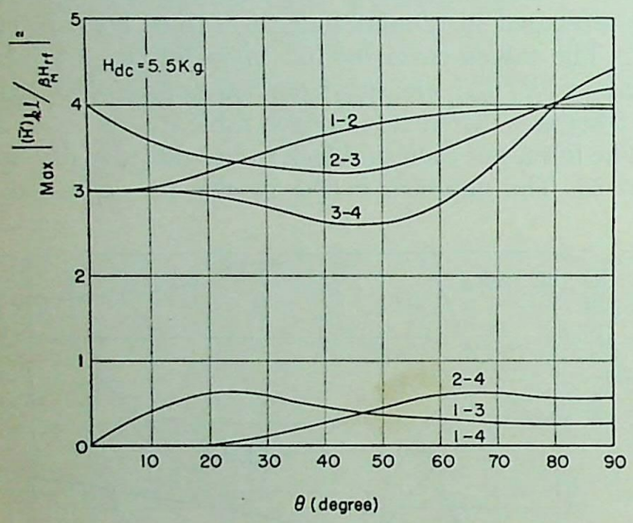

FIG. 29.

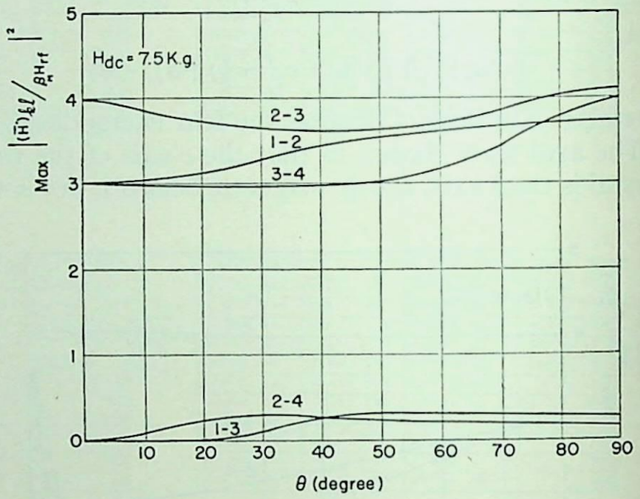

FIG. 31.

floating-point decimal form, since the blocks were prepared directly from the printed output of the computer to avoid transcription errors. The numbers can be converted to ordinary form by following the rule

$$abcde\ gh \equiv a \cdot bcde \times 10^{(gh\ 50)}.$$

The symbols *, N, or CR following a number indicate that the number is negative. For example, 56 423 51CR in the tables equals -56.423 in ordinary decimal form.

The maximum possible transition probability matrix element for optimum orientation of $\mathbf{H}_{rf}$ is either $\beta_M{}^2$ or $(\alpha^2+\gamma^2)$, whichever is larger. The maximum values for all the transitions have been plotted *vs* θ for several different values of H_{dc} in Figs. 24–31. The operation of the selection rules and the rapid variations in regions where levels curve strongly are very evident.

Since the calculations were performed, it has been found that D is negative, not positive as used in these calculations. This does not invalidate the calculations, but does require some simple modifications. To obtain correct answers for negative D, the signs of the E_j's should be reversed, and the signs of α and γ should be reversed. This of course does not change the squares of the matrix elements. When these corrections are made, the subscript J equals one in the tables and curves of this Appendix refers to the highest energy level, while J equals four refers to the lowest energy level. For example the subscript one dash two in the figures or tables refers to transitions between the two top-most levels of the ruby energy level spectrum.

I. THEORETICAL SURVEY

A. Introduction

THE investigation of gamma radiation has encompassed all the important properties of electromagnetic radiation: energy, intensity as a function of energy and direction of propagation, multipolarity, and polarization. The emission of gamma rays of discrete and characteristic energies was associated early with the existence of sharp, well-defined energy levels in nuclei, whose properties determine the intensities (transition probabilities) of the radiations. Of equal interest are the radiation patterns (angular distributions) of emitting nuclei which have been oriented in some prescribed fashion, for the spatial distribution is intimately connected to the multipole character of the radiation (My 38, Ha 40). By relatively simple measurements, therefore, it is often possible to establish the multipolarity of a gamma ray, at least in the case of a pure multipole.

There still remains an essential ambiguity, since the radiation may be either electric or magnetic. This property is associated with the parity of the radiation. The ambiguity in the parity is immediately resolved if the linear polarization of the radiation is known (Fa 48, Ha 48). Moreover, a knowledge of the polarization can be used to untangle the results in the case of mixed multipoles (Zi 50). It is sometimes possible to resolve such ambiguities with indirect arguments based on observations of associated phenomena. The measurement of polarization, however, provides a direct means of attack on such problems.

The radiation from nuclei may also be circularly polarized and a measurement of this polarization provides valuable additional information (Go 46, Fa 49, Ha 51, To 52, St 53). In a discussion of linear and circular polarization two types of nuclear orientation are distinguished, *alignment* and *polarization*. In the

TABLE I. Summary of conditions which produce nuclear alignment or polarization, and the corresponding types of correlations. The abbreviations dir, pol, circ, and align stand for direction, (linear) polarization, circular polarization, and alignment, respectively. The symbol LT(B) represents a low temperature orientation of the Bleaney type which produces alignment, LT(RG) represents a method of the Rose-Gorter type which leads to polarization. In each case only the most complex condition or correlation is listed. Thus if the circular polarization of the initial gamma ray is measured, its direction also is measured and one may have a dir-dir or dir-pol correlation as well as a circ-circ correlation.

Initial particle	Initial condition	Type of orientation	Type of correlation
p, n, etc.	dir	align	p-γ dir-pol
p, n, etc.	pol	pol	p-γ pol-circ
β	dir	pol	β-γ dir-circ
γ	dir	align	γ-γ dir-pol
γ	pol	align	γ-γ pol-pol
γ	circ	pol	γ-γ circ-circ
...	LT(B)	align	"align"-pol
...	LT(RG)	pol	"pol"-circ

case of *alignment* an axis of rotational symmetry is established, but the sense of this axis is not determined. In the case of *polarization* an axis is established which provides a single preferred direction in space. If the spin of the nuclear state is j and its component along the axis is m and if the (relative) population of the mth sublevel is $w(m)$, then the condition for alignment is $w(m)=w(-m)$ and that for polarization is $w(m) \neq w(-m)$. If the $w(m)$ are all equal, the nuclei are not oriented.

From an assemblage of aligned nuclei the radiation can show linear polarization but not circular polarization (Ha 48). Only if there is nuclear polarization will there be a component of circular polarization. Moreover, the processes which produce nuclear orientation can be classified according to the type of orientation which is produced, either alignment or polarization. In Table I the various processes are summarized and classified in this manner and the possible polarization correlation for each case is listed (in addition to the references already cited, see Si 51, Wo 49, To 52a, Si 53a, Le 56). This tabulation illustrates the formal way of designating a correlation. For example, a γ-γ direction-polarization correlation represents the measurement made on a γ-γ cascade in which the (linear) polarization of one gamma ray is determined relative to the direction of the other gamma ray. Two general methods are available for producing orientation. In one a nuclear particle is observed with or without polarization, and in the other an external or atomic field is employed at very low temperature.

The literature on the theory of direction-direction correlations is voluminous and detailed (see the comprehensive list of references given in De 57a). In the present survey, the theoretical results are presented (without derivation) in a manner which stresses the application to polarization experiments in order to provide a basis for the discussion in Part III.

B. Linear Polarization Distribution

The general expression for the intensity distribution of linearly polarized radiation has been given in several different forms by many authors (Ha 48, Zi 50, Ll 52, St 53, To 53, Sa 53, Si 53a, Bi 53, Sa 55b, Ma 58). The various expressions are equivalent and differ only superficially to cover different experimental situations or degrees of complexity. In this review we give three forms, two of which are generally appropriate for the direction-polarization correlation but differ enough to make one or the other preferable in certain problems, while the other is designed specifically for the case of nuclear orientation at low temperature. It is convenient to make such a classification, partly for historical reasons, although in many instances the differences are hardly more than a matter of nomenclature.

The direction-direction correlation for two radiations in a nuclear process is given in a concise form by (Co 53, Bi 53, De 57a)

$$W(\theta)=\sum_{\nu} A_{\nu}(1)A_{\nu}(2)P_{\nu}(\cos\theta). \qquad \text{(I-1)}$$

Here $P_{\nu}(\cos\theta)$ is the ordinary Legendre polynomial, θ is the angle between the directions of the two radiations, and 1 and 2 stand for sets of quantum numbers for the first and second radiations, respectively. The summation over ν is over all integral values (including zero) for which the coefficient of $P_{\nu}(\cos\theta)$ does not vanish. If we let $1 \rightarrow L_1 L_1' jj'$ and $2 \rightarrow L_2 L_2' jj'$ and sum the expression over all allowed sets of values of these quantum numbers, we can treat problems in which both the intermediate state and the radiations are of a mixed nature. The quantities L_n and L_n' represent possible values of the total angular momentum (multipolarity) of the nth radiation, while j and j' are possible total angular momenta for the intermediate state. Because of their great complexity, problems of this general type have not been studied extensively, especially in connection with polarization studies of gamma rays.

In most of the cases which have been studied experimentally, the intermediate state is characterized by unique spin and parity and the radiations are mixtures involving not more than two components. With these restrictions Eq. (I-1) is greatly simplified, not so much in form as in the complexity of the computation. We adhere to the notation which seems to provide the greatest ease in calculation through the use of published tables. The summation in Eq. (I-1) is now restricted to the even integers (including zero) and, after setting $j=j'$ for the intermediate state, the factorization of the coefficient of $P_{\nu}(\cos\theta)$ is complete. Hence, writing out the summation over the L's explicitly, we have (Bi 53, Fe 55)

$$A_{\nu}(n)=F_{\nu}(L_n L_n j_n j)+2\delta_n F_{\nu}(L_n L_n' j_n j) + \delta_n{}^2 F_{\nu}(L_n' L_n' j_n j), \qquad \text{(I-2)}$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

which is the expression that is applicable to gamma radiation. The intensity ratio of the L_n and L_n' radiation is denoted by δ_n^2 (δ_n is real) and j_n is the total angular momentum of the nth state, i.e., either the initial (1) or the final (2) state. Equation (I-1), is normalized so that $A_0(n)=1+\delta_n^2$. The most complete compilation of the functions $F_\nu(L_nL_n'j_nj)$ is that given in Fe 55 which covers all cases of apparent interest for even ν.

If the nth radiation is a material particle (e.g., an alpha particle), then it is only necessary to replace each $F_\nu(L_nL_n'j_nj)$ in Eq. (I-2) by $F_\nu(L_nL_n'j_nj)b_\nu(L_nL_n')$ and δ_n by $\delta_n\cos\xi$ (leaving δ_n^2 unchanged, however), where the "particle factor" (Bi 53) is

$$b_\nu(LL')=\frac{2[L(L+1)L'(L'+1)]^{\frac{1}{2}}}{L(L+1)+L'(L'+1)-\nu(\nu+1)}, \quad \text{(I-3)}$$

and ξ is an appropriate phase angle. If, in addition, the particle has a spin, it is convenient to employ the channel spin formalism. The total correlation function is then an incoherent superposition of the functions corresponding to each value of the channel spin obtained by compounding the spins of the two interacting particles. In beta decay and in Coulomb excitation the particle factors are more complex in that they involve specific features of the interactions. These factors are discussed in Al 56 (Coulomb excitation) and Bi 53 (beta decay). The β-γ circular polarization correlation is discussed in Sec. C following.

If unobserved intervening radiations are present, (I-1) is generalized (Sa 54), for transitions between nuclear states of well-defined spin and parity, to

$$W(\theta)=\sum_\nu A_\nu(1)U_\nu(2)\cdots U_\nu(n-1)A_\nu(n)P_\nu(\cos\theta). \quad \text{(I-1')}$$

The function

$$U_\nu(m)=(-1)^{j_{m+1}-j_m-L_m}[(2j_{m+1}+1)(2j_m+1)]^{\frac{1}{2}} \times W(j_mj_mj_{m+1}j_{m+1};\nu L_m)$$

is inserted for each unobserved transition $j_m(L_m)j_{m+1}$. The quantity $W(j_mj_mj_{m+1}j_{m+1};\nu L_m)$ is the Racah coefficient. For mixed radiation $U_\nu(L_m)+\delta_m^2U_\nu(L_m')$ (normalized to $1+\delta_m^2$) is used. The intervening radiation may be any kind of particle.

The prescription for obtaining the linear polarization distribution in a direction-polarization experiment can now be stated simply as follows. In each term of (I-1) characterized by (L_2L_2') and ν, replace $P_\nu(\cos\theta)$ by the expression (Ll 52, Sa 55b, De 57a),

$$P_\nu(\cos\theta)+(\pm)_{L_2'}\cos2\gamma\kappa_\nu(L_2L_2')P_\nu^{(2)}(\cos\theta). \quad \text{(I-4)}$$

Without loss of generality it is assumed that the linear polarization is observed for the second radiation. The direction of the linear polarization is specified by γ, the angle between the polarization vector and the plane of the reaction. In practice only two values of γ (0 and 90°) are usually considered, so that $\cos2\gamma=\pm1$. In the discussion of the experiments, the intensities of polarized radiation for these two directions is designated by J_0 and J_{90} or $J_{\parallel}$ and $J_\perp$ (J_θ, J_ϕ are also used in the literature). The quantity often given is the ratio J_0/J_{90}, although theoretically the polarization excess or difference (J_0-J_{90}) is the more natural quantity, as pointed out by Fano (Fa 49). Thus we write

$$P_1W(\theta)=(J_0-J_{90}) =\sum(\pm)_{L_2'}A_\nu\kappa_\nu(L_2L_2')P_\nu^{(2)}(\cos\theta), \quad \text{(I-5)}$$

which may be normalized to the total unpolarized intensity

$$W(\theta)=(J_0+J_{90})=\sum A_\nu P_\nu(\cos\theta) \quad \text{(I-6)}$$

if so desired. In these expressions the coefficient $A_\nu(1)A_\nu(2)$ or $A_\nu(1)U_\nu(2)\cdots A_\nu(n)$ has been shortened to A_ν and the sum is over ν and whatever quantum numbers are appropriate. The $P_\nu^{(2)}(\cos\theta)$ appearing in the polarization distribution is the unnormalized associated Legendre function. Numerical values for $P_\nu^{(2)}(\cos\theta)$ are given in Table II(a). The other quantity $\kappa_\nu(LL')$ appearing in (I-4) depends on the multipolarity of the radiation. It is given by (Ll 52)

$$\kappa_\nu(LL')=-\left[\frac{(\nu-2)!}{(\nu+2)!}\right]^{\frac{1}{2}}\frac{C(LL'\nu,11)}{C(LL'\nu,1-1)}, \quad \text{(I-7)}$$

where $C(LL'\nu,11)$ is the familiar vector addition coefficient. Numerical values for these coefficients are presented in Table II(b). Finally, in (I-4) the + or −

	4	0	−4	−9/15
	6	0	0	1

sign is to be employed according as the $2^{L_2'}$-pole radiation is electric or magnetic in character.‡

For the case of mixed radiation from a single intermediate level the polarization distribution can be written more explicitly as

$$W(\theta,\gamma)=W(\theta)$$
$$+(\pm)_{L_2'}\cos 2\gamma \sum_\nu A_\nu(1)\mathcal{A}_\nu(2)P_\nu^{(2)}(\cos\theta). \quad \text{(I-8)}$$

The sum is over even ν (excluding zero). The coefficient $A_\nu(1)$ is given by (I-2) or a suitable modification, if the first radiation is not a gamma ray or there are intervening radiations. The new coefficient $\mathcal{A}_\nu(2)$ differs only in the inclusion of the κ's with appropriate signs [so as to leave unchanged the sign convention in (I-8)]. Thus

$$\mathcal{A}_\nu(2)=-\kappa_\nu(L_2L_2)F_\nu(L_2L_2j_2j)$$
$$+2\delta_2\kappa_\nu(L_2L_2')F_\nu(L_2L_2'j_2j)$$
$$+\delta_2{}^2\kappa_\nu(L_2'L_2')F_\nu(L_2'L_2'j_2j). \quad \text{(I-9)}$$

In this case $L_2'=L_2+1$.

In a number of the problems studied experimentally, the complexity of the direction-direction correlation is limited to $\nu=0$ and 2. The direction-polarization correlation then becomes [with $\mathcal{A}_2=A_2(1)\mathcal{A}_2(2)$]

$$W=A_0+A_2P_2\pm\cos 2\gamma\,\mathcal{A}_2P_2^{(2)}. \quad \text{(I-10)}$$

Unless the directional correlation is nearly isotropic, a measurement of the polarization easily determines the correct sign in this expression and hence the parity of the radiation. The measurement can also be decisive in removing an ambiguity regarding the mixture of the radiation, as can be seen by inspecting (I-9) and Table II(b). There is one interesting exception in this particular example, namely, the case of pure dipole or pure quadrupole radiation. For both $L=1$ and $L=2$ we have, using (I-9) and Table II(b)

$$W=1+A_2P_2\pm\tfrac{1}{2}\cos 2\gamma A_2P_2^{(2)} \quad \text{(I-10')}$$

and for $\theta=90°$, we have

$$\frac{J_0}{J_{90}}=\frac{1-\frac{1}{2}A_2\pm\frac{3}{2}A_2}{1-\frac{1}{2}A_2\mp\frac{3}{2}A_2}. \quad \text{(I-10'')}$$

However, this expression does not hold for a dipole-quadrupole mixture. It is a quite general result that the polarization measurement can provide vital information on mixtures in addition to the determination of parity.

The earliest development of the theory (Ha 48, Zi 50) gave a somewhat different but entirely equivalent form for the direction-polarization correlation function, which has been used extensively in experimental work. If the direction-direction correlation is expressed as in (I-6), then the second form of the direction-polarization correlation which we treat is obtained simply by replacing the coefficient $A_\nu(L_2L_2')$ in each term by§

$$A_\nu(L_2L_2')+(\pm)_{L_2'}a_\nu(L_2L_2')\cos 2\gamma. \quad \text{(I-11)}$$

The angle γ and the sign convention are the same as used in the foregoing. In this prescription the new coefficients a_ν can be expressed in terms of the old ones A_ν. Writing the series in $\cos^\nu\theta$ as well as in $P_\nu(\cos\theta)$, we have

$$W(\theta)=\sum A_\nu(L_2L_2')P_\nu(\cos\theta)=\sum Q_\nu(L_2L_2')\cos^\nu\theta \quad \text{(I-12)}$$

$$P_1W(\theta)=\sum(\pm)_{L_2'}a_\nu(L_2L_2')P_\nu(\cos\theta)$$
$$=\sum(\pm)_{L_2'}q_\nu(L_2L_2')\cos^\nu\theta \quad \text{(I-13)}$$

$$a_\nu(L_2L_2')=\sum_n \alpha_nA_n(L_2L_2') \quad \text{(I-14)}$$

$$q_\nu(L_2L_2')=\sum_n \beta_nQ_n(L_2L_2'). \quad \text{(I-14')}$$

The coefficients α_n and β_n depend on L_2, L_2', and ν. Numerical values for these coefficients are provided in Table III for pure multipoles, in Table IV for mixed radiation of the same parity, and in Table V for mixed radiation of opposite parity. We note here that $\alpha_0=\beta_0=\alpha_1=\beta_1=0$. Many examples of the use of this formula-

TABLE III(b). Numerical values of the coefficients in the series $q_\nu(LL)=\Sigma_n\beta_nQ_n(LL)$ (cf. Zi 50, Ha 48). For odd ν, all $\beta_n=0$.

	4	0	−4	−7
	6	0	0	1

‡ Most authors give this condition in more elegant fashion by defining a quantity σ equal to 0 or 1 depending on the character of the radiation. Since there is no unanimity in the definition of this quantity, we prefer the foregoing statement (De 57a) in the hope of reducing confusion. The sign convention depends on the direction chosen for $\gamma=0$ and on the sign used in (I-7).

§ This substitution is obtained from the one used in the foregoing by expanding the associated Legendre function in terms of the ordinary functions.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

tion occur in the literature. We cite here the case of the pure octupole gamma ray in the reaction $F^{19}(p,\alpha)O^{16*}$, $(\gamma)O^{16}$, $E_\gamma=6.1$ Mev. At $E_p=0.33$ Mev it is known that the proton is captured in an s-state, so that the α-γ emission can be treated as an independent two-stage process. From the measurement of the direction-direction correlation (Ar 50, Ba 50) one selects the theoretical result

$$W(\theta)=1+111\cos^2\theta-305\cos^4\theta+225\cos^6\theta. \quad \text{(I-15)}$$

With the aid of Table III(b), one finds directly for the direction-polarization correlation for an octupole radiation

$$P_1W(\theta)=\pm\tfrac{1}{3}[(2Q_2-Q_6)-(2Q_2-12Q_4-19Q_6)\cos^2\theta -(12Q_4+21Q_6)\cos^4\theta+3Q_6\cos^6\theta]. \quad \text{(I-16)}$$

Inserting the numerical values of the direction-direction coefficients, one has

$$P_1W(\theta)=\pm[-1+131\cos^2\theta -355\cos^4\theta+225\cos^6\theta]. \quad \text{(I-17)}$$

The linear polarization is complete at $\theta=118°$ (or 62°), i.e., at that angle $J_0/J_{90}=0$ or ∞ depending on whether the radiation is magnetic or electric. The measurement of this quantity is discussed in Part III.

A problem frequently encountered is that of the dipole-quadrupole mixture in the radiation from a discrete level. From Tables III(a) and IV(a) we obtain

$$a_0(11)=-A_2(11) \quad a_0(12)=-\tfrac{1}{3}A_2(12) \quad a_0(22)=A_2(22)-\tfrac{1}{6}A_4(22)$$
$$a_2(11)=A_2(11) \quad a_2(12)=\tfrac{1}{3}A_2(12) \quad a_2(22)=-A_2(22)-\tfrac{5}{6}A_4(22)$$
$$a_4(22)=A_4(22). \quad \text{(I-18)}$$

		3	1/2	
2	3	1	3/2	2
		3	−3/2	−3
		5	0	1

Inserting these quantities into (I-13), we find (changing the sign of the dipole term)

$$P_1W(\theta)=\pm[(A_2-\tfrac{4}{3}A_2(12)-\tfrac{1}{6}A_4) -(A_2-\tfrac{4}{3}A_2(12)+\tfrac{5}{6}A_4)P_2+A_4P_4]. \quad \text{(I-19)}$$

In this expression A_2 and A_4 are coefficients of the total correlation function, while $A_2(12)$ is the mixed coefficient. From this result we obtain at $\theta=90°$ and for even parity ($M1+E2$)

$$J_0=A_0+A_2+A_4-2A_2(12) \quad \text{(I-20)}$$
$$J_{90}=A_0-2A_2-\tfrac{1}{4}A_4+2A_2(12). \quad \text{(I-21)}$$

This example is a generalization of the one given above, (I-10″).

The third form of the direction-polarization correlation arises because of the convenience of discussing certain problems in terms of the magnetic sublevels of the radiating state as has been recognized by many authors. Because of the obvious physical insight provided by the method in the study of nuclear orientation, it has been the starting point of theoretical developments in this field (St 52a, To 53). Hence, we write

$$W(\theta)=\sum_m w(m)I_m{}^{LL}(\theta), \quad \text{(I-22)}$$

where $I_m{}^{LL}(\theta)$ is the intensity distribution of 2^L-pole radiation from the mth sublevel of the radiating state of angular momentum j, $w(m)$ is the relative population of this sublevel, and the summation over m is from $-j$ to j. If the angular momentum j_f of the final state is greater than zero, then we have further:

$$I_m{}^{LL}(\theta)=\sum_M |C(jLj_f;mM)|^2F_M{}^{LL}(\theta), \quad \text{(I-23)}$$

where the coefficient is the vector addition coefficient

and $F_M^{LL}(\theta)$ is the intensity distribution of an (L,M)-pole. Associated with each $F_M^{LL}(\theta)$ there is of course a distribution function $f_M^{LL}(\theta)$ for linear polarization. Then,

$$F_M^{LL}(\theta,\gamma)=F_M^{LL}(\theta)\pm\cos 2\gamma f_M^{LL}(\theta) \qquad \text{(I-24)}$$

can be inserted in place of $F_M^{LL}(\theta)$ in (I-23) to produce the direction-polarization distribution (generalized to mixed radiation), namely,

$$W(\theta,\gamma)=\sum_m w(m)\sum_M\sum_{LL'}C(L)C(L')\delta_L\delta_{L'}$$
$$\times[F_M^{LL'}(\theta)\pm\cos 2\gamma f_M^{LL'}(\theta)]. \qquad \text{(I-25)}$$

(Agreement with previous notation is obtained if $\delta_L=1$). The $F_M^{LL'}(\theta)$ and $f_M^{LL'}(\theta)$ are given in Table VI.

There are several empirical examples of angular distributions which correspond to a single (L,M) pole. The reaction $F^{19}(p,\alpha)O^{16*}(\gamma)O^{16}$ has already been cited. In Table IV we see that the distributions given in (I-15, I-17) correspond to a pure (3,1)-pole. A second example is the capture reaction, $H^2(p,\gamma)He^3$. The measured directional distribution is fitted very closely by the function $F_0^{11}(\theta)\sim\sin^2\theta$. The polarization distribution is, therefore, [Table IV(b)]

$$F_0^{11}(\theta,\gamma)=(1\pm\cos 2\gamma)(1-\cos^2\theta). \qquad \text{(I-26)}$$

At $\theta=90°$ the polarization ratio $J_0/J_{90}=0$ or ∞ depending on whether the radiation is magnetic or electric. The measurement of this quantity is discussed in Part III.

For an angular distribution or correlation it is clearly possible to obtain the population numbers $w(m)$ from a knowledge of the preceding transitions (Li 49). In a nuclear orientation problem the population numbers are functions of the temperature and of the method used to produce orientation. In a given method they can also depend on specific parameters which may vary from one experiment to the next. The calculation of $w(m)$ has been treated very thoroughly in the literature and, insofar as possible, general formulas have been provided. In Table VII we list the methods of producing orientation which have been generally discussed and in the last column we give references which deal with the computation of $w(m)$.

For purposes of computation it is advantageous to retain as much as possible of the formulation which makes use of the functions $F_\nu(LL'j_nj)$. In an equation such as (I-1′) it is only necessary to replace the coefficient $A_\nu(1)$ by an orientation parameter $B_\nu(j)$ which describes the orientation of the initial state. Equation (I-1′) retains its generality. The orientation parameter is merely a linear combination of the population numbers (Gr 55a, Bl 57),

$$B_\nu(j)=(2\nu+1)^{\frac{1}{2}}\sum_m C(j\nu j;m0)w(m). \qquad \text{(I-27)}$$

For the linear polarization distribution we need only

TABLE VI(b). The functions $F_M^{LL'}(\theta)$ and $f_M^{LL'}(\theta)$, both given in the form $k\Sigma b_n\cos^n\theta$. In each case $F_M^{LL'}(\theta)$ is tabulated on the first line and $f_M^{LL'}(\theta)$ on the second line (cf. Ar 50, Zi 50). The upper sign corresponds to $M>0$; the lower to $M<0$.

the even quantities and of these the following will generally suffice:

$$B_0=1$$

$$B_2=[(1/5)j(j+1)(2j-1)(2j+3)]^{-\frac{1}{2}} \times[\sum_m m^2w(m)-(1/3)j(j+1)]. \quad \text{(I-28)}$$

The calculation of these quantities for the various experimental techniques is discussed in the references given in Table VII.

The orientation parameters are given in To 52 in a form which differs from the B's only in normalization. The expression for $\nu=2$ is

$$f_2=j^{-2}[\sum_m m^2w(m)-(1/3)j(j+1)]. \quad \text{(I-29)}$$

When the directional distribution has been obtained by any one of the foregoing techniques, the polarization distribution can be derived from it in the usual fashion with the substitution indicated by (I-4) or (I-11).

The polarization-polarization correlation has been discussed by several authors (Fa 48, Ma 51, Ll 52, Bi 53) and a general expression for it can be found in Ll 52. This type of correlation has not received much attention experimentally, since it provides very little additional information (Ha 48, Bi 53) to compensate for the increased experimental difficulties.

In a measurement of the γ-γ direction-polarization correlation, it has not always been feasible to distinguish the gamma rays in the detectors. It is then necessary to mix the $\gamma_1-\gamma_2$ direction-polarization function with the $\gamma_2-\gamma_1$ function according to the respective efficiencies of detection.

C. Circular Polarization Distribution

The γ-γ circular-circular correlation can be written in concise form (Go 46, Al 57) as

$$W(\theta p_1p_2)=\sum_\nu(-p_1)^\nu A_\nu(1)(-p_2)^\nu A_\nu(2)P_\nu(\cos\theta). \quad \text{(I-30)}$$

The summation is over the odd and even integers (including zero), and $p_n=\pm1$ according as the circular polarization of the nth radiation is right or left handed.‖ The coefficient $A_\nu(n)$ can be obtained from (I-2) which is valid for odd ν. The coefficients $F_\nu(L_nL_n'j_nj)$ for odd ν have been tabulated in Al 57.

If the expression (I-30) is summed over a p_n, the total intensity of the corresponding gamma ray is obtained. Thus, we find,

$$W(\theta)=\sum_{p_1p_2}W(\theta p_1p_2)=2\sum_{p_1}W(\theta p_1p_2)$$
$$=2\sum_{p_2}W(\theta p_1p_2)=\sum_{\nu\text{ even}}A_\nu(1)A_\nu(2)P_\nu(\cos\theta), \quad \text{(I-31)}$$

which is just the direction-direction correlation. Hence there are no direction-circular (or linear-circular) correlations. If, on the other hand, the excess of circular polarization (right handed minus left handed) is measured for either gamma ray or both, one obtains

$$P_3W(\theta)=\sum_{p_1p_2}p_1p_2W(\theta p_1p_2)=2\sum_{p_1}p_1p_2W(\theta p_1p_2)$$
$$=2\sum_{p_2}p_1p_2W(\theta p_1p_2)$$
$$=\sum_{\nu\text{ odd}}A_\nu(1)A_\nu(2)P_\nu(\cos\theta). \quad \text{(I-32)}$$

The quantity P_3 is the degree of circular polarization, as defined by Fano (Fa 49). It is analogous to the quantity P_1 defined for the linear polarization [see (I-5)]. In addition, it follows that

$$\sum_{p_1p_2}p_1W(\theta p_1p_2)=\sum_{p_1p_2}p_2W(\theta p_1p_2)=0,$$

which shows again there is no direction-circular correlation.

In the case of nuclear polarization produced by orientation at low temperatures, we merely identify the coefficient $A_\nu(1)$ in (I-32) with the orientation parameter $B_\nu(j)$. In terms of the population numbers $w(m)$, the most important parameter is (To 52, Bl 57)

$$B_1=2\sqrt{3}\sum_m mw(m).$$

or

$$f_1=j^{-1}\sum_m mw(m). \quad \text{(I-33)}$$

References which deal with the computation of these parameters are given in Table VII. The most important feature of B_1 is that its sign depends on the sign of the hfs interaction which produces the nuclear polarization. In turn the sign of the interaction depends on the sign of the nuclear magnetic moment. A measurement of the degree of circular polarization gives the sign in (I-32) and thus yields the sign of the magnetic moment.

TABLE VII. Some methods of producing nuclear orientation at low temperatures.

Method	Type of orientation	Applied field	References
External field (Brute force)	pol	$>10^5$ gauss	Go 34, Ku 35, Si 51, St 53a, Po 54, Kh 55, St 57a, Bl 57

		1	± 1	1	4	
		0	⋯	0	0	
2	3	2	$(14)^{\frac{1}{2}}/21$	−12	7	5
		1	$(35)^{\frac{1}{2}}/105$	48	7	50
		0	$(280)^{\frac{1}{2}}/105$	−18	−7	25
3	3	3	$\pm 1/6$	9	−14	5
		2	$\pm 1/6$	6	14	−20
		1	$\pm 1/6$	3	14	25
		0	⋯	0	0	0

The degree of circular polarization can be written in terms of the population numbers directly. In analogy to (I-25) for the case of linear polarization, we have

$$P_3W(\theta)=\sum_m w(m)\sum_M\sum_{LL'}C(L)C(L')\delta_L\delta_{L'}g_M{}^{LL'}(\theta), \quad \text{(I-34)}$$

where $C(L)$ stands for $C(jLj_f;mM)$. The function $g_M{}^{LL'}(\theta)$ gives the degree of circular polarization for an (LL',M) pole. A few of these functions are listed in Table VIII.

Circularly polarized radiation may be produced following the capture or emission of a polarized particle such as a neutron or a proton (Ha 51, Bi 51). The only case of importance so far has been the capture of polarized thermal neutrons as discussed in Part III. Since the orbital angular momentum is zero, there is no complication in applying the formalism of this discussion. In this case $A_1(1)$ in (I-32) becomes $\frac{1}{2}F_1(\frac{1}{2}\frac{1}{2}j_1j)$, by analogy with an absorbed gamma ray. The functions $F_1(\frac{1}{2}\frac{1}{2}j_1j)$ are tabulated in Table IX. As an example, consider $j_1=0$, $j=\frac{1}{2}$, $j_2=\frac{1}{2}$, and $L=1$. From Table IX we obtain $F_1(\frac{1}{2}\frac{1}{2}0\frac{1}{2})=-2.00$ and in Al 57 we find $F_1(11\frac{1}{2}\frac{1}{2})=-1.00$. Thus (I-32) becomes

$$P_3=+\cos\theta.$$

At $\theta=0$ (along the direction of the neutron polarization), $P_3=+1$ and the gamma rays are completely circularly polarized (right handed).

TABLE IX. Numerical values of $F_1(\frac{1}{2}\frac{1}{2}j_1j)$.

j_1	j	$F_1(\frac{1}{2}\frac{1}{2}j_1j)$	j_1	j	$F_1(\frac{1}{2}\frac{1}{2}j_1j)$	j_1	j	$F_1(\frac{1}{2}\frac{1}{2}j_1j)$

1	3/2	−1.491	5/2	3	−1.333	4	9/2	−1.277
3/2	1	0.816	3	5/2	0.976	9/2	4	1.033
3/2	2	−1.414	3	7/2	−1.309	9/2	5	−1.265

For the β-γ direction-circular correlation (Le 56, Al 57, Ga 57, Mo 57) the formal procedure is the same. For the beta particle, we write (Al 57)

$$A_\nu(\beta)=\sum_{L_1L_1'}F_\nu(L_1L_1'j_1j)b_\nu(L_1L_1'), \quad \text{(I-35)}$$

where $b_\nu(L_1L_1')$ is the particle factor for the beta ray. The mixing of multipole orders in the beta radiation is governed by the particle factors which are characteristic of the beta process. The particle factors for allowed beta transitions are given in Table X which is an extension of the table given by Alder *et al.* (Al 57). For the degree of circular polarization, we obtain from (I-32)

$$P_3=-[A_1(\beta)/A_0(\beta)]A_1(\gamma)P_1(\cos\theta),$$

where

$$A_1(\beta)=[F_1(11j_1j)\lvert M_{GT}\rvert^2S_1{}^{(11)}+F_1(01j_1j)\lvert M_{GT}\rvert\cdot\lvert M_F\rvert S_1{}^{(01)}],$$

$$A_0(\beta)=\lvert M_F\rvert^2S_0{}^{(00)}+\lvert M_{GT}\rvert^2S_0{}^{(11)}.$$

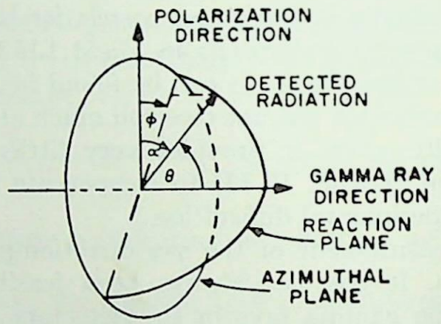

FIG. 1. Angles and vectors involved in a reaction sensitive to the linear polarization of a gamma ray, presented so as to apply to all such reactions discussed. The phrase "detected radiation" can represent a Compton scattered gamma ray, a photoproton from the photodisintegration of the deuteron, etc.

Let

$$S_0{}^{(00)}=\tfrac{1}{4}\lvert C_F\rvert^2,\quad S_0{}^{(11)}=\tfrac{1}{4}\lvert C_{GT}\rvert^2,\quad a=\lvert C_{GT}/C_F\rvert^2,$$

and $x=a^{\frac{1}{2}}M_{GT}/M_F$.

Then,

$$A_1(\beta)/A_0(\beta)=\tfrac{2}{3}(p/E)\times[F_1(11j_1j)Gx^2+F_1(01j_1j)Ia^{\frac{1}{2}}x]/(1+x^2),$$

where $\frac{2}{3}(p/E)G=S_1{}^{(11)}/S_0{}^{(11)}$ and $\frac{2}{3}(p/E)I=S_1{}^{(01)}/S_0{}^{(11)}$. This is the form and notation given in Bo 58. The experimental results on the beta-gamma correlation and on the electron distribution from polarized nuclei (Wu 57) have shown that $G=\pm 1$ for positrons and electrons. As an example, consider the Co^{60} decay, $5(\beta)4(2)2(2)0$. The beta and gamma radiations are pure. For the first gamma ray, with $G=-1$, we find

$$P_3=\tfrac{2}{3}(v/c)(0.774)(-0.645)\cos\theta=-\tfrac{1}{3}(v/c)\cos\theta$$

from the tables in Al 57. For the second gamma ray a factor must be inserted for the unobserved gamma ray $[\cos(J_1J_1')]$ but the numerical result is the same.

			$S_1^{(01)}=\frac{1}{6}(p/E)\{\mathrm{Re}(C_SC_T'^*+C_S'C_T^*-C_VC_A'^*-C_V'C_A^*)+(Z\alpha/p)\,\mathrm{Im}(C_SC_A'^*+C_S'C_A^*-C_VC_T'^*-C_V'C_T^*)\}$

II. POLARIZATION-SENSITIVE PROCESSES

Primary emphasis is given in this part to those processes that have proved the most practicable and useful in the detection of polarization. They are presented in the approximate order of their importance as determined chiefly by the frequency of application. Section D, Part II, contains a brief discussion of some of the processes which have not as yet found use in the study of nuclear gamma rays.

A. Compton Effect

(a) *Sensitivity to Plane Polarization*

The sensitivity of the Compton effect to the polarization of an incident gamma ray can be obtained from the Klein-Nishina formula (Kl 29, Ni 29) which gives the differential cross section for the process. In almost all cases encountered experimentally the direction of polarization of the scattered photon is not of interest. Thus, for the present discussion the most useful form of the Klein-Nishina expression is the one in which a summation has been made over all directions of polarization of the scattered photon with the result¶

$$d\sigma_\phi=\frac{r_0^2}{2}\frac{k^2}{k_0^2}\left[\frac{k_0}{k}+\frac{k}{k_0}-2\sin^2\theta\cos^2\phi\right]d\Omega, \qquad \text{(II-1)}$$

where $r_0=e^2/m_0c^2$ is the classical radius of the electron, $d\Omega$ is the element of solid angle into which the photon is scattered, θ is the angle through which the incident photon is scattered, ϕ is the angle between the electric vector of the incident photon and the plane of scattering, and k_0 and k are the energies of the incident and scattered photons, respectively. These energies are related by the expression

$$k=\frac{k_0}{1+(k_0/m_0c^2)(1-\cos\theta)}. \qquad \text{(II-2)}$$

The angles and vectors involved in a Compton scattering are illustrated in Fig. 1.

The effect of polarization is contained in the $\cos^2\phi$ factor of the last term of (II-1) which shows that the scattering is a maximum in the plane normal to the electric vector of the incident photon. As the energy of the incident gamma ray approaches zero the sum of the first two terms in the brackets approaches two. Thus in the limit of zero energy at $\theta=90°$ the Compton effect has an ideal response to polarization, i.e., the differential cross section is zero when $\phi=0°$ and a maximum when $\phi=90°$. At any given θ, an increase in the energy k_0 produces a decrease in the efficiency of analysis as expressed by the asymmetry ratio, $R=d\sigma_{90}/d\sigma_0$. Of especial interest is $\theta_{\max}$, the value of θ which makes R a maximum for a given energy k_0. This $\theta_{\max}$ is 90° for $k_0=0$ and decreases with increasing energy as shown in Fig. 2, which gives values of $\theta_{\max}$ up to an energy of about 6 Mev. A similar curve for energies up to about 1.5 Mev is given in Me 50.**

Figure 2 also shows the values of R at $\theta=\theta_{\max}$ plotted

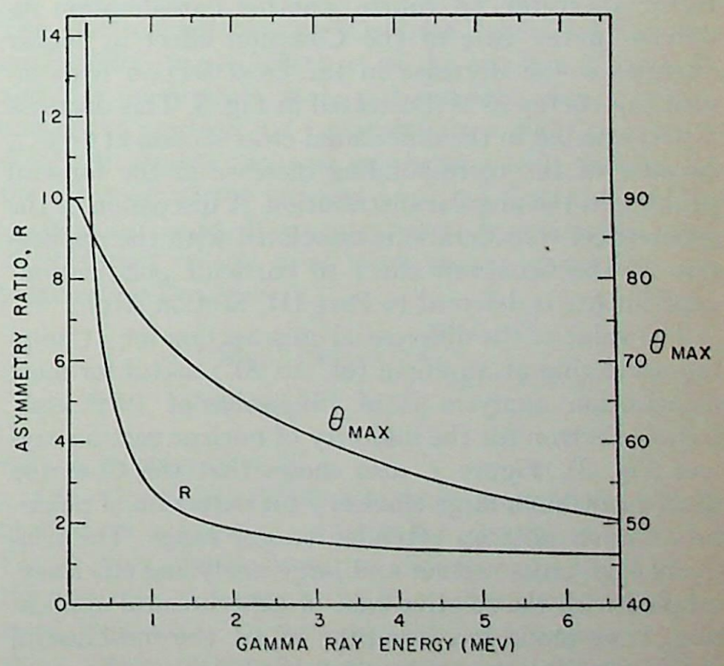

FIG. 2. The Compton scattering angle $\theta_{\max}$ at which the asymmetry ratio R is maximum, and the asymmetry ratio R for $\theta=\theta_{\max}$ as a function of incident photon energy up to about 6 Mev, the highest energy at which a Compton polarimeter has been used.

¶ A more detailed treatment including the derivation of this and other forms of the differential cross section can be found in He 44; see also Ev 55.

** There is disagreement between the latter curve and the one given here, which becomes larger as the energy increases from zero. The reason for this discrepancy is not known: perhaps an approximation valid only in the region of small energy was made in the calculations for the curve in Me 50. In the curve presented here no approximations have been made.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

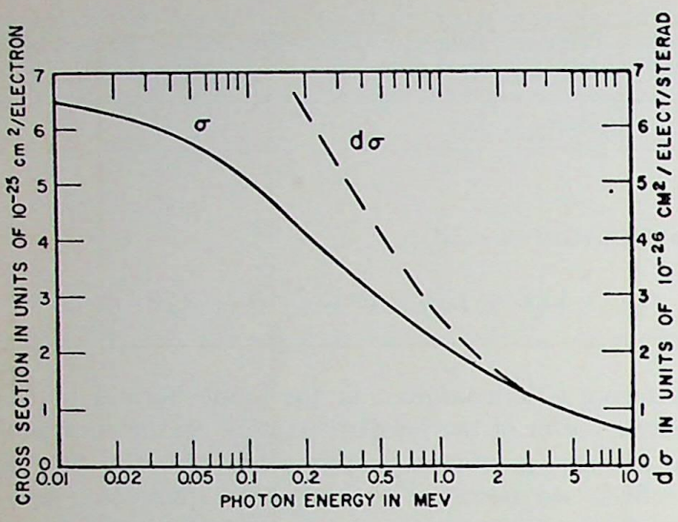

FIG. 3. Total cross section σ for the Compton effect (curve from Da 52a), and the differential cross section $d\sigma$ at $\theta=\theta_{max}$, as a function of incident photon energy.

as a function of energy. This figure shows that beyond about 2 Mev the value of R decreases very slowly as it approaches a value of one at infinite energy. Consequently, the Compton effect might in some cases be useful at energies as high as 10 Mev since at least a 10% effect would exist. However, its use at this energy might be somewhat marginal since the values of R given in Fig. 2 are for an ideal geometry. In any practicable experimental arrangement the value of R is considerably reduced by the angular spread of the detector apertures. Of course, another consideration involved in the case of the Compton effect at higher energies is the decrease in the cross section with increasing energy as is illustrated in Fig. 3. This decrease is accentuated in the differential cross section at $\theta=\theta_{max}$ because of the corresponding increase in the forward peaking in the angular distribution. A discussion of the geometrical considerations associated with the application of the Compton effect to particulr polarization experiments is deferred to Part III, Section A(c).

The value of the differential cross section for a Compton scattering at an angle (65° to 90°) useful for most polarization analyses is of the order of 10^{-26} cm^2/sterad/electron for the majority of nuclear gamma rays (see Fig. 3). Figure 2, also shows that the Compton effect furnishes a large efficiency for detection of polarization over quite an extended energy range. The relatively high cross section and large analyzing efficiency, coupled with the relative ease of experimental application, have made the Compton effect the most useful of the polarization-sensitive mechanisms.

(b) Sensitivity to Circular Polarization

Interest in the sensitivity of the Compton effect to circular polarization has increased considerably with the recent investigations of nonconservation of parity in weak interactions by means of experiments on the circular polarization of gamma rays following beta decay. Although the scattering of circularly polarized gamma rays by polarized electrons had been discussed by earlier workers (Bi 51, Ha 51, Cl 52), the first effective experimental study of the effect was made by Gunst and Page (Gu 53). In this work the total cross section is given as $\sigma=\sigma_0\pm\sigma_1$ where σ_0 and σ_1 are the parts unaffected and affected, respectively, by circularly polarized gamma rays. Gunst and Page measured the cross section for the effect at $k_0=2.62$ Mev and found a value of $\sigma_1/\pi r_0^2=0.089\pm0.007$ in good agreement with the theoretical value, 0.093, found from expressions calculated by Stehle (see Gu 53). The experiment was done by measuring the difference in intensity of the 2.62-Mev gamma rays from ThC″ which were transmitted through an iron bar 30-cm long when magnetized, and then demagnetized. Although the gamma rays were initially unpolarized, they can be considered as consisting of equal components of right and left circularly polarized radiation. Consequently, when the magnetic field is applied, one of these components is preferentially scattered.

Lipps and Tolhoek (Li 54, Li 54a; see also Fr 38, Fa 49, To 56), have derived the Compton cross section in a general form with all polarizations taken into account,

$$d\sigma=r_0^2(k^2/k_0^2)\Phi(\mathbf{k}_0,\mathbf{k},\xi^0,\xi,\zeta^0,\zeta)d\Omega, \qquad \text{(II-3)}$$

where ξ^0, ξ, ζ^0, and ζ are the respective polarization vectors of the incident and scattered photon and of the electron before and after interaction, and $\Phi(\mathbf{k}_0,\mathbf{k},\xi^0,\xi,\zeta^0,\zeta)$ is a linear function of these polarization vectors. The function Φ can be separated into 16

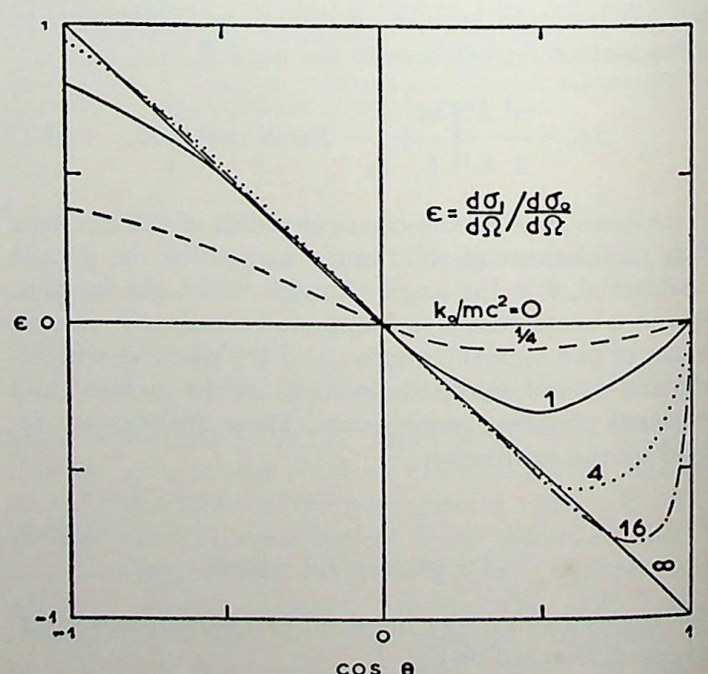

FIG. 4. Polarization-sensitive part $d\sigma_1$ of the differential Compton cross section for electrons polarized along the axis of incident circularly polarized photons. The curves are normalized to the polarization-insensitive cross section $d\sigma_0$ and plotted for several energies as a function of cosθ, where θ is the angle through which the photon is scattered (figure from Gu 53).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

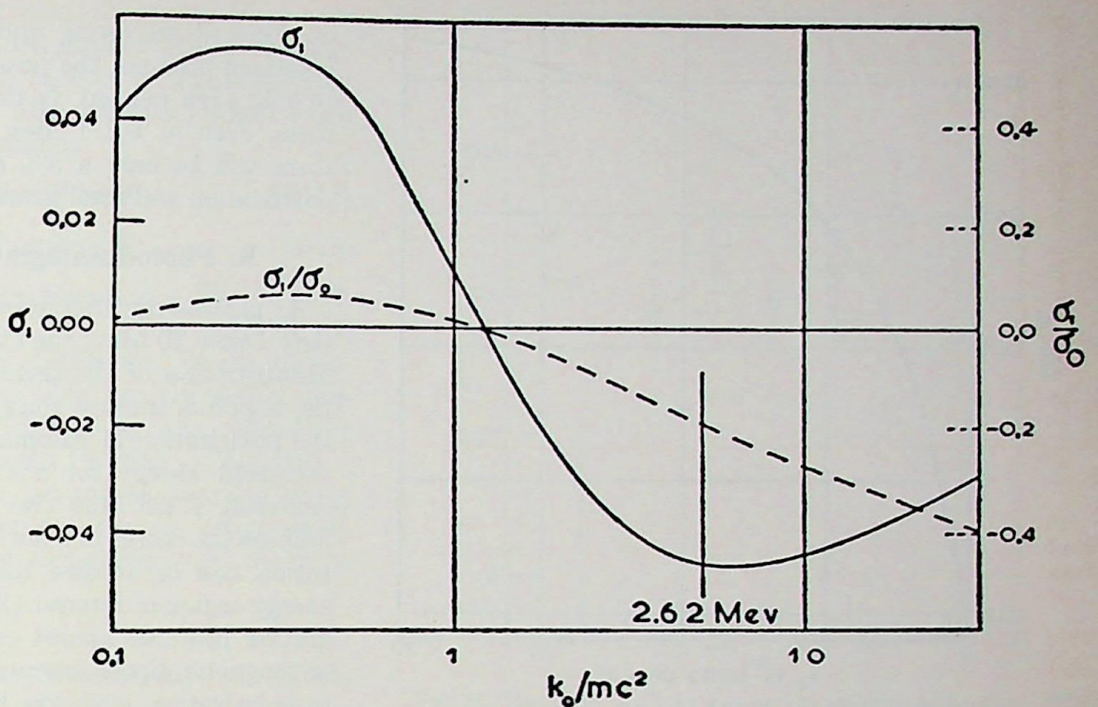

FIG. 5. Polarization-sensitive part σ_1 of the total Compton cross section (in units of $2\pi r_0^2$) for the same electron and photon polarizations as in Fig. 4. In the dashed curve σ_1 is normalized to σ_0, the polarization-insensitive part of the total cross section. The curves are plotted against incident photon energy (figure from Gu 53).

terms, depending on the 16 different ways of choosing sets of polarization vectors. Thus,

$$\Phi=\Phi_0+\Phi_1+\Phi_2+\Phi_3+\Phi_4, \qquad \text{(II-4)}$$

where Φ_0 is independent of polarizations,

$$\Phi_1=\Phi_1(\xi^0)+\Phi_1(\xi)+\Phi_1(\zeta^0)+\Phi_1(\zeta), \qquad \text{(II-5)}$$

$$\Phi_2=\Phi_2(\xi^0,\xi)+\Phi_2(\zeta^0,\zeta)+\Phi_2(\xi^0,\zeta^0)+\Phi_2(\xi,\zeta)+\Phi_2(\xi^0,\zeta)+\Phi_2(\xi,\zeta^0), \qquad \text{(II-6)}$$

and Φ_3, and Φ_4 depend on 3 and 4 polarization vectors, respectively. Explicit expressions are given in Li 54a for all the $\Phi_0,\cdots,\Phi_4$.

Thus far, the only experiments performed have involved not more than two polarizations. It is necessary then to average over unobserved initial polarizations and sum over unobserved final polarizations in order to obtain the cross section for some definite experiment. Since the states represented by $-\xi$ and $-\zeta$ are orthogonal to those represented by ξ and ζ, the terms which are functions only of the unobserved polarizations will vanish in these averages and sums.

For the case of interest here the initial photon polarization ξ^0 and the initial electron polarization ζ^0 are specified. For this case, (II-3) takes the form,

$$d\sigma(\xi^0,\zeta^0)=4r_0^2(k^2/k_0^2)\times[\Phi_0+\Phi_1(\xi^0)+\Phi_1(\zeta^0)+\Phi_2(\xi^0,\zeta^0)]d\Omega. \qquad \text{(II-7)}$$

In this expression Φ_0 gives the usual Klein-Nishina formula independent of polarization, $\Phi_1(\zeta^0)\equiv 0$, and $\Phi_1(\xi^0)=0$ if no linear polarization of the gamma ray is present. Hence, with

$$d\sigma=d\sigma_0+d\sigma_1 P \qquad \text{(II-8)}$$

we have (To 56)

$$Pd\sigma_1=4r_0^2(k^2/k_0^2)\Phi_2(\xi^0,\zeta^0)d\Omega=-\tfrac{1}{2}Pr_0^2\left(\frac{k^2}{k_0^2}\right)\left(\frac{k_0}{k}-\frac{k}{k_0}\right)\cos\theta d\Omega. \qquad \text{(II-9)}$$

The electron polarization has been taken parallel (or antiparallel) to the direction of the incident photon,†† and P is the product of the polarizations of the photon and of the electron. (P is positive for a right circularly polarized gamma ray and an electron spin parallel to the direction of the incident photon.) Equation (II-9) is given in Gu 53. If an integration is performed over $d\Omega$, the part of the total cross section dependent on polarization becomes

$$\frac{\sigma_1}{2\pi r_0^2}=\frac{1+4k_0^2+5k_0^2}{k_0(1+k_0)^2}-\frac{1+k_0}{2k_0^2}\ln(1+2k_0). \qquad \text{(II-10)}$$

with k_0 in units of m_0c^2.

The ratio of the differential cross sections $d\sigma_1/d\sigma_0$ is plotted as a function of $\cos\theta$ for several energies in Fig. 4. This graph shows the difference in the sign of the response to polarization in the forward and backward quadrants. In general, also, the response at a given angle increases with increasing energy. The polarization-dependent total cross section σ_1 is presented as a function of energy in Fig. 5. The change in sign of σ_1 at $E=1.25m_0c^2=0.65$ Mev arises as a result of the difference in sign of $d\sigma_1$ for forward and backward directions together with the fact that the forward Compton scattering becomes more dominant at higher energies.

†† This condition is easily removed (see Gu 53 and Li 54a).

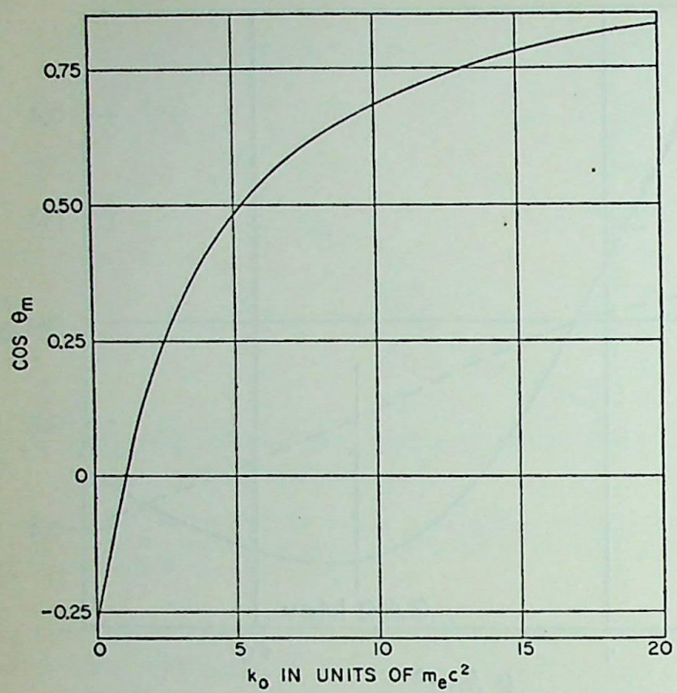

FIG. 6. Cosine of the Compton scattering angle which yields the maximum relative azimuthal anisotropy due to circular polarization, plotted as a function of the incident photon energy. In this case the circular polarization is perpendicular to the electron polarization (figure from Be 57).

This discussion has led to expressions applicable to the case in which circularly polarized gamma rays are scattered from electrons polarized parallel or antiparallel to the initial direction of propagation of the gamma ray. This is the case most used so far in experiments on circular polarization of gamma rays. Virtually all of these experiments detect the difference in the intensity of gamma rays transmitted through, or scattered forward, from magnetized iron, when the magnet is turned on and when it is turned off or reversed.

Recently Beard and Rose (Be 57) have suggested the use of the case in which the circularly polarized gamma rays are scattered from electrons polarized perpendicular to the initial direction of gamma-ray propagation. This case offers the advantage of determining an azimuthal asymmetry from two simultaneous measurements at opposite azimuthal scattering angles in the plane of the electron spin and photon propagation vector. Beard and Rose show‡‡ that at a certain scattering angle $\theta=\theta_m$, the relative azimuthal anisotropy J_1/J_0 is a maximum. Figure 6 gives a graph of $\cos\theta_m$ as a function of photon energy k_0. In Fig. 7, J_1/J_0 at $\theta=\theta_m$ is shown as a function of the energy of the incident photon. For completely polarized electrons, J_1/J_0 reaches a maximum value of 0.33 at 0.511 Mev.

The most significant practical limitation involved in applying the above cases to an experiment is the fact that only about 2 electrons of the 26 in an iron atom are polarized. Thus in all of the experiments performed on forward scattering and transmission of circularly polarized photons, the possible effects amount at most to only a few percent. In the case treated by Beard and Rose, even at 0.511 Mev where J_1/J_0 is maximum, there will be only a 5% effect (for complete photon polarization and ideal geometry).

‡‡ The cross section may be obtained in the manner that led to (II-9) except that the electron polarization is taken perpendicular to the direction of the incident photon.

B. Photodisintegration of the Deuteron

At gamma-ray energies below 20 Mev, and particularly below 10 Mev, the existing theory for the photodisintegration of the deuteron is satisfactory. This is the region of interest since we are concerned only with the polarization of gamma rays of nuclear origin. The threshold energy for the photodisintegration of the deuteron, 2.225 Mev (Be 56), places a definite lower limit on the energy of a nuclear gamma ray whose polarization can be studied using this mechanism. In the energy region of interest (2.225 to 20 Mev) the disintegration proceeds almost entirely by an electric dipole or magnetic dipole interaction. The former is sensitive to polarization, while the latter is not.

The cross section for the photodisintegration of the deuteron in the form derived by Bethe and Longmire (Be 50 and Be 56), assuming a central force potential, is expected to be valid below about 10 Mev. The differential cross section for electric dipole disintegration, the one that is polarization-sensitive is given by

$$d\sigma^e=2\left(\frac{e^2}{\hbar c}\right)\left[\frac{\gamma k^3}{(\gamma^2+k^2)^3}\right]\left(\frac{1}{1-\gamma r_{0t}}\right)\cos^2\alpha d\Omega, \quad \text{(II-11)}$$

where α is the angle between the direction of polarization of the gamma ray and the direction of motion of the proton (or neutron), and r_{0t} is the effective neutron-

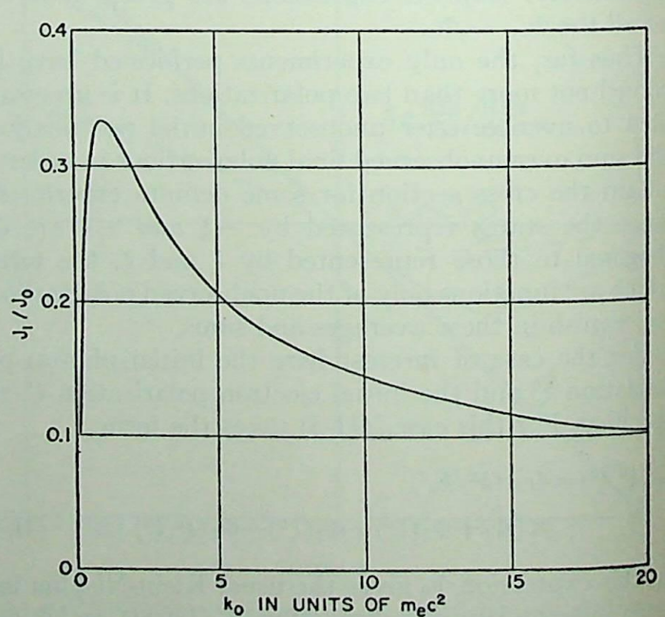

FIG. 7. Maximum relative azimuthal anisotropy J_1/J_0 resulting from Compton scattering of incident circularly polarized photons, plotted as a function of incident photon energy. The circular polarization is perpendicular to the electron polarization (figure from Be 57).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by eGangotri S3 Foundation USA

proton range in the triplet state. The parentheses containing r_{0t} represents a correction to the zero-range approximation for the cross section, which is given by the rest of the expression. The quantities γ and k can be obtained from the expressions

$$E=h\nu-W_1=\hbar^2k^2/M \qquad \text{(II-12)}$$

$$W_1=\hbar^2\gamma^2/M, \qquad \text{(II-13)}$$

where $h\nu$ is the energy of the gamma ray, W_1 the binding energy of the deuteron, and M the mass of the nucleon. That the angular distribution of the photoprotons varies as $\cos^2\alpha$ has been experimentally confirmed by Wilkinson (Wi 52) using the completely polarized gamma rays from the reaction $D_2(p,\gamma)He^3$.

Since it is usually the azimuthal distribution of photoprotons or photoneutrons that is observed in determining the polarization of a gamma ray, the more useful form of (II-11) is

$$d\sigma_{\phi^e}=\frac{2e^2}{hc}F(\gamma,k)\sin^2\theta\cos^2\phi d\Omega, \qquad \text{(II-14)}$$

where θ and ϕ are the usual polar coordinates. The direction of propagation of the gamma ray is given by $\theta=0$, and its direction of polarization by $\theta=90°$, $\phi=0$. The geometrical relationship of θ, ϕ, and α is illustrated in Fig. 1.

If the photodisintegration proceeded entirely by an electric dipole transition, the reaction would produce an ideal response to polarization in the sense defined above, namely that $R=d\sigma_{90}/d\sigma_0=0$.§§ Over a large part of the energy range of interest this is nearly the case. However, as the gamma-ray energy is decreased to the threshold value the reaction proceeds increasingly

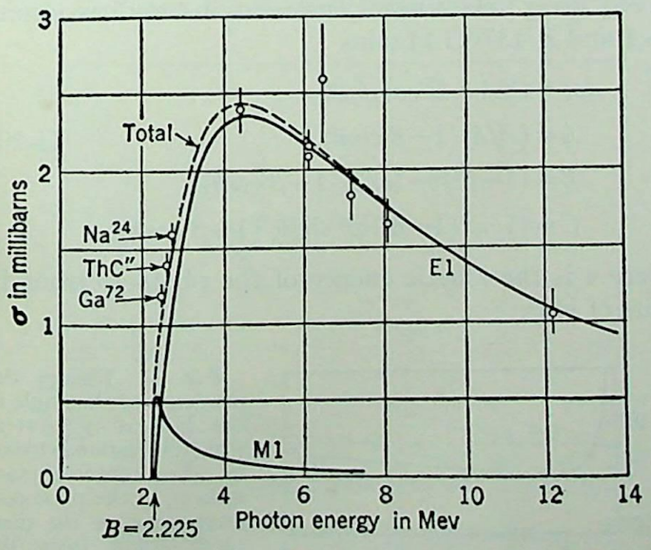

FIG. 8. Total cross section for the photodisintegration of the deuteron as a function of incident photon energy. Solid curves show the electric dipole and magnetic dipole cross sections as labeled, and dashed curve shows their sum. Points show representative experimental data (figure from Ev 55).

§§ In the Compton effect we have $R=\infty$ for an ideal response.

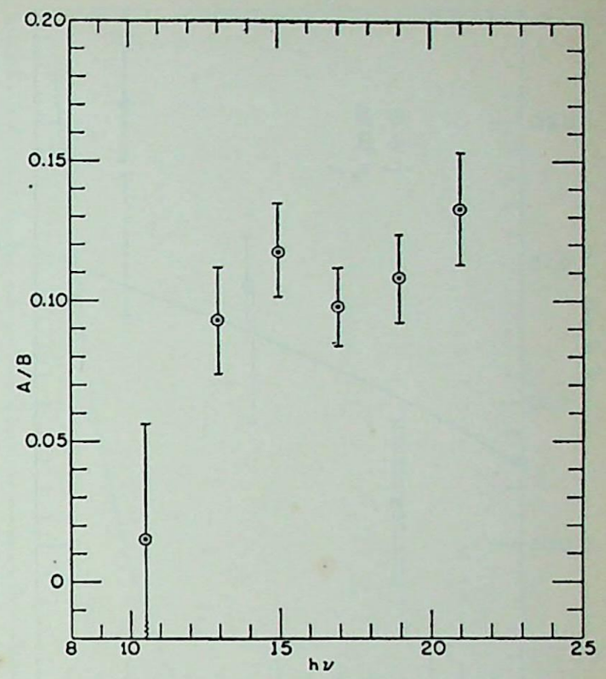

FIG. 9. The ratio A/B as a function of energy in Mev. This ratio is a measure of the isotropic term in the cross section for the photodisintegration of the deuteron. A noticeable effect starts at about 10 Mev (figure from Wh 58).

by the magnetic dipole interaction which yields an isotropic distribution of photoprotons. The total cross section for this process is given by (Se 53 and Be 50)

$$\sigma^m=\frac{2\pi}{3}\frac{e^2}{hc}\left(\frac{h}{Mc}\right)^2(\mu_n-\mu_p)^2\frac{k\gamma[\gamma-1/a_s]^2}{(k^2+\gamma^2)(k^2+1/a_s^2)}R(E), \qquad \text{(II-15)}$$

where μ_n and μ_p are the magnetic moments of the neutron and proton, respectively, a_s is the singlet scattering length, and $R(E)$ is a correction for the nonzero range of the neutron-proton force, which has been derived by Salpeter (Sa 51).

Since the presence of the magnetic dipole interaction diminishes the polarization sensitivity of the reaction as a whole, it is of interest to compare the total cross sections for the magnetic and electric processes as a function of the gamma-ray energy. The total cross section for the electric dipole process, obtained by integrating (II-11) over θ and ϕ, is

$$\sigma^e=\frac{8\pi}{3}\left(\frac{e^2}{\hbar c}\right)\left[\frac{\gamma k^3}{(\gamma^2+k^2)^3}\right]\left(\frac{1}{1-\gamma r_{0t}}\right). \qquad \text{(II-16)}$$

The two cross sections in the zero-range approximation (i.e., without the range correction given by the last factor in each expression) are compared in Fig. 8 (Ev 55). The sum of the two cross sections is also shown as are several experimental points which agree fairly well with the curve and indicate the extent of validity of the zero-range approximation.

Other effects, which generally tend to diminish the ideal polarization sensitivity of the electric dipole dis-

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

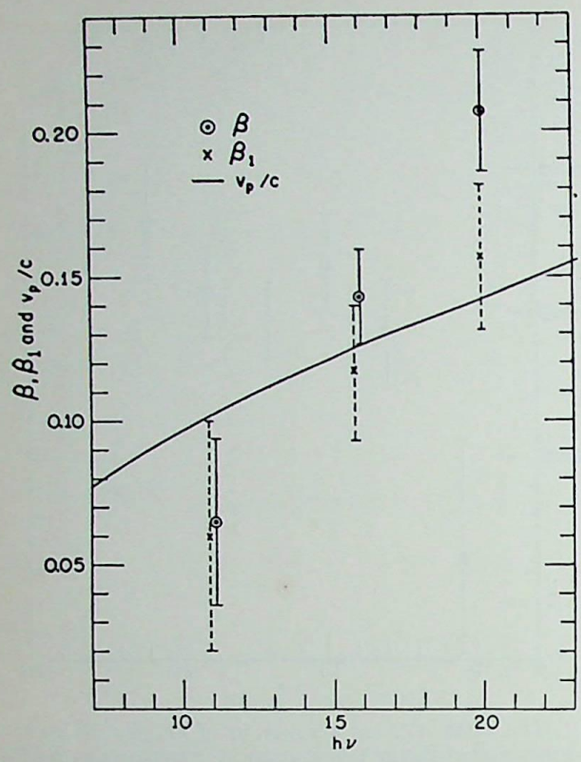

FIG. 10. The asymmetry coefficients β and β_1, as defined by (II-17) and (II-18), as a function of incident photon energy. Values of β and β_1 are obtained after first determining A/B. For comparison the theoretical prediction $v/c=[(h\nu-W_1)/Mc^2]^{\frac{1}{2}}$ (Ma 49) is plotted (figure from Wh 58).

integration, arise at energies above 10 Mev, and especially above 20 Mev. Since the nature of these effects is under current theoretical discussion, (Hu 57a) we confine attention to the empirical situation. The cross section is given in either one of the following forms (Wh 58):

$$d\sigma/d\Omega=A+B\sin^2\theta(1+2\beta\cos\theta), \qquad \text{(II-17)}$$

$$d\sigma/d\Omega=(A+B\sin^2\theta)(1+2\beta_1\cos\theta). \qquad \text{(II-18)}$$

The term in β or β_1 is attributed to the onset of the electric quadrupole interaction. In the recent experimental work by Whetstone and Halpern (Wh 58), values of A/B and β or β_1 have been determined as shown in Figs. 9 and 10. These values of A/B, along with those of Allen (Al 55), are in good agreement with the recent calculations of de Swart and Marshak (De 58).

All these expressions are given in the center-of-mass system. Thus, in addition to the forward asymmetry which appears at higher energies, a forward asymmetry arises experimentally in the laboratory system because of the forward momentum of the gamma ray. This effect is illustrated in Fig. 11 which gives the laboratory angle corresponding to 90° in the center-of-mass system. In the range of interest the shift is not large.

The magnetic dipole reaction and the deviations from the $\cos^2\alpha$ dependence above 10 Mev constitute the only significant effects that diminish the efficiency for detection of polarization in the energy region of interest here. In fact, from about 4 to 12 Mev the asymmetry ratio $R=d\sigma_{90}/d\sigma_0$ is less than 0.04. Perhaps the only serious drawback to the use of the photodisintegration of the deuteron in the detection of polarization is the relatively low total cross section ($\sim 10^{-27}$ cm^2; see Fig. 8).

C. Photoelectric Effect

The earliest measurements of polarization in the kev range made use of the photoelectric effect. Experiments using polarized photons having energies less than 40 kev (Wi 23, Bu 24, Ki 31) confirmed the basic theoretical prediction (Au 27, So 30) that the distribution of photoelectrons should vary approximately as $\cos^2\alpha$. As in the case of the photodisintegration of the deuteron, this distribution in terms of polar angles is $\sin^2\theta\cos^2\phi$, where α, θ, and ϕ are defined in the same way as before (Fig. 1).

The distribution has been calculated for electrons ejected from the K shell. Correspondingly, almost all the work dealing with the polarization sensitivity of the photoelectric effect has been concerned with emission from the K shell,|| || since it constitutes about 80% of the total emission for the energies of interest here (below about 1 Mev).

Fischer (Fi 31) and Heitler (He 44) have given the differential cross section in a nonrelativistic form (good to energies of about $\frac{1}{2}m_0c^2$):

$$d\sigma_\phi=r_0^2Z^5\frac{(32)^{\frac{1}{2}}}{137^4}\left(\frac{m_0c^2}{k_0}\right)^{7/2}\times\frac{\sin^2\theta\cos^2\phi}{[(1+k_0/2m_0c^2)^2-\beta\cos\theta]^4}d\Omega, \qquad \text{(II-19)}$$

where $\beta=v/c$ and Z is the atomic charge. Sauter (Sa 31, Sa 55) using relativistic considerations and assuming $\beta\sim 1$ and $Z/137\ll 1$ obtains

$$\begin{aligned} &d\sigma_\phi\sim C(A+B\cos^2\phi)d\Omega,\\ &A=(\epsilon^2/4)(1-\beta\cos\theta), \qquad \text{(II-20)}\\ &B=(1-\beta^2)^{\frac{1}{2}}-(\epsilon/2)(1-\beta\cos\theta)\\ &C=(1/\epsilon)^4(1-\beta^2)^{\frac{1}{2}}\beta^2\sin^2\theta/(1-\beta\cos\theta)^4, \end{aligned}$$

where ϵ is the kinetic energy of the photoelectrons in units of m_0c^2.

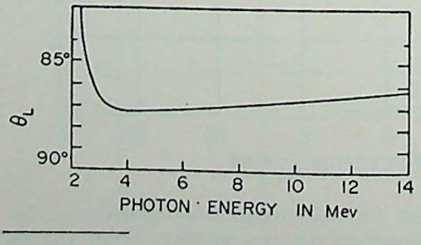

FIG. 11. Energy dependence of the angle in the laboratory system which corresponds to 90° in the center-of-mass system, in the photodisintegration of the deuteron (data from Wi 51a).

|| || A nonrelativistic calculation by Schur (Sc 30) gives an azimuthal distribution for the electrons ejected from the L_I level similar to the nonrelativistic K-shell distribution. However, the emissions from the L_I shell represent only a small fraction of those emissions (20%) which are not from the K shell.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

In these expressions there is a pronounced forward asymmetry in the angular distribution which increases as the energy of the gamma ray is increased. This effect is illustrated in Fig. 12 which gives theoretical curves for the photoelectron distribution as a function of θ for several energies. In the nonrelativistic case the response to polarization is ideal, i.e., $R=d\sigma_{90}/d\sigma_0=0$. In the relativistic case, however, the response is decreased by the fractional amount A/B. Another effect predicted by (II-20) is that the favored direction of emission of the photoelectron changes by 90° as the gamma-ray energy passes through 0.51 Mev. This is shown in Fig. 13.¶¶ Accordingly, above 0.51 Mev the photoelectron would be emitted preferentially normal to the direction of polarization of the gamma ray.

A series of measurements with polarized photons (>40 kev) designed to investigate this and other features of Sauter's expression has been carried out by Hereford and co-workers. Hereford (He 51, He 51a) studied the azimuthal distribution of the photoelectrons ejected from lead by the polarized radiation from positron-electron annihilation, and found a much greater asymmetry in the azimuthal distribution than predicted by (II-20). In a revised experiment Hereford and Keuper (He 53) obtained a result in rough agreement with that predicted by Sauter, if his equation, which is valid chiefly for low Z, is applied to the case of lead. McMaster and Hereford (Mc 54) continued the experiments by measuring the azimuthal asymmetry using photons (from Co^{60}) which had been polarized by Compton scattering. By changing the angle of scattering they were able to obtain polarized gamma rays of different energies. Their measured values of R fell below unity above about 0.55 Mev, showing fair agreement with the theoretical curve in Fig. 13.

Brini *et al.* (Br 57) recently repeated the experiment

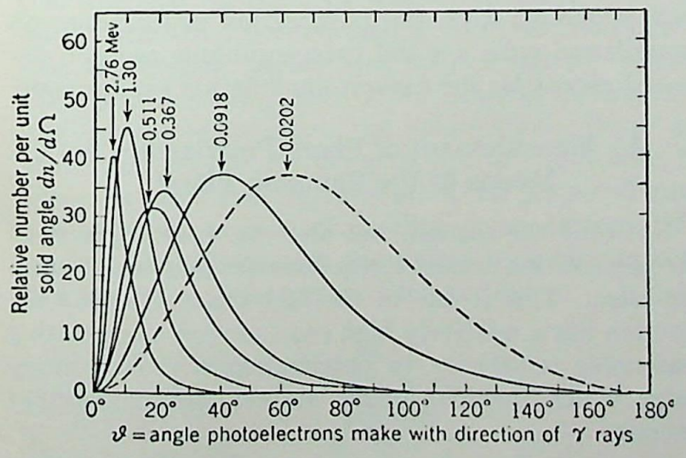

FIG. 12. Differential cross sections for photoelectrons ejected from the K shell, plotted against the angle of emission. The curves for the different photon energies are not normalized with respect to each other. Solid curves are calculated from Sauter's relativistic formula (Sa 31), the dashed curve from Fischer's non-relativistic formula (Fi 31) (figure from Ev 55).

¶¶ In this figure it is the reciprocal of R (as previously defined) that is plotted.

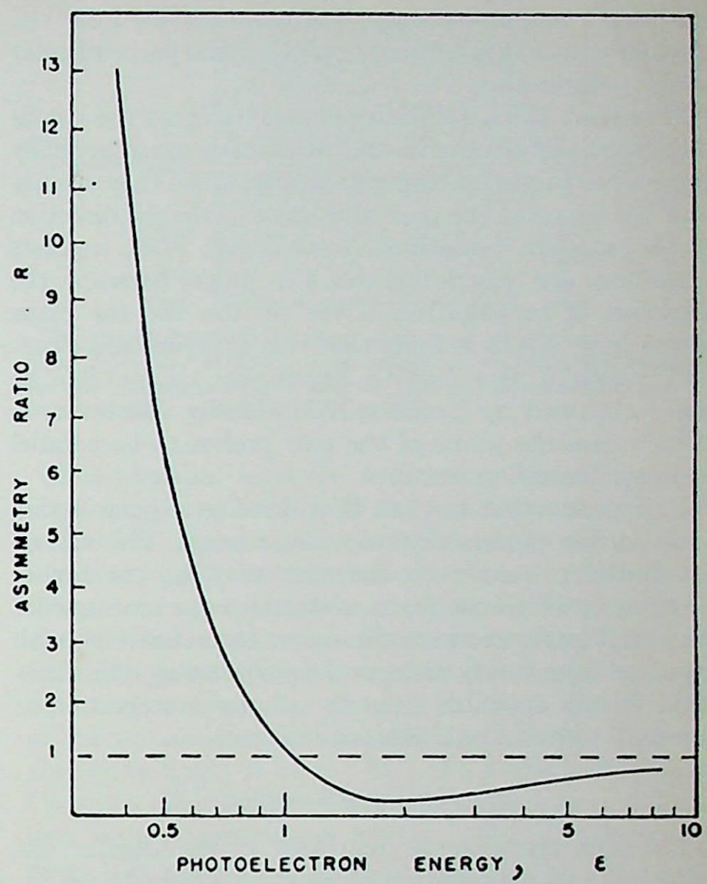

FIG. 13. Asymmetry ratio $R=d\sigma_0/d\sigma_{90}$ for photoelectrons ejected from the K shell by linearly polarized photons for $\theta=90°$, as calculated from Sauter's formula (Sa 31). The abscissa is the incident photon energy in units of m_0c^2 (figure from Mc 54).

of McMaster and Hereford, but did not find the 90° shift in the polarization response. Their data agree better with a theoretical curve of Archibald as given in Br 57. Apparently the knowledge of the polarization sensitivity of the photoelectric effect at higher energies is still somewhat uncertain. However, it is clear that the reaction can be used for gamma-ray energies which are well below 0.5 Mev.

The primary disadvantage of the photoelectric effect as an analyzer of polarization is that it requires detection of the photoelectron. Low-energy electrons are somewhat more difficult to detect than are the gamma rays in a typical Compton process. Furthermore, the scattering of low-energy electrons will present a serious problem.

D. Other Polarization-Sensitive Processes

(a) *Pair Production*

Berlin and Madansky (Be 50a) have investigated the possibility of using pair production as a polarization analyzer. Assuming a perfectly plane polarized incident photon they have calculated the expected asymmetry ratio $R=d\sigma_{90}/d\sigma_0$ for several different experimental cases. They prefer the experimental arrangement in which all pairs in a particular plane are counted re-

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

gardless of angle or energy. For this case $R=1.23$; i.e., the pair emission is a maximum in a plane perpendicular to the polarization.

However, Wick (Wi 51) pointed out that the conditions specified by Berlin and Madansky are practically impossible to realize experimentally, since they specify that the plane of the pair contains exactly the direction of the incident quantum. Accordingly, Wick suggests removing the restriction on the angle between the direction of propagation of the photon and the plane of the pair. He then finds that this experimental situation yields a polarization sensitivity comparable to those obtained by Berlin and Madansky. However, in Wick's case the plane of the pair prefers to be parallel to the polarization vector.

Pair production has not been used as a polarization analyzer for gamma rays of nuclear origin. This can be attributed primarily to the fact that, at the higher energies at which the reaction would prove most useful, the small angle between the pairs, the relatively small expected asymmetry ratio, and the scattering difficulties make it less desirable than the photodisintegration of the deuteron as a polarization analyzer.

(*b*) *Nuclear Photoeffect*

Although the general treatment of the angular distribution and polarization of reaction products (Bl 51, Si 53) is applicable to photonuclear reactions, Agodi (Ag 57) has given a specific treatment of the polarization sensitivity of photonuclear reactions. Without using a model for the nucleus for the photonuclear reaction, Agodi shows on quite general grounds (conservation of parity and angular momentum) that the azimuthal dependence of the differential cross section assumes a form proportional to $(1+\alpha\cos^2\phi)$, where ϕ is the azimuthal angle as defined in Fig. 1. This result is quite general regardless of whether a single or mixed multipole transition is involved in the photonuclear process. In the case in which a single multipole is reponsible for the transition, the value of α for a completely polarized incoming gamma ray can be determined from the angular distribution (in θ) coefficient, if it is known. Such is not generally the case, however, when two or more multipoles contribute to the transition.

Apart from the photodisintegration of the deuteron, the most promising of all the known photonuclear reactions is the reaction $Be^9(\gamma,n)Be^8$. Since the threshold energy is about 1.66 Mev and the cross section at 9.5 Mev is about 1.6 mb, this reaction could compete with the photodisintegration of the deuteron as an effective analyzer of polarization for gamma rays if the value of α were large enough.

(*c*) *Photofission*

Winhold and Halpern (Wi 56), Katz *et al.* (Ka 58), and others have shown experimentally that certain nuclei subject to photofission exhibit anisotropy in the angular distribution of the fission fragments. Two such nuclei, the even-even nuclei, Th^{232} and U^{238}, for example, show angular distributions of the form $(a+b\sin^2\theta)$. Although the form of the distribution remains the same over the energy range studied (5 to 20 Mev), the ratio b/a varies from values of the order of 10 near threshold (just above 5 Mev) to values of the order of 0.1 in the vicinity of 20 Mev. The anisotropic distribution is assumed to result from an electric dipole interaction. Consequently, although the azimuthal distribution produced by polarized photons has not yet been studied, the foregoing angular distribution implies a polarization sensitivity proportional to b/a. Other nuclei, such as the odd-A nuclei, U^{235} and Pu^{239}, have essentially isotropic angular distributions and thus are not expected to manifest any sensitivity to polarization.

Although the photofission cross sections in the energy region of interest here are of the order of 10 mb, the fact that appreciable anisotropy in the angular distribution is confined to the region roughly 2 to 3 Mev above threshold places some limitation on the potential use of photofission as a polarization analyzer. In addition, if neutron-induced fission or spontaneous fission is present, the detection of the photofission might become very difficult.

III. MEASUREMENTS OF POLARIZATION OF NUCLEAR GAMMA RAYS

The following discussion is organized primarily on the basis of the type of polarization-sensitive mechanism involved. Attention has been given to chronological order only insofar as it lends itself to a logical development. The development of technique has also been a consideration in selecting experiments for discussion. A complete listing and outline of the experiments is attempted in Table XIII at the end of Part III. Since this discussion is primarily devoted to experiments on *nuclear* gamma rays, the polarization experiments on annihilation radiation and bremsstrahlung are not discussed except for the earliest annihilation experiments.

A. Measurement of Plane Polarization by Means of the Compton Effect

Not only the earliest, but also the most utilized, of the polarization sensitive reactions has been the Compton effect. This is due to the fact (Part II) that the reaction has a relatively high cross section along with a reasonable sensitivity to polarization over an energy range which includes many nuclear gamma rays of interest.

In general, a polarimeter that uses the Compton effect consists of a scatterer and an analyzer which detects the scattered radiation. The elements of such a polarimeter are shown in Fig. 14. Here the polarimeter consists of the elements B and C. Gamma rays from the source impinge on the Compton scatterer B and the scattered radiation is detected by the analyzing element

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

C. As a general rule B and C are crystals of scintillation counters and coincidence between B and C are measured. This makes it considerably easier to isolate and detect the desired Compton events. A polarization measurement is made by determining N_0/N_{90} (often called $N_{\parallel}/N_{\perp}$), the ratio of the coincidence counting rate when C is placed at $\phi=0°$ to that when it is placed at 90°. In principle, B could be merely a piece of scattering material, and the polarization measurement would depend only on the single counting rate in C at the 0° and 90° positions. However, in this case the shielding (and electronic discrimination) would have to be exceedingly good to prevent direct radiation from the source being recorded in C. See Sec. (a).

Except in the earliest experiments, a polarimeter has generally consisted of an organic scintillator for the scatterer and a sodium-iodide crystal for the detector of the scattered gamma ray. An organic scintillator, a material of low Z, makes a good scatterer because it permits fairly free escape of the scattered photons. Naturally, sodium iodide is the best analyzing crystal because of its high efficiency and good resolution for the detection of gamma rays. The objection to the use of sodium iodide for this purpose in the earliest experiments was the long decay time of its pulses. Development of suitable electronic techniques has greatly diminished this difficulty.

Circular polarization experiments utilizing the Compton effect are discussed in the last section of this part.

(*a*) *Early Experiments on Annihilation Radiation*

Although this paper deals mainly with the polarization of gamma rays of nuclear origin, for convenience and historical interest we begin with a brief discussion of the first measurements of polarization, those performed in order to detect the mutually perpendicular polarizations of the two quanta resulting from the annihilation of a positron and an electron. This prediction of the pair theory was pointed out by Wheeler (Wh 46). Assuming that two Compton polarimeters would be used to detect the polarizations, Pryce and Ward (Pr 47) and Snyder *et al.* (Sn 48) calculated the expected azimuthal distribution of one scattered quantum relative to the other. This is an example of a polarization-polarization correlation with the angle between the two polarimeters fixed at 180°.

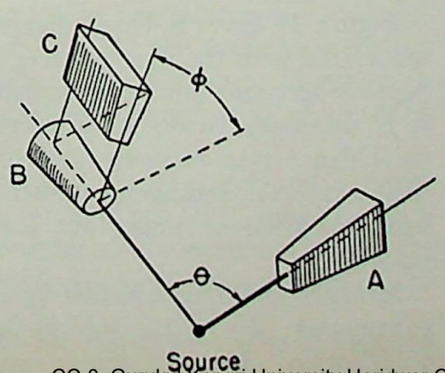

FIG. 14. Schematic diagram of experimental arrangement of scintillating crystals in an apparatus designed to measure a direction-polarization correlation. Crystals B and C constitute the polarimeter; crystal A is the directional counter (figure from Me 50).

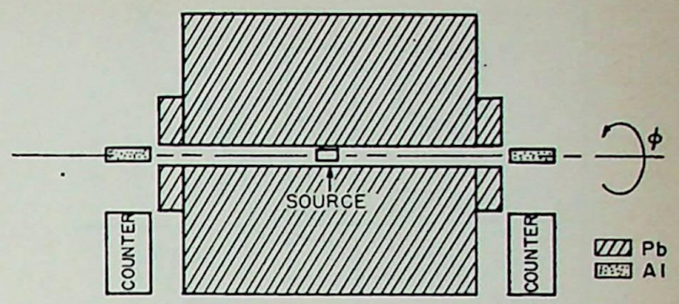

FIG. 15. Schematic diagram of typical experimental arrangement for study of linear polarization of annihilation radiation. In this illustration the scatterers are made of aluminum. The counters are in the parallel (‖) position.

The essential features of the experimental arrangement are shown in Fig. 15. The positron source (Na^{22} or Cu^{64}) is placed at the center of a hole about $\frac{3}{8}$ in. in diameter bored through the center of a lead block with dimensions approximately 6×6×6 in. The oppositely directed annihilation radiation beams emerging from the openings then impinge upon cylindrical scatterers (not detectors in this case) about 1 in. long. The detectors of the scattered radiation are placed so that the mean scattering angle is about 82°, the angle at which the Compton effect exhibits optimum sensitivity to polarization for this gamma-ray energy. (Fig. 2.) The experiment then consists in determining $N_{\perp}/N_{\parallel}$, the ratio of the coincidence counting rate when the axes of the two detectors are at right angles to each other to that when they are parallel.

Bleuler and Bradt (Bl 48) using G-M counters with end-windows as detectors confirmed the predicted correlation, although their results have a relatively large margin of error. They obtained $N_{\perp}/N_{\parallel}=1.9\pm0.3$ as compared to the theoretically predicted ratio of ~1.7 for their geometry. Shortly thereafter, Hanna (Ha 48a) performed the experiment using G-M tubes and obtained values of $N_{\perp}/N_{\parallel}$ which were consistently lower than the theoretical values. Vlasov and Dzhelepov (Vl 49) obtained 1.7 ± 0.2. However, the approximations used in obtaining the theoretically expected ratio for their geometry were sufficiently rough that essentially there was only qualitative agreement with the theory. Wu and Shaknov (Wu 50) repeated the experiment using anthracene scintillation counters and obtained a value of $N_{\perp}/N_{\parallel}=2.04\pm0.08$, which compares well with the theoretical value of 2.00 for their geometry.

(*b*) *Direction-Polarization Correlation*

The arrangement of the scintillation crystals for a direction-polarization correlation experiment is shown in Fig. 14, in which A is the crystal of the counter which is insensitive to polarization and records only the direction of one gamma ray and B and C are the crystals of the Compton polarimeter which measures the linear polarization of the other gamma ray. The phototubes associated with the three crystals are em-

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

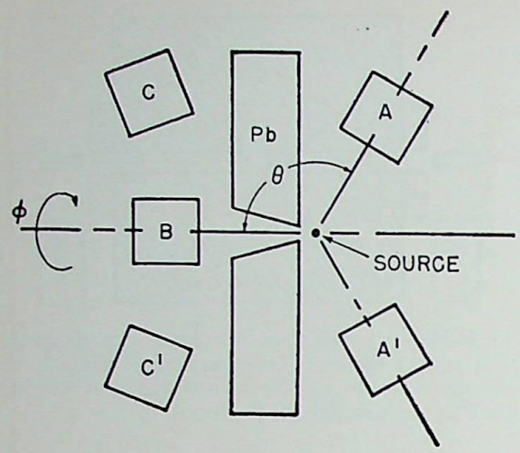

FIG. 16. Schematic diagram of apparatus of Metzger and Deutsch. Two additional counters are used to increase the yield in the measurement of the direction-polarization correlation. In the position shown, $\phi=0$ (after Me 50).

ployed in a triple-coincidence circuit. Thus, a measurement of the polarization is obtained from the ratio of the triple-coincidence yields with crystal C at $\phi=0°$ and at $\phi=90°$. The direction-polarization correlation is then obtained by determining this ratio as a function of the correlation angle θ. The ratio of the counting rates is N_0/N_{90} from which one obtains the true polarization ratio J_0/J_{90} discussed in Part I.

Thorough consideration must be given to the possibility of recording "false" coincidences as a result of radiation being counted and scattered among the three crystals in combinations different from the one desired. Usually a good shield is placed in front of counter C to diminish the amount of direct radiation from the source or scattered radiation from A arriving at C. This shield diminishes the chance that one gamma ray goes to A while the other one goes to C and is then scattered to B, or that one gamma ray goes to B while the other goes to A and is scattered to C.

As mentioned in Part I, there is little to be gained (Ha 48) by putting a polarimeter at A as well as at B, C. Furthermore, if the corresponding direction-direction correlation is known it is only necessary in virtually all cases to measure the direction-polarization correlation at a single angle. This angle is usually selected so as to maximize the effect and it is often 90°.

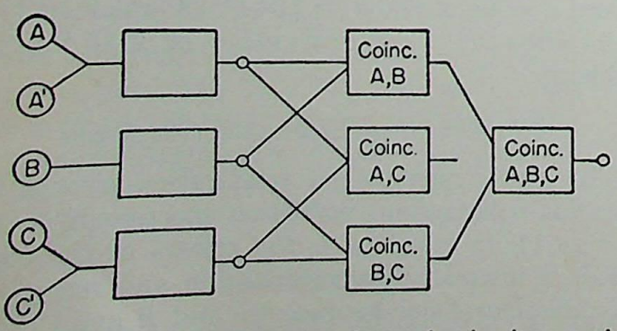

FIG. 17. Block diagram of the electronic circuits associated with the experimental arrangement shown in Fig. 16. Empty blocks represent appropriate stages of amplification, etc. (figure from Me 50).

Metzger and Deutsch (Me 50) first used the technique of the direction-polarization correlation in the study of several gamma-gamma cascades. The method has been extended by others to the study of correlations in which the radiation whose polarization is not analyzed is some other type of particle, either emitted or absorbed.

(c) *Experiments of Metzger and Deutsch*

The classic experiments of Metzger and Deutsch (Me 50) exemplify the techniques involved in the measurement of direction-polarization correlations. Figure 16 is a schematic diagram of the experimental arrangement. Naphthalene was used for all of the crystals in this arrangement, but Metzger and Deutsch suggest the use of anthracene would be an improvement.

Counters A' and C' add to the original coincidence combination ABC three more equivalent (theoretically and experimentally) combinations ABC', $A'BC$, $A'BC'$, so that the real coincidence yield is increased by a factor of four. The addition of C' also, to a first approximation, cancels the effect of any small asymmetry resulting from a possible misalignment of the axis of the polarimeter.

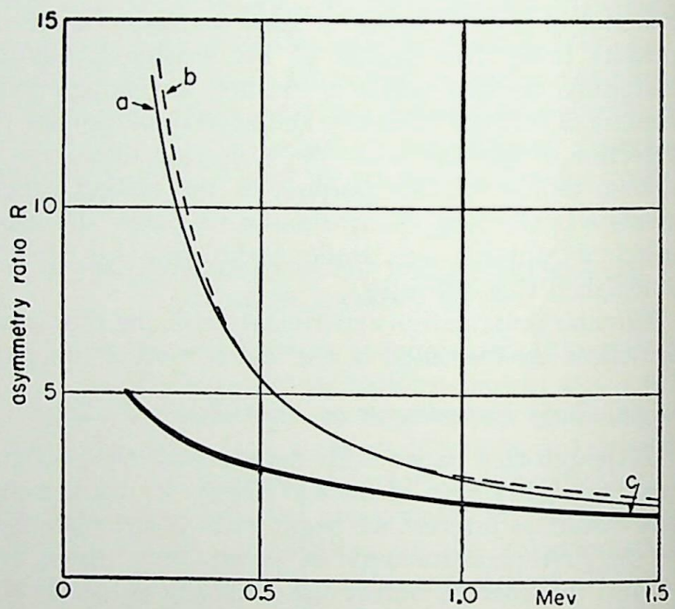

FIG. 18. Asymmetry ratio R as a function of gamma-ray energy in Mev for different geometries: (a) $\theta_c=80°$, ideal geometry; (b) $\theta_c=(\theta_c)$ max, ideal geometry; (c) $\theta_c=80°$, $\Delta\theta_c=55°$, $\Delta\phi=60°$ (figure from Me 50).

Figure 17 gives a block diagram of the electronics associated with the five counters. This system makes it possible to count double coincidences separately, which it is necessary to do in order to monitor the triple-coincidence rate properly and to determine the accidental rate. An arrangement such as this, or its equivalent, has been an important feature of all Compton polarimeters.

Metzger and Deutsch distinguish three polarization parameters: $p=J_0/J_{90}$, which describes the state of polarization of the gamma ray incident upon the

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

polarimeter; R, the asymmetry ratio, which is a measure of the polarization sensitivity of the polarimeter taking into consideration nonideal geometry; and N_0/N_{90}, the ratio of the triple-coincidence counting rates with the polarimeter set at $\phi=0$ and $\phi=90°$. These three parameters are related through the expression

$$N_0/N_{90}=(p+R)/(pR+1). \qquad \text{(III-1)}$$

For the case of ideal geometry (Part II) R is simply the ratio of two differential cross sections for Compton scattering, i.e., $R=d\sigma_{90}/d\sigma_0$. There is an angle of scattering*** $\theta_c=(\theta_c)_{\max}$ at which R is a maximum for ideal geometry. The dependence of R on the energy of the initial photon, as calculated by Metzger and Deutsch, is given as curve b in Fig. 18 for $\theta_c=(\theta_c)_{\max}$. Curve a shows the dependence of R for $\theta_c=80°$, which Metzger and Deutsch chose as a mean value. In order

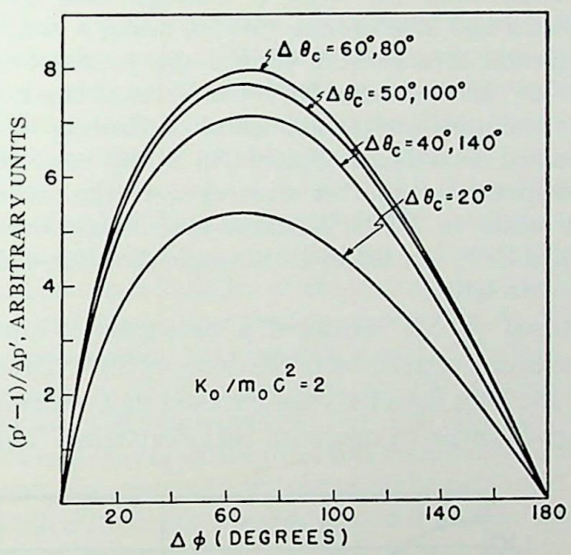

FIG. 19. Figure of merit of a Compton polarimeter as a function of the spread in the angle ϕ, for various spreads in θ_c. Incident photon energy equal to 1 Mev, and $p=1.2$. The curves do not differ significantly from those in Me 50.

to obtain statistically significant counting rates, however, it is necessary to use angular spreads $\Delta\theta_c$ and $\Delta\phi$, which are considerably greater than zero, so that R is appreciably reduced. Metzger and Deutsch use $(p'-1)/\Delta p'$ as a figure of merit for a polarimeter, where p' is the observed polarization ratio, and $\Delta p'$ its error. This quantity is given as a function of the angular spreads in Figs. 19 to 22 for two gamma-ray energies. For angular spreads of 60°–70°, the figure of merit is a maximum over a wide range of energy. Hence, it is possible to design an efficient polarimeter of considerable versatility.

The actual spreads used by Metzger and Deutsch were $\Delta\theta_c=55°$ and $\Delta\phi=60°$. That these were the effective values was determined experimentally in the following way. The partially polarized radiation result-

*** Here, θ_c is used for the scattering angle to distinguish it from the correlation angle θ.

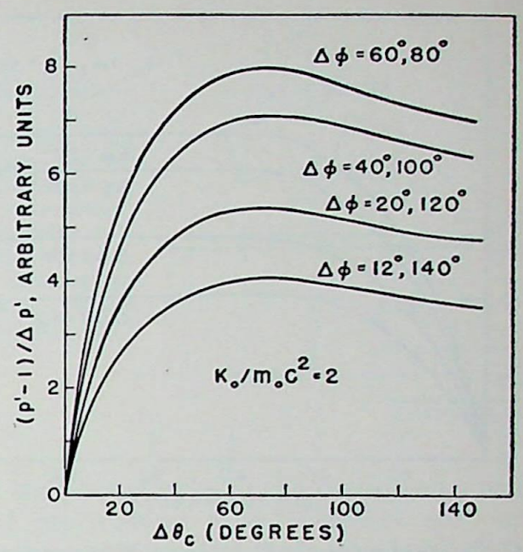

FIG. 20. Figure of merit of a Compton polarimeter as a function of the spread in the angle θ_c, for various spreads in ϕ. Incident photon energy equal to 1 Mev, and $p=1.2$. The curves do not differ significantly from those in Me 50.

ing from the Compton scattering of a collimated beam of gamma rays from a strong Co^{60} source impinged on the scattering crystal of the polarimeter. The degree of polarization p of this radiation is known through the Klein-Nishina formula. A measurement of N_0/N_{90} then determines R through the use of (III-1). With this value of R, the angular spreads $\Delta\theta_c$ and $\Delta\phi$ are obtained for the energy appropriate to the scattered quanta. With these values of $\Delta\theta_c$ and $\Delta\phi$, the curve for R as a function of energy was then constructed and is given as curve c in Fig. 18.

With the equipment and techniques discussed, Metzger and Deutsch measured the direction-polarization correlations in the decays of Sc^{46}, Co^{60}, Rh^{106}, and Cs^{134}. Essentially as a check on the experimentally known direction-direction correlations (Br 48) and to elucidate the method, the polarizations were measured as a function of θ. For each nucleus, possible direction-polarization correlations were calculated from the known coefficients of the direction-direction correlation. Thus, for the cascade $j_1(L_1)j(L_2)j_2\rightarrow 4(2)2(2)0$, the

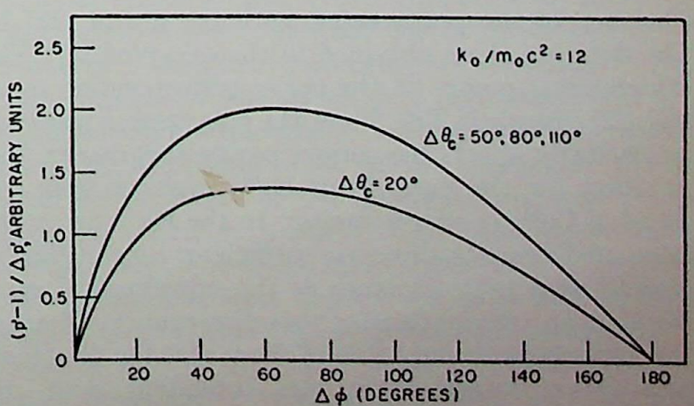

FIG. 21. Figure of merit of a Compton polarimeter as a function of the spread in ϕ, for various spreads in θ_c. Photon energy equal to 6 Mev, and $p=1.2$.

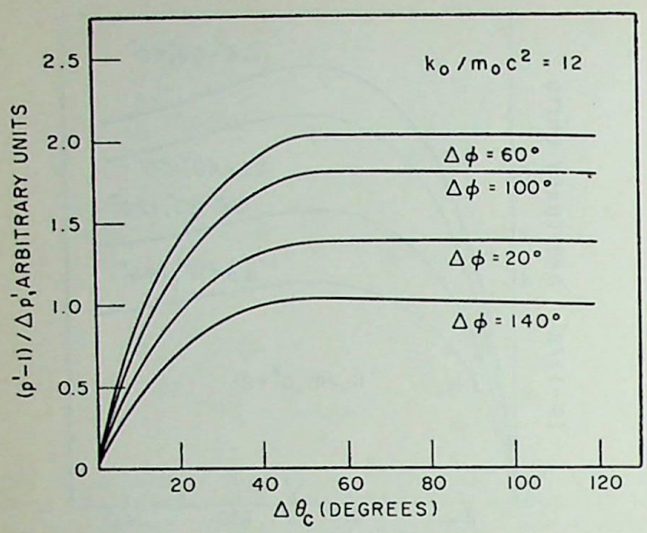

FIG. 22. Figure of merit of a Compton polarimeter as a function of the spread in θ_c, for various spreads in ϕ. Photon energy equal to 6 Mev, and $p=1.2$.

direction-direction correlation is

$$W(\theta)=1+(1/8)\cos^2\theta+(1/24)\cos^4\theta.$$

The direction-polarization correlation can be written down from Table III(b). At $\theta=90°$, for example

$$W(90,\gamma)=1\pm\cos 2\gamma(1/8+1/24).$$

The sign is + or − according as the radiation is electric or magnetic. This expression applies if the first gamma ray goes to the directional counter and the second to the polarimeter, or if the gamma-ray paths are interchanged. In the experiment, both processes were observed indistinguishably with about equal efficiencies. Hence (at $\theta=90°$),

$$p=\frac{J_0}{J_{90}}=\frac{2+(\pm)L_1 0.17+(\pm)L_2 0.17}{2-(\pm)L_1 0.17-(\pm)L_2 0.17}$$

and $p=1.40$, 1, or 0.71 depending on whether the gamma rays in the cascade are $(E2,E2)$, $(E2,M2)$ or $(M2,E2)$, or $(M2,M2)$. The complete correlation can be worked out in similar fashion.

Figure 23 gives the three curves modified by the efficiency of the polarimeter, with the aid of (III-1). The data are those obtained in the decay of Sc^{46}. The experimental points fit the curve corresponding to an $(E2,E2)$ cascade in Ti^{46}. Thus, the polarization measurement clearly selects the correct parity assignment. The situation for the cascade in Ni^{60} resulting from the decay of Co^{60} is entirely similar. In the Rh^{106} decay the calculated direction-direction coefficients for a 0(2)2(2)0 scheme were twice as large as the experimental ones. Without an explanation for this discrepancy, Metzger and Deutsch were only able to show that the direction-polarization measurement was consistent with the direction-direction measurement. The experimental result was interesting in that the polarization changes direction at $\theta\simeq 120°$, attaining large values on either side of this angle. In the case of Cs^{134}, the possible participation of other coincident gamma rays in the correlation made a unique assignment impossible. Again the direction-polarization correlation was consistent with the direction-direction correlation, and the result was not unlike that for Sc^{46} and Co^{60}.

(d) *Other Measurements with Radioactive Sources*

Since the Metzger-Deutsch experiments, there have been many other measurements of direction-polarization correlations in a variety of nuclei. The same basic techniques are common to all. Naturally, there have been modifications and improvements to fill the needs of each new experiment. Accordingly, in the review of the remaining experiments using the Compton polarimeter only those techniques which represent relatively distinctive additions to the art are discussed.

Shortly after the work of Metzger and Deutsch, Williams and Wiedenbeck (Wi 50) using a similar experimental arrangement verified the results on Rh^{106} and Co^{60}. In the case of Rh^{106} the factor of two between the theoretical and experimental coefficients could be explained according to Spiers (Sp 50) by assuming the participation of another state close to the second excited state in Pd^{106}. Williams and Wiedenbeck also studied Cs^{134}, but found an isotropic direction-polarization correlation.

Stump (St 52) measured a beta-gamma direction-polarization correlation in the decay of Sb^{124}. The source and the beta detector were enclosed in a vacuum container in order to minimize beta scattering. The beta

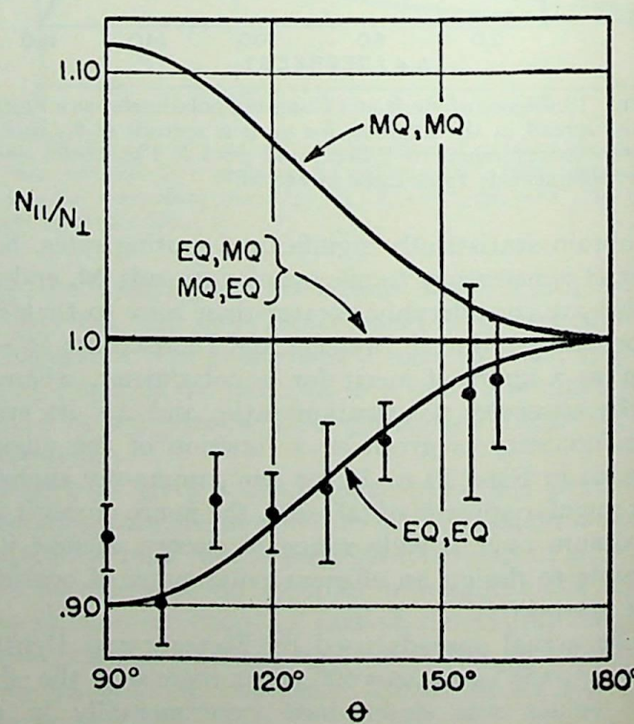

FIG. 23. Gamma-gamma direction-polarization correlation in the decay of Sc^{46}. The ratio $N_{11}/N_\perp$ is plotted against θ. The three curves correspond to the different parity assignments in the spin sequence 4-2-0 (figure from Me 50).

Savitribai Phule Pune University Handwar Collection. Digitized by S3 Foundation USA

detector consisted of a thin crystal of anthracene mounted on the end of a light pipe leading to a photomultiplier tube outside the vacuum chamber. The polarimeter was considerably improved in efficiency by using an anthracene crystal as the scattering crystal and two oppositely placed sodium-iodide crystals as detectors of the scattered gamma rays. Since the angular correlation coefficients were already known (St 51) and quadrupole radiation is involved, it was necessary to take measurements only with the polarimeter at 90° to the beta counter. Stump found a value of about 1.1 for the ratio N_0/N_{90}. This datum, used in conjunction with the correlation coefficient, led to the conclusion that no parity change occurred in the gamma transition.

Further work on the radioactive nuclei Co^{60}, Cs^{134}, and Sb^{124} was done by Kloepper *et al.* (Kl 52). Plastic scintillators and type 5819 phototubes were used. The phototubes were shielded from magnetic fields in order to reduce the spurious dependence of the coincidence rate upon counter position. Residual effects were investigated by comparing the triple-coincidence rate to the single-channel counting rates at the various positions. In addition to monitoring the single rates, the various double-coincidence combinations, and the resolving time, the instrument was checked with observations at $\theta=\pi$, where N_0/N_{90} must equal 1.0. The gamma-gamma direction-polarization correlation for Co^{60} was measured to establish the reliability of the instrument. The result agreed with the earlier measurements (Me 50, Wi 50).

The polarization measurements on Cs^{134} agreed with the results of Metzger and Deutsch (Me 50), but not with those of Williams and Wiedenbeck (Wi 50). It was pointed out that both the direction-polarization and the direction-direction correlations could be explained with a $4(E2)2(E2)0$ decay scheme, provided a 35% isotropic component is assumed to be present in both correlations.

In the case of Sb^{124} the gamma-gamma directional and polarization correlations were essentially isotropic. The authors suggested a $3(10\%\ E2;\ 90\%\ M1)2(E2)0$ decay scheme. The beta-gamma direction-polarization correlation was also studied with this source. The measurement agreed with the result of Stump (St 52) confirming the $E2$ nature of the radiation.

Additional work on the decay of Cs^{134} was done by Robinson and Madansky (Ro 52) who measured a polarization-polarization correlation for the gamma rays. The experiment was quite similar to the investigations on annihilation radiation (see Fig. 15). In fact, Robinson and Madansky first performed the experiment with annihilation radiation in order to determine experimentally the effective solid angle corrections. The signals from the two scattering crystals (stilbene) went to a coincidence circuit (7×10^{-8} sec), the output of which triggered an oscilloscope. The pulses from the two analyzing crystals (NaI) were delayed, one more than the other, and displayed on the (triggered) oscilloscope. A coincidence analysis could be made by visual inspection of the photographs of the oscilloscope traces. The ratio of the number of coincidences with analyzing counters perpendicular to the number with the counters parallel was 0.91 ± 0.08. This result is not in disagreement with assignments of spins and parities made from the other correlation experiments on this nucleus (Wa 50, Pe 51, Ro 51).

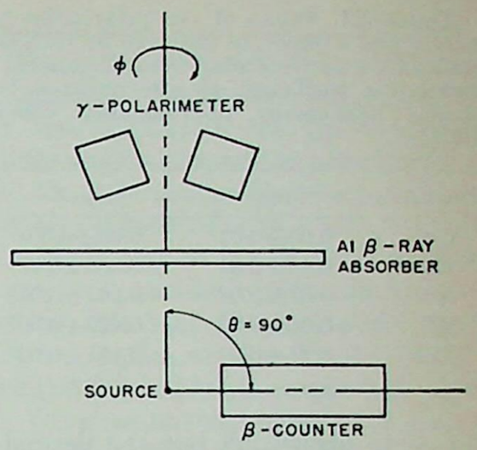

FIG. 24. Schematic diagram of the apparatus of Hamilton *et al.* which uses two equivalent counters in the polarimeter. This apparatus was used to measure beta-gamma polarization correlations (figure from Ha 53a).

A study of the direction-polarization correlation for the cascade involving the first two excited states of Pb^{208} in the ThC″ decay was made by Kraushaar and Goldhaber (Kr 53). Again, a polarimeter of the Metzger-Deutsch type was used and a value for the efficiency was obtained by observing the polarization of scattered Co^{60} radiation. However, a more realistic value for the efficiency of the polarimeter was obtained by measuring the already known direction-polarization correlations for Co^{60} and Rh^{106} sources. For the measurement in the Pb^{208} cascade, a value of $N_0/N_{90}=0.958\pm0.3$ was obtained. This result, in conjunction with the result of Petch and Johns (Pe 50) on the direction-direction correlation, indicates an assignment of $4(E2)2(E2)0$ to the cascade in Pb^{208}.

Direction-polarization correlations in the beta-gamma decay from K^{42}, As^{76}, Rb^{86}, Sb^{124}, and Cs^{134} were studied by Hamilton *et al.* (Ha 53a). They used a two-counter polarimeter having stilbene crystals placed symmetrically with respect to the polarimeter axis, as shown in Fig. 24, so that each counter played a dual role as scatterer and analyzer. The aluminum plate prevented beta particles from reaching the counters of the polarimeter. The entire apparatus was surrounded by an aluminum can which served as a light shield and contained a helium atmosphere in order to reduce electron scattering. Hamilton *et al.* discuss thoroughly the dependence on angle of the spurious triple-coincidence rates associated with the various possible scattering combinations. The single and double rates, as in previous experiments, were determined quite accurately as a check on the proper operation of the instrument.

In the case of Sb^{124}, Cs^{134}, and As^{76} there are additional beta-gamma cascades involving beta particles whose energies are lower than in the cascades under study. In these cases an aluminum absorber was intro-

TABLE XI. Values of the polarization correlation coefficient C(obs) and C(pred), as observed by Ha 53a and as predicted (on basis of no parity change for the gamma) from the directional correlation coefficient Q_2+Q_4 reported by other workers for similar beta-energy discrimination conditions. (Table from Ha 53a).

Nucleus	Q_2+Q_4	C(pred)	C(obs)*
Cs^{134}	0.00±0.01	0.00±0.003	0.009±0.013
Rb^{86}	0.13±0.01	−0.068±0.005	−0.060±0.025
As^{76}	0.07±0.02	−0.067±0.018	−0.114±0.035
K^{42}	−0.06±0.02	0.022±0.007	−0.007±0.016
Sb^{124}	−0.27±0.04	0.151±0.022	0.142±0.010

duced to absorb all but the desired high-energy beta particles. The effect of spurious triple coincidences caused by gamma rays reaching the beta crystal was determined by making runs with absorbers of various thickness, but all thick enough to absorb all beta particles.

In these experiments a quantity C is defined which is the coefficient characterizing the angular variation of the intensity of triple coincidences as a function of azimuthal angle of the polarimeter. Thus

$$N_\phi = 1 + C\cos^2\phi, \qquad \text{(III-2)}$$

so that $N_0/N_{90}=1+C$. Table XI compares the values of C obtained experimentally with values derived from the direction-direction coefficients determined by other workers.††† At $\theta=90°$, the polarization ratio is [see Sec. (c)]

$$p=\frac{J_0}{J_{90}}=\frac{1\pm(Q_2+Q_4)}{1\mp(Q_2+Q_4)}$$

for pure dipole ($Q_4=0$) or pure quadrupole radiation, the upper signs holding with no parity change, the lower ones with parity change. From (III-1), one obtains N_0/N_{90} and hence C. In the case of Cs^{134}, an isotropic direction-polarization correlation is observed as predicted. For Rb^{86}, As^{76} and Sb^{124}, the observed polarization agrees with that predicted for no parity change in the gamma transition from the first excited state. An essentially isotropic direction-polarization correlation is observed for K^{42}.

Brazos and Steffen (Br 56) have studied the direction-polarization correlation of the 0.722–0.566-Mev gamma-ray cascade resulting from the decay of the 50-day In^{114} isomer to Cd^{114}. The oppositely placed analyzing crystals were rotated automatically about an axis through the scatterer and source once every hour to minimize the effect of possible electronic fluctuations. The measurement indicated a $4(E2)2(E2)0$ cascade, which is also favored by the directional correlation measurements on this cascade (Br 56).

The direction-polarization correlation in the 1.24–0.845-Mev gamma-ray cascade in the decay of Co^{56} has been measured by Wood and Jastram (Wo 55). A liquid scintillator was used as the scattering counter. Using the direction-direction coefficients (Hu 55) and the polarization measurement on the 0.845-Mev gamma ray, it was established that this gamma ray was electric quadrupole (no parity change).

An investigation of the spins and parities of the first three excited levels in Ce^{140} and the first two in Sr^{88} was conducted by Bishop and Perez y Jorba (Bi 55) by means of direction-direction and direction-polarization correlations. They used scattering crystals (made of polystyrene activated with diphenyl tetrabutadiene) of two sizes, one for low the other for high-energy gamma rays, since too large a crystal at a given energy makes double scattering too probable. They limited the double scattering to 15% in their experiments. Single-channel pulse-height analyzers were used in the channels of both the directional counter and the scattering counter. In the case of the scattering counter, energy discrimination is desirable since the polarimeter is in effect a crude Compton spectrometer. Thus, the window of the pulse-height analyzer selects the pulses from Compton recoil electrons in the scattering crystal corresponding to a gamma ray of a given energy scattered at a given (approximately) angle. Figure 25 shows a pulse-height spectrum obtained this way for the gamma rays from Sr^{88} following the beta decay of Y^{88}.

The decay scheme in Ce^{140}, following beta decay of La^{140}, is fairly complex as shown by the level diagram in Table XIII. Bishop and Perez y Jorba measured the direction-polarization correlation with the 1.60-Mev gamma ray going to the directional counter and either the 0.329-, 0.487-, or 0.815-Mev gamma ray going to the polarimeter. The experimental value of N_0/N_{90} (1.077±0.022) was consistent with assignments of $3^--4^+-2^+$ or $3^+-4^--2^-$ for the first three excited states taken in descending order. However, on the basis of the Goldhaber-Sunyar rule, giving 2^+ for the first excited state, and on considering transition probabilities in the beta decay to these states, the first possibility was naturally chosen. Again, in the case of the simple cascade in Sr^{88} the measurements were most consistent with the possibilities $3^--2^+-0^+$ or $3^--1^+-0^+$ for the first two excited states and the ground state. The first possibility was chosen since it agrees best with internal-conversion data (Pe 48, Me 52a).

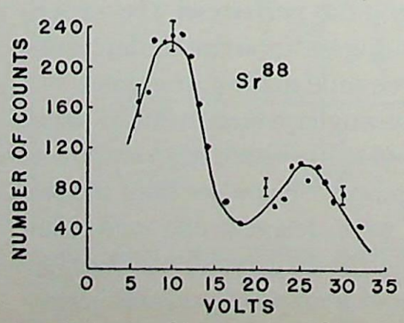

FIG. 25. Pulse-height spectrum of recoil electrons (in the scatterer) which are in coincidence with scattered gamma rays detected by the analyzing counters of the polarimeter. The gamma rays are from Sr^{88} produced in the decay of Y^{88} (figure from Bi 55).

††† The directional correlation results used were the following: K^{42} (Be 50b, St 51), As^{76} (Wa 50a, Ri 52), Rb^{86} (St 51, Ri 52), Sb^{124} (Be50b), Cs^{134} (Be 50b, St 50).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

The Sr^{88} gamma rays were also studied by Coleman (Co 56). His Compton polarimeter was used as a pulse-height analyzer by summing the pulse from the scattered electron in the scattering scintillator with that from the scattered gamma in the analyzing counter. With this technique the analyzing counter can subtend a large solid angle at the scattering scintillator without loss of resolution. The pulse-height spectrum obtained with this "total absorption" polarimeter is presented in Fig. 26. Separate polarization measurements were made on each member of the 0.91–1.85-Mev cascade in Sr^{88}. The results show that the parities of the 1.85- and 2.75-Mev levels are even and odd, respectively, in agreement with the results of Bishop and Perez y Jorba (Bi 55).

Later, using the same equipment, Coleman (Co 56a) studied the polarization correlation of the 0.99–1.33-Mev gamma-ray cascade in Ti^{48} produced in the decay of V^{48}. He discusses the problem of ambiguity arising from a multipole mixture when the result of a direction-direction correlation is used to determine level assignments. Brazos and Steffen (Br 56) showed in their work on the Cd^{114} levels that the ambiguity could be reduced by measuring the direction-polarization correlation. In addition, the mixing ratio may be determined when both correlations are known. This problem is illustrated in Part I. For the cascade in Ti^{48}, pure quadrupole radiation was established giving the assignment $4(E2)2(E2)0$.

The gamma-gamma direction-polarization correlations in the Co^{60} and Na^{24} decays were studied by Estulin *et al.* (Es 56). The experimental arrangement used was similar to that of Metzger and Deutsch. The measurements on Co^{60} were made to determine the reliability of those on Na^{24}. In each case the value of N_0/N_{90} indicated an $(E2,E2)$ transition in the cascade, leading to assignments of positive parity for the first two excited states in Ni^{60} and Mg^{24}.

Stelson and McGowan (St 57) have measured the direction-polarization correlation in the 133–482-kev cascade in Ta^{181}. They used NaI(Tl) crystals, 3 in. thick and 3 in. in diameter, in the counters of the correlation arrangement except in the Compton scatterer which was an anthracene scintillator, $1\frac{1}{2}$ in. thick by $\frac{3}{4}$ in. in diameter. The output of a fast-slow triple-coincidence circuit gated a 20-channel pulse-height analyzer on which was displayed the pulse-height spectrum from the analyzing counter of the polarimeter. The effectiveness of the polarimeter had been determined by measuring the polarization of gamma rays resulting from the Coulomb excitation of 2^+ levels in even-even nuclei (see next section). The direction-direction measurements (Mc 54a, Pa 55, He 55) had indicated two possible assignments for the 133–482-kev decay: $5/2(E2)9/2(E2+M1)7/2$ and $1/2(E2) \times 5/2(E2+M1)7/2$. The experimental value of N_0/N_{90} obtained in the polarization measurement clearly agreed with the latter assignment with even parities for the levels. The direction-polarization correlation was measured with both liquid and solid Hf^{181} sources as a check on possible systematic errors. It was estimated that the 4% contribution of 136.82-kev radiation from the decay of the 618.9-kev state just above the 615-kev state, did not significantly affect the results.

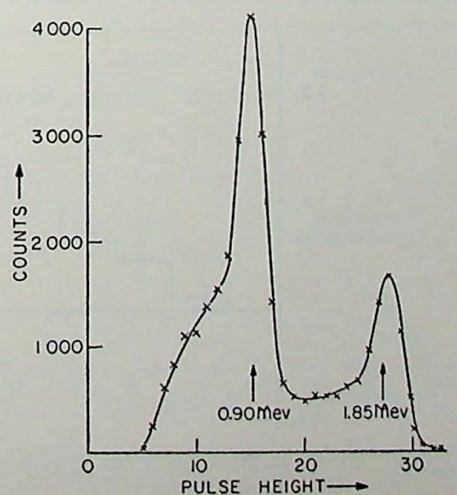

FIG. 26. Pulse-height spectrum of gamma rays from the same decay as in Fig. 25, observed using a "total absorption" polarimeter (figure from Co 56).

(e) *Measurements on Gamma Rays from Nuclear Reactions and Coulomb Excitation*

French and Newton (Fr 52) applied these methods to an alpha-gamma direction-polarization correlation in the $F^{19}(p,\alpha)O^{16*}(\gamma)O^{16}$ reaction. This experiment was exceptional in that an octupole transition (Ar 50, Ba 50) is involved and complete polarization is expected at an angle of 118° with respect to the coincident α particle as seen in Part I. Furthermore the gamma-ray energy was 6.13 Mev. Even though both the crystal absorption and the polarization sensitivity of the Compton process are low at this gamma-ray energy, a Compton polarimeter was still used successfully. Figure 2 shows that $R=1.27$ at this energy. After correcting for the angular spreads in the apparatus, the authors obtain values of 0.84 and 1.19 for the asymmetry ratio for magnetic and electric octupole radiation, respectively. Since the experimental ratio was 1.14 ± 0.06, it was concluded that the radiation is electric octupole. This gave an assignment of odd parity to the 6.13-Mev state in O^{16}, and even parity to the compound state in Ne^{20} and the ground state of F^{19}, assuming that the ground state of O^{16} is even.

McGowan and Stelson (Mc 58) have measured the polarization of gamma rays resulting from the Coulomb excitation of several odd-A nuclei. In general, these gamma-rays are from mixed $M1+E2$ transitions. Sometimes, a measurement of the direction-direction correlation between the gamma rays and the incident beam will determine the ratio $E2/M1$ in addition to specifying the spin of the excited state which is involved. However, the value of $E2/M1$ or of the spin often remains ambiguous. Such ambiguities can usually be resolved by a direction-polarization measurement.

The equipment and the techniques were essentially

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

the same as those used by these workers in their study of the gamma rays from Ta^{181} discussed in the preceding section. The only basic change is that the bombarding beam and target replace the directional counter and source, since the correlation in this case is between bombarding particle and gamma ray. With this method ambiguities in $E2/M1$ for the gamma-ray transitions or uncertainties in the spin of the first excited states of the following nuclei have been resolved: Mo^{95}, Rh^{103}, Ag^{107}, Ag^{109}, Cd^{111}, Cd^{113}, Au^{197}, Tl^{203}, and Tl^{205} (see Table XIII).

Litherland and Gove (Li 58) have measured the polarizations of the 1.64-, 0.94-, and 1.37-Mev gamma rays from the $C^{12}(He^3,p)N^{14}$, $O^{16}(He^3,p)F^{18}$, and $Mg^{24}(p,p'\gamma)$ reactions, respectively. The measurements on the 1.64-Mev gamma ray showed that the 3.95-Mev level in N^{14} had the same parity (positive) as the first excited state. Similarly the 0.94-Mev level in F^{18} had the same parity (positive) as the ground state. The measurements on Mg^{24} were performed at the 2.01- and 2.40-Mev resonances and in both cases very large polarizations were found for the gamma rays emitted at 90°. The results also indicate that the first excited state of Mg^{24} has the same parity (positive) as the ground state.

(*f*) *Measurements on Gamma Rays from Aligned Nuclei*

Of the several possible methods used for orienting nuclei,‡‡‡ the two that have been used the most in the experiments with gamma-ray polarization are the Bleaney method (nuclear alignment) and the Rose-Gorter method (nuclear polarization). Either one or both of these methods was used in the gamma-ray polarization experiments now to be described. The method of Rose and Gorter (Go 48, Ro 49) takes advantage of the nuclear polarization produced by magnetic hyperfine coupling in paramagnetic ions which have been polarized by an external magnetic field. In Bleaney's method (Bl 51a) no external field is used. Instead, the internal crystalline field is used to produce the nuclear alignment, through the magnetic hyperfine coupling in paramagnetic ions. In any nuclear orientation method the very low temperatures which are required are produced by adiabatic demagnetization.

The gamma rays emitted by aligned nuclei are linearly polarized. In fact, all the phenomena and the nomenclature which are associated with the direction-polarization correlation have their counterpart in the alignment-polarization correlation.

Bishop *et al.* (Bi 52), using Bleaney's method, made polarization measurements on the gamma rays emitted from aligned sources of Co^{58} and Co^{60}. After adiabatic demagnetization, values of $N_{\parallel}/N_{\perp}$ were measured with a Compton polarimeter as a function of $1/T^*$ by letting the source warm up (Fig. 27). The magnetic temperature T^* is obtained by measuring the susceptibility and applying Curie's law. The polarization of both gamma rays together in the 4–2–0 cascade in Ni^{60} and of the 805-kev gamma ray from Fe^{58} showed that all these quadrupole transitions (established in the case of Fe^{58} by Da 52) were electric.

Bishop *et al.* (Bi 54) in a later experiment measured the linear polarization of the gamma rays from aligned Mn^{54} nuclei. This was done both by Bleaney's method and by that of Rose and Gorter, a greater gamma-ray polarization being obtained with the latter technique. Since the Rose-Gorter method uses an external magnetic field, the scintillation crystals of the polarimeter were mounted on the ends of light pipes, and the photomultipliers were magnetically shielded. With each method the values of $N_{\parallel}/N_{\perp}$ (obtained as a function of $1/T^*$) showed that the radiation from the first excited state of Cr^{54} at 835 kev had positive parity and was therefore electric quadrupole (Gr 54).

Again using Bleaney's method, Bishop *et al.* (Bi 55a) measured the polarization of the 123-kev radiation from the 137-kev level of Fe^{57} in the decay of Co^{57}. This work was accompanied by a measurement of the alignment-direction correlation. It was known (Al 54) that the 123-kev transition is predominantly dipole. The measurement of $N_{\parallel}/N_{\perp}$ as a function of $1/T^*$ indicated that the transition is predominantly magnetic, thus confirming the suggested parity assignments to the 14- and 137-kev levels (Le 55). From the polarization measurements and the directional correlation a value of $(E2/M1)^{\frac{1}{2}}=+0.19\pm0.02$ was obtained.

Cacho *et al.* (Ca 55), using Bleaney's method, found a value for $N_{\parallel}/N_{\perp}$ of 1.58 at $1/T^*=40$ for radiation from the 145-kev first excited state of Pr^{141} in the Ce^{141} decay. This led to the conclusion that the transition is predominantly magnetic dipole. The polarization study in conjunction with the directional correlation (Ca 55, Am 56) gave $(E2/M1)^{\frac{1}{2}}=0.08\pm0.02$.

The linear polarizations of the quadrupole (Hu 56a) gamma rays, coming from the 6–4–2–0 cascade in Cr^{52}, following the decay of Mn^{52} were investigated by Huiskamp *et al.* (Hu 57) using the Rose-Gorter method. The Compton polarimeter which they used also served as a Compton spectrometer [see Sec. (d)] to analyze the

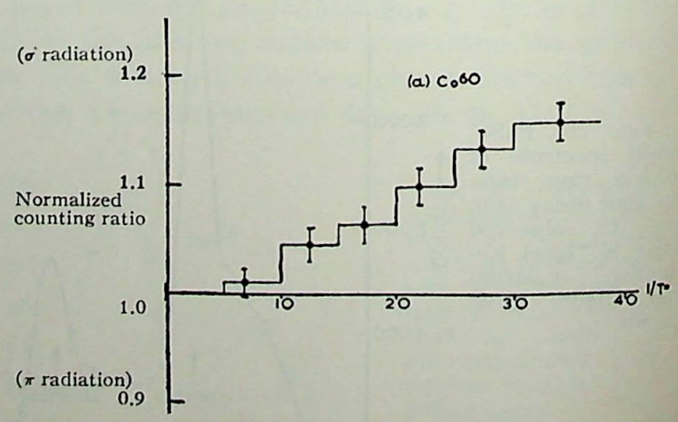

FIG. 27. Linear polarization of the gamma rays from an aligned Co^{60} source as a function of $1/T^*$ (figure from Bi 52).

‡‡‡ Extensive discussions of the methods of orienting nuclei are given in St 57a and Bl 57.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

0.73-, 0.94- and 1.46-Mev gamma rays in the cascade. The energy resolution was sufficient to determine the polarization of each of the three gamma rays. In each case, the radiation was found to be electric.

The same apparatus and method also were used by Diddens *et al.* (Di 58) to polarize Co^{56} nuclei in the study of the levels in Fe^{56}. The Compton polarimeter used as a spectrometer displayed sufficient resolution (14% at 2.76 Mev, 25% at 1.2 Mev) so that the linear polarizations of five gamma rays (0.845, 1.24, 1.75, 2.61, and 3.25 Mev) could be measured satisfactorily. As in the work on Mn^{52} a plastic scintillator was used as the scatterer in the polarimeter instead of NaI(Tl) because it was found that pair production in the NaI with its resulting annihilation radiation produced a serious background for the more energetic gamma rays. The authors also investigated the alignment-direction correlations for the above and other gamma rays produced in the decay of Co^{56}. From all their measurements and with the work of others (Sa 55a) they obtained spins and parities for the 0.845-, 2.08-, 3.45-, 3.84-, and 4.10-Mev levels (see Table XIII). Also the 0.845-, 1.24-, and 3.25-Mev gamma rays were found to be electric quadrupole, whereas the 1.75- and 2.61-Mev gamma rays were magnetic dipole.

B. Measurement of Plane Polarization by Means of the Photodisintegration of the Deuteron

Next to the Compton effect, photodisintegration of the deuteron has proved the most useful polarization-sensitive reaction for gamma rays. In Part II, it was shown that the electric dipole photodisintegration serves as an ideal polarization-sensitive mechanism for gamma rays of energies ranging from about 4 Mev to about 12 Mev. The main disadvantages of the reaction are its low cross section ($\sim 10^{-27}$ cm^2) and the fact that the presence of the isotropic magnetic interaction makes it unsuitable for gamma rays whose energies are much below 4 Mev. It can however be used well above 12 Mev without serious loss of sensitivity.

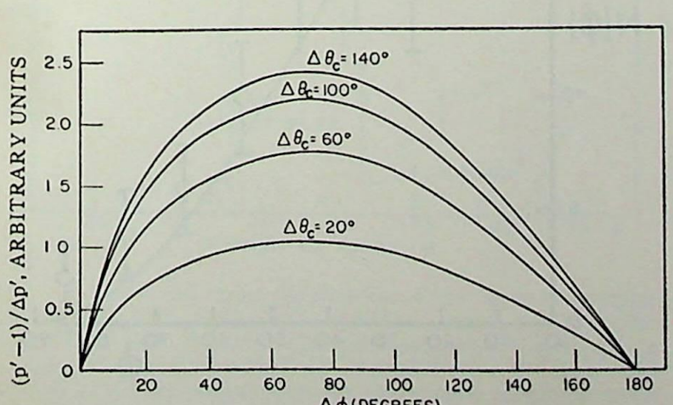

FIG. 28. Figure of merit of a polarimeter using the photodisintegration of the deuteron, plotted as a function of the spread in the angle ϕ, for various spreads in θ_c (computed for $p=1.2$).

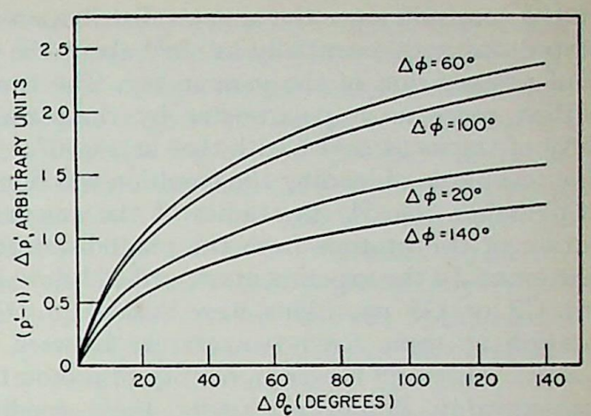

FIG. 29. Figure of merit of a polarimeter using the photodisintegration of the deuteron, plotted as a function of the spread in angle θ_c, for various spreads in ϕ (computed for $p=1.2$).

(a) *Experimental Considerations*

Two methods of utilizing the polarization sensitivity of the deuteron are apparently feasible. One method would be very similar to the Compton polarimeter. The gamma rays would impinge on a "scatterer" containing deuterium, and the photoneutrons would be detected in one (or two) side counters. Almost all the discussion of the Compton polarimeter can be applied to this case. Thus, the advantage of making the "scatterer" itself a detector is obvious. In this case the photoproton would be detected. A very serious drawback to such a polarimeter would be the very high background of events from Compton scattering and pair production. This difficulty might be overcome with modern techniques such as the use of time-of-flight to isolate the neutrons. The advantage of the method over the Compton polarimeter would be its increased sensitivity to polarization at high gamma-ray energy. Its advantage over the emulsion technique, described in the following, would be its possible use in a direction-polarization measurement requiring the detection of coincident radiations. Figures 28 and 29 show the figure of merit for such a polarimeter for various angular spreads. The conditions are the same as in the corresponding calculations for the Compton polarimeter, Figs. 19 to 22, except that here the energy is not an important parameter as long as the electric dipole disintegration is dominant (as assumed in Figs. 28 and 29). That the polarization sensitivity is practically independent of θ_c is reflected in the continued rise of the curves as $\Delta\theta_c$ increases in Fig. 29. The curves in Figs. 28 and 29 can be used in the analysis of data obtained in the emulsion technique.

The simplest polarimeter using the photodisintegration of the deuteron, and the one used in all the experiments performed so far, consists of a nuclear emulsion impregnated with heavy water (D_2O). The emulsions are mounted so that the plane of the emulsion is normal to the direction of propagation of the gamma rays. In this position the maximum number of photoprotons will

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

lie in the emulsion since the angular distribution of the photoprotons goes essentially as $\sin^2\theta$ about the direction of propagation of the gamma ray. The emulsion can then serve as a polarimeter by comparing the density of tracks at $\phi=0°$ with that at $\phi=90°$.

The technique of loading the emulsion was first used by Goldhaber (Go 51) in studies of the angular distribution of the protons from the photodisintegration of deuterons. In the experiments described below, either Ilford C2 or G5 emulsions were soaked in D_2O to saturation at some fixed temperature between 10°C and 20°C. Although the grain density of proton tracks is considerably diminished under these conditions, satisfactory range definition can be obtained in Ilford C2 emulsions with appropriate developing techniques. Better definition can be achieved using Ilford G5 emulsions but in this case precautions must be taken to reduce fogging if low-energy gamma or x-radiation is present.

The amount of water absorbed by a saturated emulsion increases with increasing temperature. However, the emulsion generally becomes too soft to use at temperatures much above 20°C. Saturation of the plates is desirable in order to attain a uniform distribution of water throughout the emulsion. If range determinations are to be made, it is essential for the proton range for a given energy to be constant throughout the emulsion. A uniform distribution of the water is important also in making depth measurements in the emulsion. If the expansion of the emulsion on soaking and the subsequent shrinkage on development do not take place uniformly, it is not possible to obtain accurate measurements on the vertical range of a track. A depth measurement depends on a knowledge of the shrinkage factor (ratio of emulsion thickness before and after development). For most purposes an adequate measurement of the shinkage factor can be obtained with a micrometer, although more elegant techniques are possible. While the emulsions are being exposed they are kept in watertight containers at a controlled temperature. Usually one plate in an exposure is saturated with H_2O to provide a background measurement.

(*b*) *Experiments Using Nuclear Emulsions*

Emulsions soaked in D_2O were first used in a polarization experiment by Wilkinson (Wi 52) in a study of the gamma rays from the $H^2(p,\gamma)He^3$ reaction. In this nonresonant reaction, the energy of the gamma ray is greater than 5.5 Mev by an amount which depends on the energy of the bombarding protons. Since the directional distribution is given by $\sin^2\theta$ (Fo 49), the gamma rays are expected to be essentially completely polarized (Part I).

Ilford C2 emulsions 100 μ thick were soaked in D_2O and placed about 7 cm from a D_3PO target. Although the reaction was weak, 120 usable proton tracks were found in the emulsion after a five-hour exposure with a 50-μa proton beam (1.1 Mev). Wilkinson adopted some simple range and depth criteria to insure the counting of desired events. Since the polarization sensitivity is independent of the polar angle, only the azimuthal angle is recorded. Figure 30 shows the azimuthal distribution of proton tracks projected on the plane of the emulsion. It confirms that the gamma rays are electric dipole and are essentially perfectly polarized. On the other hand, if it is assumed from other evidence (Fo 49) that the gamma rays are completely polarized, then the experiment serves to confirm the ideal polarization sensitivity of the photodisintegration of the deuteron for gamma rays of about 6 Mev.

Fagg and Hanna (Fa 53) used the photodisintegration process to measure the polarization of the 6.13-, 6.9-, and 7.1-Mev gamma rays from the $F^{19}(p,\alpha)O^{16*}(\gamma)O^{16}$ reaction, at $E_p=0.874$ Mev. Ilford C2 emulsions 400 μ thick were soaked to saturation in D_2O and placed 4 cm from a thin target, with the plane of the emulsion normal to the gamma rays emitted at 90°. Several exposures of about 250 μa-hours each were made. Complete resolution of the 6.9-, and 7.1-Mev gamma rays could not be expected but it was essential to isolate the strong 6.13-Mev radiation from the other two. This could be done in a simple manner which permitted (relatively) rapid counting, with the result shown in Fig. 31. In essence, a single depth criterion was adopted: an acceptable proton track must be in sharp focus along its complete range. The utility of the technique is seen by writing the photoproton distribution, (II-14), in terms of projected range $p=R\sin\theta$:

$$d\sigma\sim p^3(R^2-p^2)^{-\frac{1}{2}}dp.$$

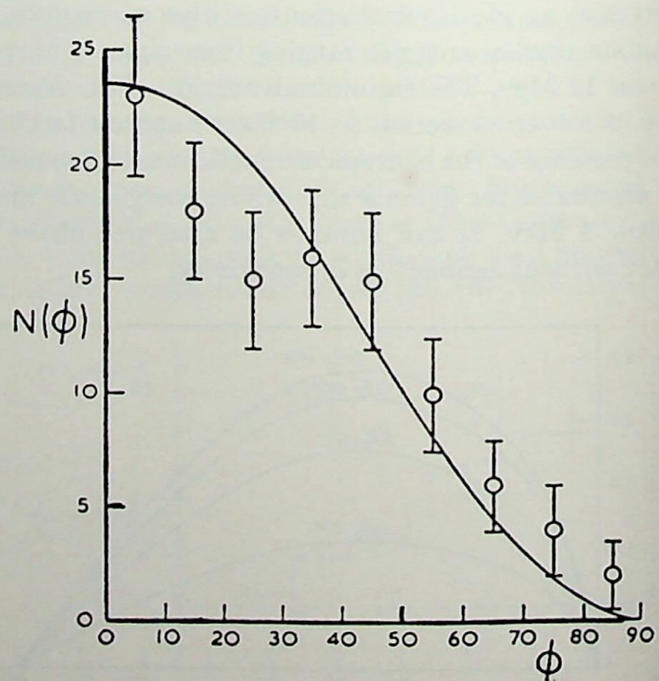

FIG. 30. Linear polarization of gamma rays from $H^2(p,\gamma)He^3$, demonstrated by photodisintegration of deuterons in impregnated emulsion. The azimuthal distribution of photoproton tracks projected onto the plane of the emulsion is shown (figure from Wi 52).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

This distribution is plotted as the dotted line in Fig. 31. Experimentally, it gives a very pronounced peaking at $p=R$. The cutoff at p_c is of course established by the depth criterion. In this case p_c was chosen to resolve the 6.13-Mev gamma ray. The resolution could be improved, by increasing p_c, without greatly decreasing the total number of accepted tracks.

With this technique enough resolution was obtained to give qualitatively the polarizations of the 6.9- and 7.1-Mev gamma rays. This qualitative information was used along with the measured polarization ratio and the directional distribution coefficient (Sa 52) for the unresolved group to deduce the parities of the 6.91- and 7.12-Mev states in O^{16}. These parities (plus and minus, respectively) agreed with those given by Seed and French (Se 52). No assignment could be made for the 6.13-Mev level since the corresponding polarization distribution was essentially isotropic, in agreement with the isotropy observed by Sanders (Sa 52) in his directional distribution measurement.

Nuclear emulsions impregnated with heavy water were also used by Hughes and Sinclair (Hu 56) in their study of the polarization of the gamma radiation from the reactions $Al^{27}(p,\gamma)Si^{28}$, $Mg^{26}(p,\gamma)Al^{27}$, and $Na^{23}(p,\gamma)Mg^{24}$. Ilford G5 emulsions (300 μ and 400 μ thick) were used in order to give well-defined tracks and to avoid fading of the tracks during the long exposures. A copper absorber $\frac{1}{8}$ in. thick was effective in preventing low-energy x-rays from blackening the plates. The targets used were thin enough so that in each bombardment a single resonance was isolated. Both the horizontal and vertical projection of each proton track was measured in the microscope and the range was calculated from these values. The following gamma rays were investigated: the 7.5- and 10.4-Mev gamma rays from Si^{28}, the 7.6- and 8.6-Mev gamma rays from Al^{27}, and the 7.2-, 8.1-, and 10.8-Mev gamma rays from Mg^{24}. A definite polarization was observed in the case of the 10.4-, 7.6-, and 10.8-Mev radiations, all of which were found to be electric in character. The 10.4-, 7.6-, and 10.8-Mev radiations had each been shown to be dipole in character in Ru 54, Ru 56, and Gr 55, respectively. The character of the radiation was used to assign even parity to the ground state and first excited state of Al^{27} (in agreement with Da 53) and to the ground state of Na^{23}. For the remainder of the gamma rays no polarization was observed. Hughes and Sinclair also include in an appendix a range-energy relation for protons up to 5 Mev in wet emulsions.

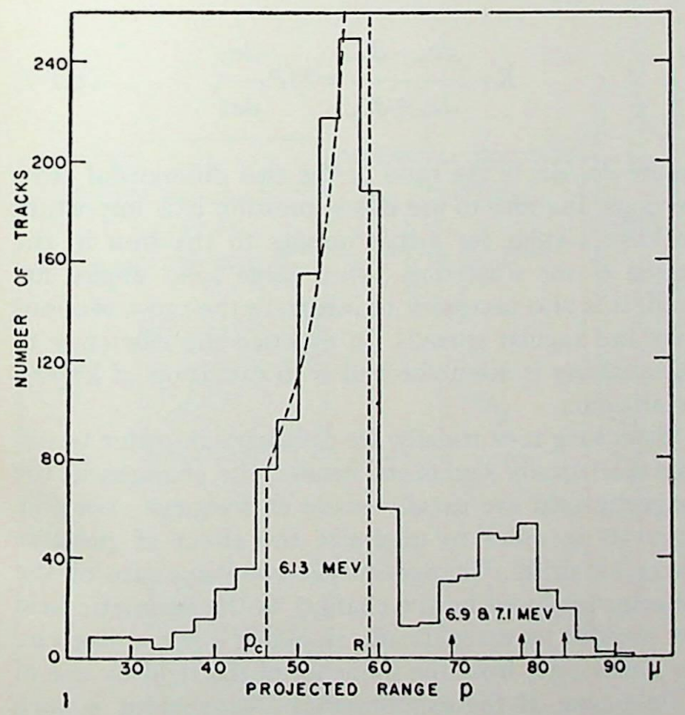

FIG. 31. Projected range distribution of the photoprotons produced by the 6.13-, 6.91-, and 7.12-Mev gamma rays from the $F^{19}(p,\alpha)O^{16*}(\gamma)O^{16}$ reaction. The photoprotons are produced in emulsions impregnated with D_2O. Dashed curve is the theoretical distribution for the projected range, assuming an empirical cutoff at P_c. R is range of photoproton resulting from the 6.13-Mev gamma ray. Arrows in the vicinity of 80 microns mark expected ranges of photoprotons from the 6.91- and 7.12-Mev gamma rays (figure from Fa 53).

C. Measurements of Plane Polarization by Means of the Photoelectric Effect

In Part II it was shown that the usefulness of the photoelectric effect for detection of gamma-ray polarization is rather doubtful. The experiments which have been performed have been primarily motivated by a desire to elucidate the photoelectric effect rather than to measure polarization. With an arrangement very similar to Fig. 15, Hereford (He 51) used two photoelectric polarimeters to observe the cross-polarization of annihilation radiation. In an improved experiment Hereford and Keuper (He 53) substituted a Compton polarimeter for one of the photoelectric detectors. These investigations were followed by the experiments of McMaster and Hereford (Mc 54) and of Brini *et al.* (Br 57) in which the polarization produced in Compton scattering was used to investigate the photoelectric effect, with the discordant results already noted in Part II.

D. Measurement of Circular Polarization by Means of the Compton Effect

Recently, considerable interest has been exhibited in the measurement of circular polarization of gamma rays. This interest has been stimulated primarily by the fundamental reformulation of the law of conservation of parity in weak interactions and the resultant introduction and confirmation of the two-component neutrino theory (Le 56, Le 57). The developments in the measurements of the circular polarization of gamma rays have progressed at a rapid rate. It is the aim here to bring together the methods and techniques of the various investigations and to collect the results which have appeared.

TABLE XII. Sign of the circular polarization effect R for right circular polarization, for the conditions listed.

Sign of R	Transmission	Scattering
−	$E_\gamma<0.63$ Mev	$\theta_c<90°$
+	$E_\gamma>0.63$ Mev	$\theta_c>90°$

(a) *Experimental Considerations*

A discussion of the Compton scattering of circularly polarized gamma rays by polarized electrons has been given in Part II. The most convenient source of polarized electrons is a ferromagnet. Experimentally the circular polarization of gamma rays is detected by observing the difference in the scattering from electrons in magnetized iron when the magnetization is reversed or when it is removed. This may be done by observing (1) the gamma rays transmitted through the magnetized iron, (2) those scattered from the iron at same appropriate angle, or (3) the electrons ejected forward from the surface of the iron. Although a considerable effect (change in the counting rate with change in magnetic field) could be expected for perfectly polarized gamma rays and electrons at certain angles and energies (Figs. 4 and 5), in practice the effect is greatly diminished by the fact that only about 2 electrons of the 26 in each iron atom can be polarized by magnetization. Therefore, the polarization effect is at most only a few percent; and quite often it is less than one percent, if the gamma-ray polarization is small.

For any one of the above methods, let N_+ denote the experimental yield of gamma rays when the magnetization of the analyzer is directed toward the source, and N_- the yield when it is directed away from the source. The experimental effect is given by

$$R=2\frac{N_+-N_-}{N_++N_-}. \qquad \text{(III-3)}$$

The sign of the effect is of great importance. It is determined by the sign of the polarization-sensitive cross section (Figs. 4 and 5) and the sense of the photon polarization. For ready reference the sign of R is given in Table XII for right circular polarization (see definition in Part I, C) and for four experimental conditions. The sign of R is reversed for left circular polarization. Hence, from the sign of the effect, one may determine the sense of the circular polarization and so also of the polarized emitting nucleus. This much alone has led to very important discoveries.

In accordance with the theoretical definition (Part I, C), the degree of circular polarization is

$$P_3=\frac{J_r-J_l}{J_r+J_l} \qquad \text{(III-4)}$$

where J_r and J_l are the number of right and left circularly polarized photons. Let J_r^0 and J_l^0 be the initial intensities and $J_r^\pm$ and $J_l^\pm$ the transmitted intensities corresponding to (+) or (−) magnetization. Then

$$J_r^\pm=J_r^0\exp\{-nt(\sigma_0 z\pm\sigma_1\nu)\}$$
$$J_l^\pm=J_l^0\exp\{-nt(\sigma_0 z\mp\sigma_1\nu)\}.$$

With $N_\pm=J_r^\pm+J_l^\pm$, we obtain for (III-3)

$$R=2P_3\tanh(-nt\sigma_1\nu), \qquad \text{(III-5)}$$

where n is the number of iron atoms per unit volume, t is the effective thickness of the iron analyzer, and ν is the number of polarized electrons per iron atom, equal to 2.06 at saturation (Ar 53). In using this formula to obtain P_3 from a measurement of R, it is necessary to find appropriate values for t and ν. Alternatively, the analyzer may be calibrated with a source of known polarization.

For the differential cross section we can write

$$d\sigma=d\sigma_0\pm fP_3 d\sigma_1, \qquad \text{(III-6)}$$

where $d\sigma_1$ is the polarization-sensitive cross section shown in Fig. 4 for the case in which the electron polarization is parallel to the photon momentum. The circular polarization P_3 and the electron polarization f are displayed explicitly. At saturation $f\cong 2/26$. Since, in an analysis by scattering, the observed intensity is simply proportional to the differential cross section, we can write§§§

$$R=2\frac{d\sigma_+-d\sigma_-}{d\sigma_++d\sigma_-}=2fP_3\frac{d\sigma_1}{d\sigma_0}, \qquad \text{(III-7)}$$

where $d\sigma_1/d\sigma_0$ is the ratio of the two differential cross sections. In order to use this expression it is important to have a value for f that applies to the iron in the region of the scattering. When large solid angles are used, it is also necessary to integrate the cross sections over the angular spreads. In practice the efficiency of the analyzer is often checked with radiation of known polarization.

Since long runs usually are necessary in order to obtain statistically significant results, the changes in the magnetic field are usually made at frequent, periodic intervals in order to minimize the effect of possible electronic drifts. Changes in the counting rate of the detector produced by the changes in the magnetic field are avoided by magnetically shielding the counter and by removing it from the influence of the field by use of a light pipe. If the experimental arrangement is such that changes in magnetic field do affect the counting rate, the effect can be controlled in the beta-gamma coincidence experiments by normalizing the coincidence rate to the gamma-ray singles rate.

§§§ If there is a component of linear polarization in the gamma radiation, the normalization of this expression is changed (Wh 55).

(b) Measurements on Gamma Rays from Polarized Nuclei (Parity Conserving)

The first experiment dealing with the circular polarization of gamma rays was performed by Clay and Hereford (Cl 52) who attempted to measure the circular polarization of annihilation radiation by detecting Compton electrons ejected in the forward direction from magnetized iron. The effects they observed are now believed to be instrumental in origin (To 56).

Using the apparatus shown in Fig. 32 Wheatley *et al.* (Wh 55) studied circularly polarized gamma rays of nuclear origin in their investigation of the gamma rays emitted from Co^{60} nuclei which had been polarized by the Rose-Gorter method. After adiabatic demagnetization the cryostat containing the source was inserted into the position shown in Fig. 32 (which shows one half of the symmetrical apparatus). It is recalled that the circular polarization is a maximum for gamma rays emitted along the axis of the nuclear polarization, and that the circular polarization changes sign if the axis is reversed. It was convenient therefore to perform the experiment by reversing the nuclear polarization (instead of the electron polarization) which is controlled by the inner magnet M_p (which shares a yoke with the outer magnet M_s). Except for the features associated with the nuclear polarization, especially in the design of the magnet, the polarimeter itself is a forerunner of more recent analyzers using the scattering method. Direct radiation is shielded from the detector, but gamma rays scattered (at angles between 45° and 70°) from the magnetized strip S (Armco iron) are recorded. The magnetization in S is produced by the magnet M_s. The dègree of circular polarization achieved was as high as 75% at the lowest temperature, 0.006°K. The observed fractional change in counting rate upon changing the direction of polarization of the nuclei was at most 3%. In this experiment the circular correlation function has the form (Part I, C)

$$P_3=[A_1P_1(\cos\theta)+A_3P_3(\cos\theta)]/W(\theta),$$

where A_1, A_3, and the coefficients in the directional function $W(\theta)$ are functions of the degree of orientation and so of the temperature. For temperatures in the region $1/T<60$, Wheatley *et al.* obtain excellent agreement with the theoretical correlation function. For lower temperatures the observed deviation may be due to imperfect knowledge of the hyperfine coupling. As we have seen the sign of the effect alone makes possible a determination of the sign of the magnetic moment of the emitting nucleus. In this case the sign of the magnetic moment of the Co^{60} nucleus was found to be positive.

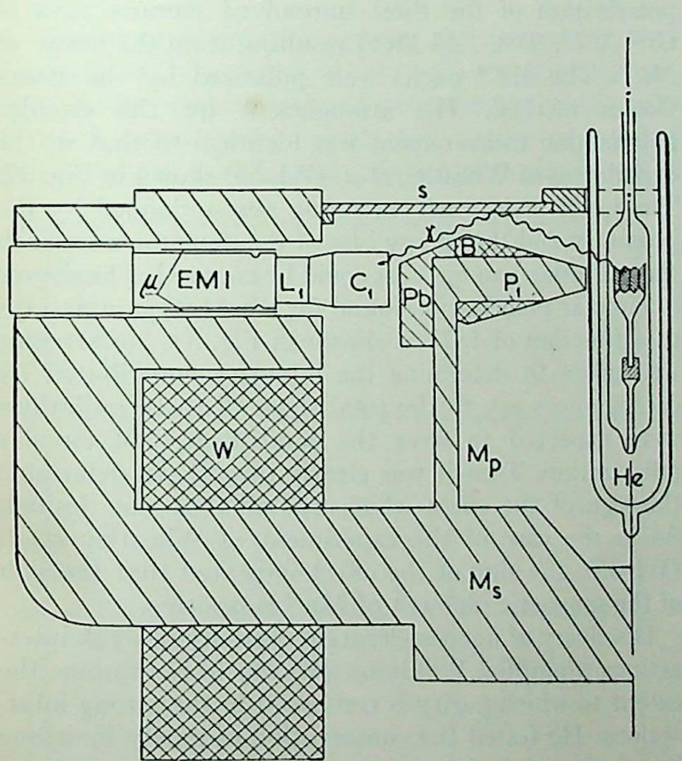

FIG. 32. Diagram of apparatus used by Wheatley *et al.* for producing and measuring circularly polarized gamma rays. A change in the differential Compton cross section is measured by changing the direction of circular polarization of the gamma rays, emitted from polarized nuclei in the cryostat, relative to the direction of magnetization in the scattering iron S. Magnet M_p (with coil B) determines the direction of polarization of the nuclei; Magnet M_s (with coil W) determines the direction of magnetization of S (figure from Wh 55).

Trumpy (Tr 57) using the apparatus shown in Fig. 33 studied the circular polarization of the gamma rays resulting from the capture of polarized neutrons by the following nuclei: S^{32}, Ca^{40}, Ti^{48}, Cr^{53}, Fe^{57}, Ni^{58}, Zn^{64}, and W^{182}. The emitting compound nucleus receives its polarization from the captured neutron. Again, the maximum circular polarization occurs for gamma rays emitted along the axis of polarization. Trumpy selected the transmission method for the analysis of circular polarization. Thermal neutrons emerge from a neutron collimator and pass through a neutron polarizer, consisting of a small iron block mounted in the gap of a magnet in which a field of 14 900 oe is produced. The polarized neutrons impinge on a target and the capture gamma rays, emerging along the directions parallel and antiparallel to the polarization, reach two sodium iodide detectors after being transmitted through the two analyzing magnets. The path through each magnet core is 8 cm long. The heavy shielding of lead and boron carbide reduces the intense background of radiation arising chiefly from neutron capture in the polarizing iron block. Particular gamma rays could be selected for study by means of energy discrimination in the detectors. The experiment was performed by recording the counts in both detectors as a function of the direction of magnetization in the analyzers and the direction of polarization of the neutrons as determined by the polarizing magnet.

Trumpy uses an explicit formula given by Biedenharn *et al.* (Bi 51) for the capture of totally polarized thermal neutrons followed by pure multipole emission. In the correlation $A_1P_1(\cos\theta)$, which measures the degree of

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

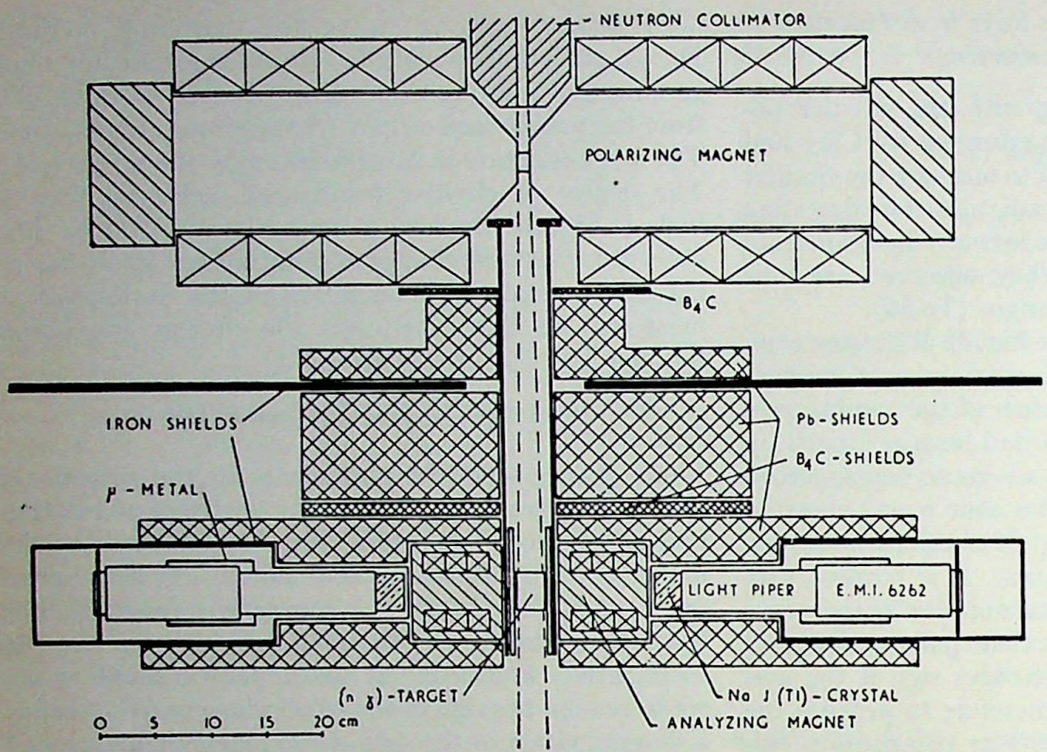

FIG. 33. Top view of experimental arrangement used by Trumpy to detect circular polarization following capture of polarized neutrons. Circular polarization is detected by measurement of the transmission through magnetized iron (figure from Tr 57).

right circular polarization, the coefficient A_1 is given by

$$A_1=2(j-j_1)\frac{L(L+1)+j(j+1)-j_2(j_2+1)}{L(L+1)(2j_1+1)}, \quad \text{(III-8)}$$

where j_1, j and j_2 are the spins of target nucleus, compound nucleus and final nucleus, respectively, and L is the multipole order of the gamma-ray transition. This is equivalent to the result obtained in Part I, C. Since one or more of the angular momenta in (III-8) are often known and $j=j_1\pm\frac{1}{2}$, a measurement of A_1 can yield definite assignments of spin (and parity). For example, if $j_1=0$, $j=\frac{1}{2}$, and $L=1$, then $A_1=1$ or $-\frac{1}{2}$ for $j_2=\frac{1}{2}$ or $\frac{3}{2}$, respectively.

The theoretical value of the circular polarization, given by A_1, is reduced in practice because of the incomplete polarization of the neutron beam (19%). The efficiency of the analyzer was determined in a manner equivalent to (III-5). In the case of S^{33} the spin of the 3.15-Mev level was found to be $\frac{3}{2}$. In Ca^{41} the spin of the 1.98-Mev level also was determined as $\frac{3}{2}$. The measurements on the 6.41- and 6.75-Mev gamma rays from Ti^{49} were consistent with spins of $\frac{1}{2}$ and $\frac{3}{2}$ for the 1.70- and 1.35-Mev states, respectively. Trumpy's results for Cr^{54} in conjunction with his angular correlation work (Tr 57a) indicated a 1(1)2(2)0 decay scheme for the 9.72-, 0.84- and 0-Mev levels. Also both the 9.72- and 8.88-Mev gamma rays are $E1$. Contrary to shell-model predictions, the results on Fe^{57} indicated that its ground state is $\frac{1}{2}^-$. A spin of $\frac{3}{2}$ was confirmed for the ground state of Ni^{59}, and either $\frac{3}{2}$ or $\frac{5}{2}$ for the ground state of Zn^{65}. The spins and multipolarity involved in the decay of the 6.18-Mev state in W^{183} were known from other work. Consequently the measurement on this nucleus constituted a verification of the direction and order of magnitude of the expected circular polarization.

In another part of their work, discussed in Part III, A(f), Huiskamp *et al.* (Hu 57) measured the circular polarization of the three unresolved gamma rays of Cr^{52} (0.73, 0.94, 1.43 Mev) resulting from the decay of Mn^{52}. The Mn^{52} nuclei were polarized by the Rose-Gorter method. The arrangement for the circular polarization measurement was identical to that in the experiment of Wheatley *et al.* (Wh 55) shown in Fig. 32. The range of forward scattering angles defined by the geometry and the energy bias of the detector were such that all three gamma rays could be counted. The degree of circular polarization found for the Mn^{52} gamma rays as a function of $1/T^*$ is shown in Fig. 34. No attempt was made to determine the intensity contributed by each gamma ray to the total since all three radiations were expected to have the same degree of circular polarization. Thus it was clearly possible to determine the sign of the effect which was all that was desired. As in the case of the experiment of Wheatley *et al.* (Wh 55), the sign of the effect indicated that the sign of the magnetic moment of Mn^{52} is positive.

Discovery of nonconservation of parity in weak interactions prompted Wilkinson (Wi 58) to re-examine the extent to which parity is conserved in the strong interactions. He tested the conservation of parity in strong interactions by three classes of experiments. One of these involves a search for circular polarization of gamma rays from a nuclear reaction in the initial state of which all particles are unpolarized. Wilkinson looked for circular polarization of the 2.14- and 7.12-Mev gamma rays from the $B^{11}(p,p')B^{11*}(\gamma)B^{11}$ and $F^{19}(p,\alpha)O^{16*}(\gamma)O^{16}$ reactions, respectively. He used

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

transmission through magnetized iron as the method of analysis for circular polarization. Since very small effects, if any, were expected, considerable precautions were taken to eliminate systematic errors resulting, for instance, from the influence of magnet reversals on the photomultipliers or from electronic drifts. The scintillating crystal was mounted at the end of a light pipe either two or four feet long. The two-foot pipe was used with the $F^{19}(p,\alpha)O^{16*}$ reaction for which greater resolution was needed. The photomultiplier was surrounded not only with a mu-metal shield but also with two coaxial iron pipes. To prevent the degraded radiation emerging from the magnet from masking the effect under study, the bias of the electronic apparatus was set to accept only the very high-energy end of the spectrum. Since the search was for such small effects, over five-hundred runs were made on each reaction. The results of the runs were carefully averaged in different ways to eliminate the possible influence of systematic errors. Average values of $N+/N-=1.00025 \pm 0.00026$ and 1.00003 ± 0.00024 were found for the boron and fluorine reactions, respectively, where $N+/N-$ is the ratio of the counting rate with the magnetic field in one direction to that in the other. Thus, within the aforementioned limits, there is no circular polarization and no nonconservation of parity.

(c) *Beta-Gamma Circular Polarization Correlation*

The measurement of circular polarization in beta-gamma decay was one of the early experiments performed after the discovery of nonconservation of parity in weak interactions (Le 56) and the revival of the two-component theory of the neutrino (Le 57). The

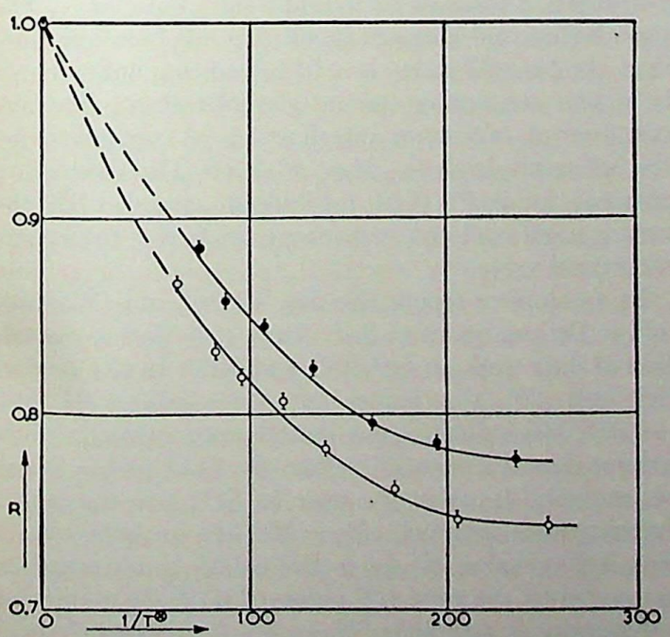

FIG. 34. Circular polarization of gamma rays emitted from a polarized Mn^{52} source. Ordinate R is the counting rate normalized to unity at $T=1°K$. Open circles correspond to the polarizing field and the induction in the scattering iron being parallel, while closed circles correspond to their being antiparallel (figure from Hu 57).

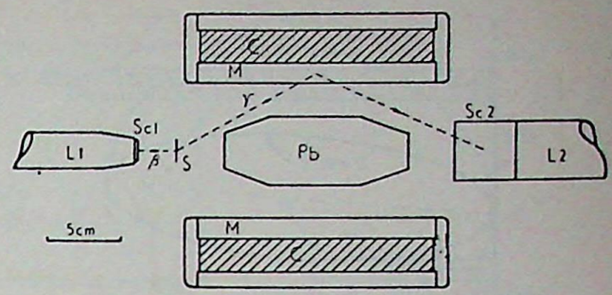

FIG. 35. Experimental arrangement used by Schopper for the beta-gamma circular-polarization correlation. Sc 1 is the beta counter using a plastic scintillator; Sc 2 is the gamma counter with a NaI(Tl) crystal; L1 and L2 are light guides; S is the source; and M is a cylindrical magnet with magnetizing coils C_1 (figure from Sc 57).

experiments have since been carried forward and have provided valuable information on the nature of beta decay. The aim of the measurements is to determine the asymmetry coefficient $A_1=-(v/c)A$ in the circular polarization correlation (Part I, C),

$$P_3=(v/c)A\cos\theta, \qquad \text{(III-9)}$$

which gives the degree of right circular polarization as a function of the angle between the beta particle and the gamma ray. Both the scattering method and the transmission method have been used to good advantage in this work, the polarizations being obtained by (III-5) and (III-7) or their equivalent. The beta-gamma circular polarization measurement provides the same information as does a knowledge of the electron distribution from polarized nuclei. The former technique has the advantage, however, of being feasible for a large number of different nuclei.

Schopper (Sc 57) first performed such a correlation experiment in the decay of Co^{60} and of Na^{22}. These nuclei have allowed‖ ‖ ‖ β transitions with $\Delta J=1$ followed by pure multipole radiation. The experimental arrangement (Fig. 35) is designed to study the circular polarization of the gamma rays emitted at an angle close to 180° measured with respect to the direction of the beta particles. The average forward scattering angle was 55°, which is about optimum for circularly polarized gamma rays of the energies used in the experiment (~1.25 Mev). Electronic discrimination in the circuits was provided in order to avoid counting backscattered gamma rays, annihilation radiation, and stray beta particles. Although light pipes were used in the detectors, possible variations in the coincidence rate produced by the changes in the magnetic field were eliminated by using the ratio of the coincidence rate to the product of the singles rates.

In the decay of Co^{60} two gamma rays are emitted in a 4–2–0 cascade, but the gamma rays can be treated as one since in this special case the polarization of the second gamma ray is the same as that of the first

‖ ‖ ‖ All of the beta transitions discussed in this section are allowed unless otherwise specified.

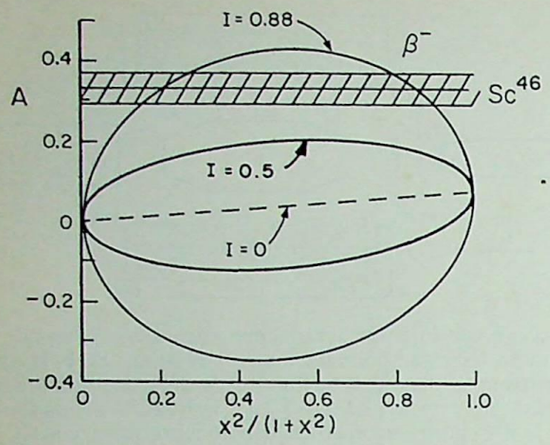

FIG. 36. Asymmetry coefficient in the beta-gamma circular polarization for a $4^+(\beta)4^+(\gamma)2^+(\gamma)0^+$ transition. The experimental value for Sc^{46} is indicated. Theoretical curves for $I=I_{max}=0.88$, $I=0.5$ and $I=0$ are shown; I is the interference term that enters into A. If $I>0$, the upper branch of the theoretical curve refers to the choice of $x=a^{\frac{1}{2}}M_{GT}/M_F>0$ and the lower branch to the case $x<0$. If $I<0$ the opposite assignment is true. The figure shows that a large value for I is required to fit the experimental data (figure from Bo 58).

(To 53). Schopper found $A=+0.39\pm0.08$ and -0.41 ± 0.07 for Na^{22} and Co^{60}, respectively. These results can be compared to theoretical values of $+\frac{1}{3}$ and $-\frac{1}{3}$ respectively. The result on Co^{60} is in accord with the experiment of Wu *et al.* (Wu 57) which measured the electron distribution from polarized Co^{60} nuclei. The opposite signs for Co^{60} and Na^{22} indicate opposite circular polarizations and show that the antineutrino emitted in negatron decay and the neutrino emitted in positron decay have opposite helicity. In a note added in proof in his paper Schopper reports a result leading to a value of $A=-0.07\pm0.05$ for Na^{24}.

Boehm and Wapstra (Bo 57, Bo 58) using a very similar experimental arrangement have studied the circular-polarization correlations in many beta-gamma decays. Their first experiments were performed on Co^{60}, Au^{198} and Hg^{203}, the latter two of which have first-forbidden beta transitions to the 0.411- and 0.279-Mev states in Hg^{198} and Tl^{203}, respectively. A refined expression for the efficiency of the analyzer was calculated by Alder,

$$\epsilon=2.90k(1+0.13k)/(1+0.36k+0.09k^2),$$

where ϵ would be the experimental effect (in percent) for a completely circularly polarized gamma ray of energy k (in units of m_0c^2). Measurements on the circularly polarized bremsstrahlung created by the beta-particles from P^{32} and Tm^{170} were made partly to check this formula and partly to establish the v/c law for the polarization of electrons emitted in beta decay. The experimental results found for P^{32} and Tm^{170} were consistent with both the formula and the v/c law. In the circular-polarization measurement performed on Co^{60} a value of $A=-0.41\pm0.08$ was found, in agreement with Schopper's value. The value of $A=0.52\pm0.16$ that was found for Au^{198} is consistent with a spin of 2 and rules out a spin of 3 for the ground state of Au^{198}. With the value of $A=-0.06\pm0.22$ for Hg^{203} (Bo 58) it was not possible to exclude a spin of $\frac{5}{2}$ for the ground state of Hg^{203} but the measurement is consistent with a spin of $\frac{3}{2}$.

Boehm and Wapstra studied further the above J-J transiton in Au^{198} along with those in Co^{58} (Bo 57a, Bo 58) and Sc^{46} (Bo 57b, Bo 58). The J-J transitions are of great interest because of the mixed nature of the beta transition. Thus the decay scheme of Sc^{46} is $4^+(\beta)4^+(2)2^+(2)0$ and differs from the Co^{60} case only in that $\Delta J=0$ instead of 1. For this decay scheme, Boehm and Wapstra write the asymmetry coefficient in compact form (Part I, C) as

$$A=(0.0834x^2+0.745a^{\frac{1}{2}}Ix)/(1+x^2), \quad \text{(III-10)}$$

where $x=a^{\frac{1}{2}}M_{GT}/M_F$, $a=(C_{GT}/C_F)^2=1.3$ (Ko 56) and I is the interference factor whose numerator is equal to S_1 for $LL'=01$ in Table X. If $I=0$, A varies from 0 to 0.083, as x goes from 0 to ∞. If $Ix>0$, then $A>0$, but if $Ix<0$, then $A<0$ except when $|Ix|<0.098x^2$. Finally, if the two-component neutrino theory with invariance under time reversal is valid, the maximum value of $|I|$ is given by $a^{-\frac{1}{2}}=0.88$. These properties are illustrated in Fig. 36 which gives curves for three values of $|I|$, namely 0, 0.5 and the maximum 0.88. The experimental result for Sc^{46}, $A=0.33\pm0.04$, is shown on the graph. The experimental value indicates a large value of $|I|$. Boehm and Wapstra give $|I|\geq0.5$ with a statistical uncertainty of 1%. Since the dominant term¶¶¶ in I is $\mathrm{Re}(C_SC_T'^*+C_S'C_T^*-C_VC_A'^*-C_V'C_A^*)$, this large value of $|I|$ rules out a pure V, T or a pure S, A interaction in this beta decay. If the maximum interference is assumed, a value of 2.2 is found for $|M_{GT}/M_F|$. For Co^{58}, Boehm and Wapstra found $A=-0.14\pm0.07$, and since the pure GT value is -0.083, no conclusion could be drawn concerning the interference term. The assumption of maximum interference, as suggested by the Sc^{46} result, leads to $|M_{GT}/M_F|>8$. The value of A obtained for Au^{198} (first forbidden) agreed with the earlier result and was consistent with the maximum theoretical value.

In a complete report (Bo 58), Boehm and Wapstra add to the treatment of Sc^{46}, Au^{198}, and Co^{58} a discussion of their work on Sc^{44}, V^{48}, and Na^{24}. In the case of Sc^{44} and V^{48}, the values of $A=-0.02\pm0.04$ and $+0.06\pm0.05$ indicate some interference since they are greater than the pure GT values of -0.17 and -0.083, respectively. If, as in the case of Sc^{46}, the maximum interference is assumed, $|M_{GT}/M_F|\cong5$ for both nuclei. For Na^{24} a value of $A=+0.07\pm0.04$ is obtained as compared to the pure GT value of 0.08. If maximum interference is assumed, $|M_{GT}/M_F|>25$. Interference between the GT and F interactions was also found by Boehm (Bo 58a) in the decay of Mn^{52}. In this example, $A=-0.16\pm0.05$, and the pure GT value is -0.056.

¶¶¶ The other term in I has a maximum value $\cong0.12$.

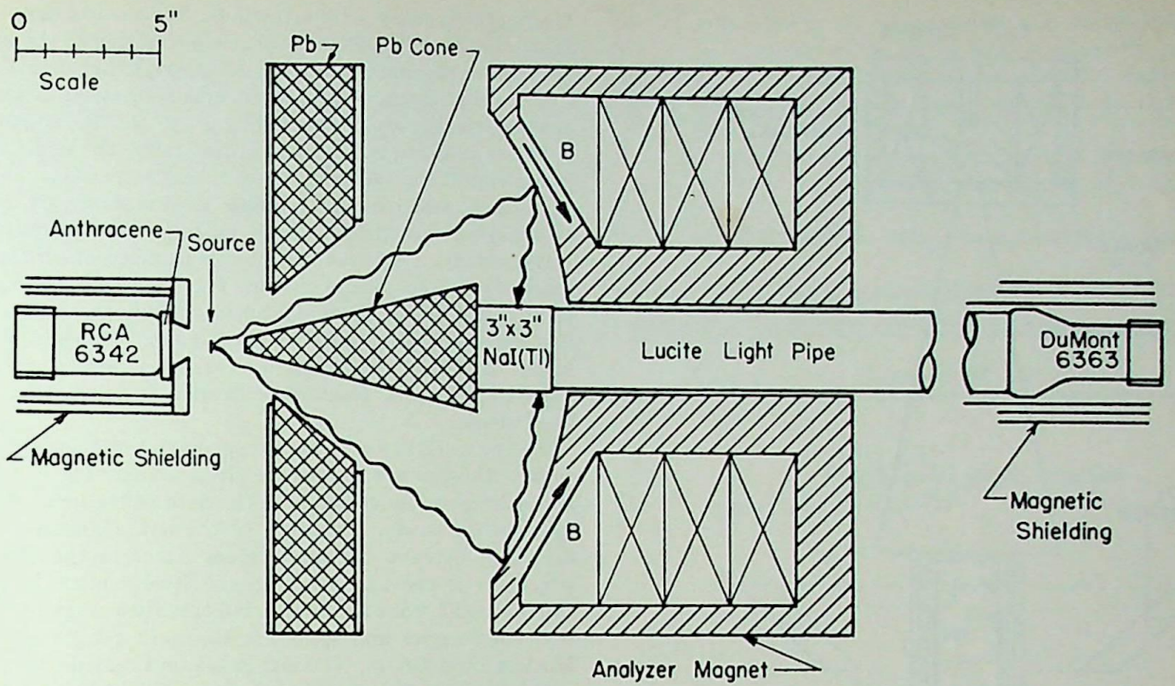

FIG. 37. Experimental arrangement of Steffen utilizing the method in which the electron polarization is perpendicular to the circular polarization (figure from St 58a).

Among the other early investigators in this field were Lundby *et al.* (Lu 57) who also made measurements on Co^{60}. Since it was felt the energy discrimination would be improved, they used the method of transmission through magnetized iron instead of the forward-scattering technique. They found a value of $A=-0.32\pm0.07$. In a note added in proof a value of $A=+0.34\pm0.14$ for Na^{22} also is given.

DeBrunner and Kündig (De 57) using the method of scattering also measured the anisotropy coefficient for Co^{60} and found $A=-0.344\pm0.09$ in good agreement with other values and with the theoretical value of $-\frac{1}{3}$. Shortly thereafter Berthier *et al.* (Be 57a) using the same equipment studied Au^{198}, the decay of which is first forbidden. It was found that $A=0.34\pm0.09$ which is somewhat smaller than the value above (Bo 58).

Again using the forward scattering from magnetized iron, Appel and Schopper (Ap 57) measured the circular-polarization correlations in Co^{60}, Zr^{95}, and Sb^{124}. The measurement on Co^{60} was primarily to test the reliability of the apparatus, but they give a value of $A=-0.35\pm0.05$ for this nucleus. In the case of the decay of Zr^{95}, the measurements were made on the unresolved 0.722- and 0.754-Mev radiations from Nb^{95}. By comparing the experimental value of $A=-0.46\pm0.09$ with possible theoretical values in the manner discussed in the foregoing (Al 57), Appel and Schopper conclude that there is probably present an ST or VA interference term. The measurements made with Sb^{124}, which has a first-forbidden transition to the 0.605-Mev state in Te^{124}, yielded a value of $A=-0.13\pm0.06$. This is smaller in absolute value than the value of $A=-\frac{1}{3}$ calculated (Al 57) on the basis of a simple once-forbidden transition.

In an effort to determine whether or not parity breakdown is a maximum, Appel *et al.* (Ap 58) remeasured more accurately the beta-gamma circular-polarization correlations in Co^{60} and Na^{22}. The measurement of the polarization correlation seems favorable for this purpose since all the necessary corrections can be calculated accurately and systematic errors can be kept small. They found $A=-0.340\pm0.035$ and $A=+0.295\pm0.054$ for Co^{60} and Na^{22}, respectively. These values compare favorably with the corresponding theoretical values of $-\frac{1}{3}$ and $+\frac{1}{3}$ for the case when nonconservation of parity and noninvariance under charge conjugation are maximum.

Steffen (St 58) also studied the circular polarization of the gamma rays from Co^{60} and Sc^{46}. He verified the dependence of the degree of circular polarization on v/c [Eq. (III-9)] and that the angular distribution varies as $\cos\theta$. For Co^{60} and Sc^{46}, values of $A=-0.34\pm0.02$ and $A=+0.24\pm0.02$ were found. Although the Sc^{46} value is smaller than that given by Bo 58, it verifies the presence of a large interference between GT and F interaction. If maximum interference between V and A interactions is assumed, $|M_{GT}/M_F|\simeq4.0$. With these nuclei Steffen (St 85a) has also used the method (Be 57) in which the electron polarization is perpendicular to the circular polarization. His experimental arrangement is shown in Fig. 37.

In a beautiful experiment by Goldhaber *et al.* (Go 58) on the 80-kev isomer of Eu^{152}, it was shown that the neutrino is left handed (negative helicity). Eu^{152} decays by electron capture to the 961-kev state in Sm^{152}. The experiment was performed by measuring the circular polarization of the 961-kev gamma rays which are subsequently resonant scattered from Sm^{152}. The ex-

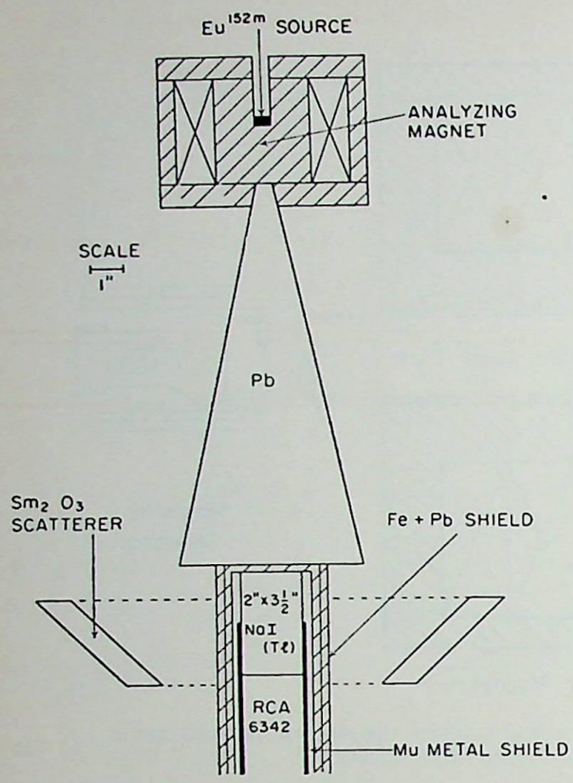

FIG. 38. Experimental arrangement for measurement of circular polarization of resonant scattered gamma rays. This arrangement was used by Goldhaber *et al.* to determine helicity of neutrinos (figure from Go 58).

perimental arrangement is shown in Fig. 38. Through conservation of energy and momentum the requirement of resonant scattering selects those gamma rays which are emitted opposite to the neutrino emitted in the electron capture. The magnetic analyzer determines the circular polarization (helicity) of the gamma rays. The helicity of the neutrino is then determined since a gamma ray emitted in the direction opposite to the neutrino will have the same helicity by conservation of angular momentum. The measurement gave negative helicity for the gamma ray and thus also for the neutrino.

E. Tabulation of Polarization Experiments on Nuclear Gamma Rays

The methods and results of the experiments discussed in the text are summarized in Table XIII. An explanation of the notation used and how the entries were made in the various columns of the table is given below.

Column I. Nucleus.—In all cases the nucleus given in this column is the nucleus emitting the gamma ray whose polarization is being measured. The experiments are listed in order of increasing mass number A.

Column II. Source of reaction.—In this column is given a level diagram of the radioactive decay or nuclear reaction used in each experiment. Frequently one diagram is applicable to several experiments and so is not repeated. The *level diagrams given in the table are not complete.* Only those levels which directly feed the gamma-ray transitions under study and those between the contributing levels and the ground state are shown in the diagram. Secondly, the level diagrams show only those transitions in the daughter or residual nucleus which give rise to the polarizations which were measured. Thirdly, only those beta transitions which lead directly to the gamma ray or cascade of gamma rays under study are given by solid arrows. Dashed arrows denote the fact that other beta transitions *may* be contributing to the intensity of the gamma ray under study but not through the particular cascade under study. Decay by positron emission, electron emission, or electron capture are designated by β^+, β^-, or EC, respectively.

In the case of the reactions in this table, the neutron, proton, or alpha particle is denoted by n, p, or α, respectively. In the case of resonant reactions, the resonant level is shown by a solid line. Nonresonant reactions show a dashed line, whereas in thick-target reactions a bracket is shown in place of all the "levels" reached in the compound nucleus. The bombarding energy is given as a dashed line in the initial nucleus. Neutron-capture reactions are shown with the "state" of the compound nucleus at the same height as that of the initial nucleus since thermal capture is involved in all cases. Coulomb excitation is denoted by a double-lined arrow.

Energy levels below 10 Mev are given to three significant figures, some of those above 10 Mev are given to four. The energies of the levels are given immediately to the right of the level, whereas the spins, when known, are given to the left. Gamma-ray energies are given between the level values either to the right or left, whichever is convenient. When the level scheme is sufficiently complicated, arrows are used to indicate the energy of the gamma ray. All energies and spins are the most recent given by the Nuclear Data Group, National Research Council (Mc 58a).

Column III. Polarization technique.—The letters given in this column denote the basic polarization technique used in each of the experiments. They are as follows:

C = Compton polarimeter detecting linear polarization.
C_f = Compton magnetic polarimeter detecting circular polarization by forward scattering.
C_t = Compton magnetic polarimeter detecting circular polarization by transmission.
D = Photodisintegration of the deuteron, detecting linear polarization by use of nuclear emulsions soaked in D_2O.

Column IV. Experimental conditions.—Three essential experimental conditions are given in this column. In order from top to bottom, as given with each experiment, they are as follows. (1) The physical entity which establishes the direction of quantization in the polarization correlation. Thus, if the direction is established by the propagation vector of an alpha particle, the entry α is made; if by a magnetic field, the entry "mag. field" is made, etc. In cases where the direction of propagation of a gamma ray in a cascade establishes the direction, the gamma ray is specified by energy when it is known. If there has been no clear discrimination between which gamma ray establishes the direction and which is accepted by the polarimeter, only the symbol γ is placed in this position. It should be noted in cases where Bleaney's method of alignment is used, that the words "crystal electric field" have been used primarily for convenience and do not in general mean that this field direction is the alignment direction. In general the alignment direction is established as the result of the coupling between the crystal electric field and the atomic orbital motion which in turn is coupled to the spins. Thus different alignment directions may occur depending on the crystal used. (2) Below entry (1) is given the angle between the axis of quantization and the axis of the polarimeter. When a complete direction-polarization correlation function is determined, the range of angles is indicated by an arrow between the extremes of the angular range. (3) Below entry (2) is specified the gamma ray whose polarization is being measured. When there is more than one gamma ray being analyzed and energy discrimination is made between each, a semicolon is placed between them. When the gamma rays are not resolved, a comma is placed between them and a (u) is inserted at the end. When there is discrimination available, but it is not specified which of the gamma rays is being analyzed, an "or" is placed between the gamma-ray entries.

Column V. Summary of results.—In the case of linear polarization measurements, the gamma rays studied are usually listed

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

first in vertical order with their multipolarities. The multipolarity is given even though additional evidence outside of the experiment listed usually is required to deduce it. In the case of the circular polarization measurements the anisotropy coefficient A is given for each gamma ray listed. In two instances N_+/N_- is used to indicate the ratio of counting rates before and after reversing the magnetic field.

The parity of a state is listed when it is of special interest, usually as designated by the author. The parity is determined, of course, only relative to other assumed or known parities. Other information such as spins, the sign of a magnetic moment, etc., is frequently given also when it is considered a significant part of the author's conclusions. As a general rule, the chief conclusion of the author is the one given.

A colon is used to connect an item given in the column with the results of the measurements made on it, e.g., "cascade: $4(E2)2(E2)0$."

A reference is made to other work (usually a measurement of

TABLE XIII (addenda). Summary of experiments. An explanation of the various entries is given in Part III, E.

Nucleus	Method	Addenda. In the second column the letters have the same meaning as before. Result and reference
N^{14}	D	Measurement of linear polarization of γ ray in $C^{13}(p,\gamma)N^{14}$ at $E_p=1.76$ Mev indicated no parity change in the transition to the ground state [Strassenburg, Hubert, Krone, and Prosser, Bull. Am. Phys. Soc. Ser. II, 3, 372 (1958)].
Mg^{24}	C_f	Measurement of β-γ circular-polarization correlation in decay of Na^{24} gave $A=+0.05\pm0.04$ in agreement with other results [R. M. Steffen and P. Alexander, reported in *Proceedings of the Rehoveth Conference on Nuclear Structure* (North-Holland Publishing Company, Amsterdam, 1958)].
P^{31}	D	Linear polarization measured at three resonances in $Si^{30}(p,\gamma)P^{31}$. The 8.04-, 8.20-, and 8.24-Mev γ rays are $E1$, $M1$, and $E1$, respectively (Tu 57).
S^{34}	C	Measurement of γ-γ direction-polarization correlation in the 1.16–2.10-Mev cascade, with the γ-rays resolved, confirmed the assignment of $2^+(M1,E2)2^+(E2)0^+$ and gave $\delta=0.13$ [C. G. Shute and P. S. Fisher, Phil. Mag. 3, 726 (1958)]
Ti^{46}	C_t	Measurement of β-γ circular-polarization correlation in the decay of Sc^{46} gave $A=+0.29\pm0.11$ in agreement with other results. [Lundby, Patro, and Stroot, quoted by M. A. Grace, Proc. Roy. Soc. (London) A246, 460 (1958).]
Ni^{60}	C_t	The β-γ circular-polarization correlation was measured as a function of v/c. Circular polarizations greater than $\frac{1}{3}v/c$ were observed, especially for small values of v/c [Page, Pettersson, and Lindqvist, Phys. Rev. (to be published)].
Sm^{152}	C_t	The experiment of Go 58 was repeated to show that the neutrino has negative helicity in the decay of Eu^{152} [I. Marklund and L. A. Page, Nuclear Phys. 9, 88 (1958)].
W^{183}	C_t	Measurement of circular-polarization of radiation following capture of polarized thermal neutrons indicated complete right circular polarization in agreement with spin assignments and the expected $E1$ character of the radiation. Result used by Tr 57 to establish the reliability of experimental arrangement.
Hg^{195}	C_f	Measurement of β-γ circular-polarization correlation on decay of Au^{198} gave $A=0.45\pm0.06$ for an electron energy range of 520–620 kev and $A=0.38\pm0.10$ for a range of 620–850 kev (R. M. Steffen and P. Alexander, see Mg^{24} above).
Hg^{198}	C	The 411-kev γ ray from Au^{198} was resonant scattered by Hg^{198} and the linear polarization of the scattered radiation was measured. A multipolarity of $E2$ was confirmed for the radiation [V. Knapp and B. S. Sood, Proc. Roy. Soc. (London) A247, 369 (1958)].
Pb^{208}	C	Linear polarization measurements [G. T. Wood and P. S. Jastram, Phys. Rev. 100, 1237(A) (1955)] along with directional measurements confirmed the assignments, of 0^+, 3^-, 5^-, 4^-, and 5^- to the first 5 states in Pb^{208} [Elliott, Graham, Walker, and Wolfson, Phys. Rev. 93, 356 (1954)].

the direction-direction correlation) if it seems particularly relevant or related to the polarization measurement. No attempt is made at completeness in the listing of relevant references.

Column VI. Reference.—The reference corresponding to each experiment listed in the table is given in this column.

ACKNOWLEDGMENTS

We would like to thank Dr. Joachim Ehrman for many helpful discussions and Dr. Francis E. Throw for his generous aid and advice in writing the manuscript. Dr. Phillip Malmberg, Mr. Ronald Fast, and Mr. Samuel Chappell were of great assistance in the search of the literature. Mr. Chappell also helped with some of the calculations. Mr. Ralph Klingler provided many of the calculations on which the tables are based. The Graphic Arts Branch of NRL supplied most of the figures and reproductions. We are grateful also to Dorothy Bodden for her careful preparation of the manuscript. One of us (SSH) would like to thank the Guggenheim Memorial Foundation for a fellowship which aided in the work.

I. INTRODUCTION

WHEN Goudsmit and Uhlenbeck proposed the spinning electron the possibility arose of having spin-polarization effects for a free electron. On the basis of Dirac's theory of the electron Mott proposed in 1929 a double scattering experiment designed to demonstrate such (transverse) polarization: the first scattering in the Coulomb field of a high-Z nucleus would serve partially to polarize an incident beam of unpolarized electrons because of the spin-orbit interaction, while the second such scattering would serve as the polarization analyzer. For a quarter century thereafter this quite difficult experiment was pursued in a number of laboratories. Approximately midway through this period it became evident that the experiment could, in fact, demonstrate the sought-for polarization, and at present there remains no doubt whatever that it can be made to work.* It is perhaps fortunate that the double scattering experiment was not crucial for Dirac theory, and that the other verifications came as early as they did.

An unfortunate situation prevailed during the 1930's and 1940's in that the whole matter of electron, positron, and gamma† polarization in general was viewed rather apathetically by many physicists. Such attention as there was, was focused almost entirely on the double scattering experiment itself. Thus the polarization effects already existing in the Klein-Nishina matrix element for Compton scattering, in the Møller matrix element for electron-electron or positron-electron scattering, in the Bethe-Heitler matrix element for bremsstrahlung, to name a few of the common electron-photon processes, continued to lie dormant‡ until quite recently.

Prior to about 1956 there was no supposition that "prepolarized" beams of electrons, positrons, or photons would be available from beta decay of nuclei. Therefore any experiments then proposed, just as with the Mott proposal, would have had to be of "second order," involving a polarizing unit to be followed by an analyzing unit. Such experiments seem to have had no strong appeal to experimenters in general.

When it turned out that parity violation in beta decay was in a sense complete, as demonstrated by the beautiful cobalt-60 experiment of Wu, Ambler, Hayward, Hoppes, and Hudson, it became clear that prepolarized beams of particles (and at times prepolarized photons) must exist. This initiated a greatly accelerated development of practical techniques for handling such polarizations. This paper discusses the various methods for analyzing electron and positron polarization, most of which were introduced and proved during the short period of about half a year following the announcement of parity violation. Photon (circular) polarization§ must be brought into the discussion

* Tolhoek [reference (T)] covers the double scattering experiment thoroughly.

† Plane polarization was discussed early, but there is no *direct* connection between such photon polarization and electron polarization.

‡ That is, spin polarization was rigorously summed or averaged at each opportunity in proceeding from matrix element to transition probability. A rare exception is the paper of Franz (F38). The spin direction having been generally taken out, circular polarization information was automatically suppressed. The justification for such averaging was considered sound: "The spin direction is not measured." We have not far to look for the reason it was not measured, and the circle is thus closed.

§ Such polarization is dealt with only lightly here. In contrast to the situation regarding particle polarization, there appears to have been introduced no new approach to this problem since the time of the Wu experiment. Reference (T) discusses the Compton effect as applied to circular polarization measurement. See also a recent review (S58) by Schopper.

because it connects with the problem of measuring free particle polarization.

The large and decisive effect found in the Wu experiment was primarily responsible for the apparent ease with which the new polarization methods succeeded. Knowledge that certain polarizations are quite probably present, and in abundance, has made for quick development of suitable experimental techniques. Also this knowledge has made for ready acceptance of most experimental conclusions relating to beta-decay polarizations, however hastily drawn a few may have been.

In the beginning of this new polarization era, one might have expected that only "first-order" experiments would appear. However, with the luxury of generally large inherent polarizations to begin with, a considerable number of second-order methods have already been successfully proved. Here the polarization one wishes to know is transferred for strategic reasons from initial particle to photon, or from particle to particle, in the first stage, and then the polarization analysis itself takes place in the second stage. Thus one requires two unlikely events in series, which makes the experiment second order.

The methods and the physics on which they are based are emphasized here, so the historical order is not followed in every case. For a given topic only a sufficient number of works is reviewed to illustrate the physics involved.‖ Closely related ideas (although perhaps not proved experimentally) are sometimes mentioned to round out the discussion. No pretense is made of reviewing all "parity results" obtained by a given method. No grand averages are made of the numbers obtained with a given radioactive source, and no pronouncements are attempted on such matters as a universal beta interaction or *PC* invariance.

The discussion cannot be divided rigidly into experimental method *versus* "theory of the method." Measurement of polarization by counter techniques (the only technique described here) is a field where it seems particularly safe to predict that a hypothetical ensemble of technicians continually trying different arrangements of scattering foils, magnets, absorbers, and so forth—with no belief in any theory and therefore no real plan—would take a long time indeed to happen upon a useful method. Each technique had to be planned in advance, hopefully at times because polarization measurement is not easy.

II. GENERAL CONSIDERATIONS

A. Polarization of Free Electrons

For an electron under no forces, solutions of the Dirac equation exist which are simultaneous eigenstates of momentum $\mathbf{p}$, of energy [eigenvalues $\pm\gamma$, where $\gamma=(1+p^2)^{\frac{1}{2}}$], and, if we wish, also of helicity. That is, letting $\mathbf{p}$ define the z direction, we may have a solution which is simultaneously as eigenstate of $H\equiv\boldsymbol{\alpha}\cdot\mathbf{p}+\beta$, of $\mathbf{p}$, and of σ_z (with eigenvalues ±1). This is possible because the operator σ_z commutes with all of the Hamiltonian *that matters* for this special case, namely, $p\alpha_z+\beta$.

But (still letting eigenvalue $\mathbf{p}$ define the z direction) we are not able to construct an eigenstate of σ_x, for σ_x anticommutes with α_z. However if the coefficient of α_z, namely p, is small, then the effect of this lack of commutation becomes correspondingly small. Thus at very low energy any component of $\boldsymbol{\sigma}$ is nearly completely measurable. For finite laboratory energy the closest we can come to having a state of precise σ_x is to take the "best" linear combination of the two eigenstates of σ_z. Mixing equal amplitudes of the latter two states with a plus (minus) sign gives $\langle\sigma_x\rangle=\pm1/\gamma$, which tends to ±1 as p tends to zero. Another real operator, $\beta\sigma_x$, does commute with α_z, and with β. Therefore, simply because the maximum expectation value of σ_x becomes so nearly zero at high energy, it does not follow that transverse polarization is somehow "unmeasurable" at high energies. This means only that techniques are required that aim at measuring $\beta\sigma_\perp$ rather than measuring $\sigma_\perp$ itself. Otherwise one might follow the course of first precessing the spin and then measuring σ_z.

In speaking of longitudinal polarization of an electron or positron we use $P_p=\langle\sigma_z\rangle$, where z is parallel to the velocity. P_p is thus a number which may range from -1 to $+1$. As is well known, a Lorentz transformation may be made along the z axis, to the rest system of the particle in particular, and P_p retains the same value. In the rest system we could for the moment suppose full polarization is some direction, say at angle θ_0 (polar angle) and ϕ_0 (azimuthal angle), referred to z and x directions. The spinor part of the state can then be given by $|+1\rangle\cos(\theta_0/2)+|-1\rangle e^{i\phi_0}\sin(\theta_0/2)$ in the rest system of the particle, or in the laboratory. For this situation the value of P_p is just $\cos\theta_0$.

Transverse polarization is denoted by P_s, and naturally a certain azimuth has to be implied. We shall mean that $P_s(\phi)=\langle\sigma_x\cos\phi+\sigma_y\sin\phi\rangle$ computed *in the rest system* of the particle. For the oblique situation given in the foregoing, $P_s(\phi)$ amounts to $\sin\theta_0\cos(\phi-\phi_0)$. Often in speaking of how much transverse polarization exists in a beam, one tacitly maximizes $|P_s|$ against ϕ before quoting the number, since the geometry of the experiment usually involves a natural choice for the reference azimuth ϕ_0 (or $\phi_0+\pi$).

Suppose we have a partially polarized beam (longitudinally polarized, for example), with $0<P<1$, say. We may consider that the fraction $1-|P|$ of the particles are unpolarized while the fraction $|P|$ are completely polarized, with the sign of P. Alternatively the same beam may be regarded as a mixture of + and

‖ The bibliography makes no attempt to list many of the excellent experiments which have corroborated, extended or improved upon those which are listed. The total literature on the subject (experimental and computational) has become quite extensive. Inasmuch as experimental technique in general seems now to be in an improvement stage rather than in a stage of new development, it seems too early to attempt complete listing.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

— polarized components in the ratio of $(1+P)/(1-P)$, which holds for either sign of P. Certain mathematical approaches favor the first view. On the other hand, most calculations proceed just as easily using the second view. Since no experimental detector can be devised to differentiate between the two situations, there is no point in debating which of these two views is the correct one.

To specify the total polarization in a beam it suffices to know three components of polarization in mutually orthogonal directions.¶ Polarization is averaged as follows: If beam number one of intensity m_1 has an amount of polarization $\mathbf{P}(1)$ and a second beam *incoherent* with the first, of intensity m_2, has $\mathbf{P}(2)$, then as a whole the polarization is

$$\mathbf{P}=[m_1\mathbf{P}(1)+m_2\mathbf{P}(2)]/(m_1+m_2).$$

B. Polarization Efficiencies

One is interested in the relative response of a polarization detector for two orthogonal spin orientations (that is, mutually orthogonal states). For example, for detecting a nonzero P_p one requires an apparatus that responds differently to a particle with $P_p=+1$ than to a particle with $P_p=-1$. All the detectors reviewed here are reversible.** Suppose for + setting of the detector that the probability, given a + particle, that it count is C_{++}, and the corresponding probability for a − particle to count is C_{+-}. Let the − setting of the detector have respective probabilities C_{-+} and C_{--}. The order of the subscripts is important. Then, if $C_{--}=C_{++}$ and also $C_{-+}=C_{+-}$, the detector is called *reversible*. We write $C_{++}/C_{+-}=r=C_{--}/C_{-+}$. (This definition of r is more useful than using C_{++}/C_{-+} or C_{--}/C_{+-} as appears in a moment.) The counting-rate ratio, + setting divided by − setting, will be $R=(1+\epsilon P)/(1-\epsilon P)$. Here the efficiency ϵ of the detector is $\epsilon=(r-1)/(r+1)$. This efficiency applies of course to one component of polarization, that associated with the ± setting of the detector.††

In practical circumstances, due to fringing fields, for example, a counting efficiency (not a polarization efficiency) may change from + setting to − setting, violating the condition for reversibility. But since the physics upon which the polarization sensitivity is based is independent of such systematic effects, it may still be that the ratio r as stated above is unambiguous. We then keep the same value of ϵ independent of the systematic effect. In such a case the counting-rate ratio has to be written more generally as $R=(C_{++}/C_{--})(1+\epsilon P)/(1-\epsilon P)$. If it should be possible exactly to reverse P, or to render $P=0$, say (and neither of these things may be easy to do), then the fact that $C_{++}/C_{--}=C_{+-}/C_{-+}$ is not unity need not hurt the final result, since this ratio can be determined empirically.

To keep the discussion simple, reversible detectors are assumed from now on. A good reason for generally thinking in terms of an efficiency ϵ instead of the corresponding ratio r is that the law of propagation for a number of "in series" effects is most clearly expressed in terms of ϵ's and not r's. For example (if we may adhere to the nonpositivistic approach), consider a particle or a beam which is polarized by an amount P_0. Suppose the polarization were transferred in the first stage of operations to some intermediate particle or beam with transfer efficiency ϵ_1, the intermediate polarization, perhaps of a different kind, being now $\epsilon_1 P_0$. Let this beam be now analyzed with efficiency ϵ_2. The over-all efficiency $\epsilon_1\epsilon_2$ is the quantity that defines the change in counting rate on reversing either P_0, ϵ_1, or ϵ_2. The rate ratio on such reversal is $R=(1+\epsilon_1\epsilon_2 P_0)/(1-\epsilon_1\epsilon_2 P_0)$. Depolarization could be taken into account by using a series of "efficiencies for preservation of polarization," numbers ϵ_d's less than +1 which would then multiply the $\epsilon_1\epsilon_2$ in this example. All of the ϵ's mentioned, including that of the detector, can as well be regarded as transfer efficiencies, since the over-all product-ϵ represents numerically the efficiency for transferring the original polarization information into a counting-rate asymmetry.

Here we have chosen to carry through a pair of *probabilities* rather than a pair of *amplitudes*. It has been tacitly assumed that physical judgement has been used throughout in choosing at each juncture a pair of orthogonal states for which any coherence between their amplitudes is of no consequence. The point is that the relative phase of their amplitudes is thrown away each time we force the calculation to tell us probability throughout the chain of events. Any blunder in such choice of states leads to grief. Often, there is considerable latitude here and we are free to choose a reasonably simple pair of states for algebraic convenience. If there is any doubt as to which pair of states to choose, which is tantamount to having doubt as to which kind of polarization it will suffice to talk about, then the amplitudes themselves could be carried through.

To return to the counting-rate asymmetry, experimenters usually prefer to discuss results in terms of the fractional change in rate between the + and − settings of the detector. This fractional change is often denoted by δ. One has

$$\delta=2\frac{R-1}{R+1}=2\frac{R_+-R_-}{R_++R_-}=2\epsilon P. \qquad (1)$$

¶ We thus have a polarization space of three dimensions for spin-$\frac{1}{2}$ particles. For photons (which are *not* spin-1 particles) a similar space can be used: The momentum direction $\mathbf{k}$ is special and pertains to circular polarization; normal to this, plane polarization may be represented, providing that azimuthal angle in this polarization space is twice the corresponding azimuthal angle in the laboratory.

** Actually, experimental situations exist and may play a role in the future where in practice the detector is not actually reversed. For example, it may have one state where it responds preferentially to $P>0$, and the other state where it is insensitive to P.

†† We could represent any polarization detector as a vector $\boldsymbol{\varepsilon}$ in a three-dimensional efficiency space. The efficiency for detecting arbitrary polarization $\mathbf{P}$ in a beam is then $\boldsymbol{\varepsilon}\cdot\mathbf{P}/|P|$. The same applies for photons.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

Concerning the factor 2 that appears in expression (1): given a pair of numbers, 100 and 101, one physicist may recognize and comment that they differ (to first order) by one percent. Another may prefer to state that these two numbers exhibit an asymmetry about their arithmetic mean of 1/201, thus a nominal one-half percent effect. We prefer the first method in discussing experimental results, even though δ will exceed 100% if experiments improve to the extent that ϵP becomes larger than 0.5.

It may be felt that density matrices and Stokes parameters are not accorded their fair place in the discussion. A number of review articles have treated these matters [T, (F57)]. The basic ideas of the experiments to be described can be put in quite simple language. This reviewer can readily believe (but would find it difficult to prove) that the majority of these experiments were conceived, made to work, and interpreted correctly, without conscious recourse to the density matrix.

Before ending the general discussion of polarization measurement we might inquire a little into measurability of more than one component of polarization. Consider some state α which means definite spin direction for the particle (in its rest system). Only one orthogonal state exists, for a spin-$\frac{1}{2}$ particle; call it β. Let us have α and β normalized in the same way, with the phase between them fixed. For any state of affairs, the polarization of the kind α is computed from the probability of finding that the particle is in state α compared to the probability it is in state β. Thus

$$P_\alpha=\frac{\text{prob}(\alpha)-\text{prob}(\beta)}{\text{prob}(\alpha)+\text{prob}(\beta)}, \qquad (2)$$

and P_β is $-P_\alpha$.

Instead of states α and β we might use a state called A, which is $\alpha+e^{i\phi}\beta$ and its orthogonal state B which is $\alpha+e^{i(\phi+\pi)}\beta$. Then the polarization of kind A, denoted P_A, is given in terms of prob(A) and prob(B) by an expression such as (2). So long as ϕ is a real number, polarization P_A is complementary to polarization P_α, since if $P_\alpha{}^2=1$, then $P_A{}^2=0$, and conversely. We may generate a third polarization $P_{A'}$ which is complementary to P_A and to $P_\alpha(A'=\alpha+ie^{i\phi}\beta, B'=\alpha+ie^{i(\phi+\pi)}\beta)$. For a particle polarized by an amount $\mathbf{P}$, we have

$$P_\alpha{}^2+P_A{}^2+P_{A'}{}^2=P^2\leqq 1. \qquad (3)$$

Of course, expression (3) is a statement of probabilities, as with expression (2). If one measures, by utterly precise means, P_A for a particle, one finds either $+1$ or -1, and expression (3) is then amended to read $P_A{}^2=1$, $P_\alpha{}^2=P_{A'}{}^2=0$.

A longitudinal polarization detector gathers *all* the longitudinal polarization information from a beam, whereas a transverse detector leaves unexplored the complementary component of transverse polarization. It is possible however to arrange to collect concurrently all the transverse polarization information in a beam of particles or photons, in which case the detector is not characterized by a single angle ϕ (supposing α to correspond to the beam direction) but strictly consists of two or more detectors operating in parallel.

C. Right *versus* Left Helicity

A right-handed particle or photon means one that "rotates" as it moves in the same manner as a standard right-hand screw. This can also be stated: When angular momentum and velocity are parallel the particle is right-handed, when antiparallel, left-handed.

In classical optics the opposite definition is in use: Right circularly polarized light is that in which the electromagnetic vectors show clockwise rotation as viewed by an observer into whose eyes the light enters, that is, an observer facing *opposite* to the direction of propagation of the light.

III. EXPERIMENTAL METHODS

A. Classification of Methods

Three different ways of analyzing spin polarization have been experimentally proved. One method makes use of the spin-orbit interaction when the particle is scattered by the Coulomb field of a nucleus, the method proposed originally by Mott (M29). Here any transverse polarization generally leads to a right-left asymmetry in the scattered intensity. This amounts to talking about a "force" $-\nabla(\boldsymbol{\sigma}\cdot\mathbf{H}')$ for e^-, where $\mathbf{H}'$ is the magnetic field experienced by the particle in moving through the Coulomb field $\mathbf{E}$, namely $-(\mathbf{v}/c)\times\mathbf{E}$. In the second method one makes use of the $\boldsymbol{\sigma}\cdot\mathbf{H}$ energy, where $\mathbf{H}$ now stands for an applied magnetic field. This method finds application where positronium is formed from polarized positrons. The third method is where one *compares* the polarization of the particle to be analyzed with a *reference* polarization residing in atomic electrons which are already aligned. In this category belongs use of electron-electron scattering (and positron-electron scattering), annihilation of very low energy positrons in a ferromagnetic material, or use of annihilation-in-flight of more energetic positrons in a magnetized foil. Also there belong here the second-order techniques where the particle polarization information is transferred to helicity of a photon, this helicity being then analyzed by Compton scattering against the polarized reference electrons.

B. Mott Scattering (and Spin Precessors)

Properly, the Mott scattering method applies to transverse polarization analysis only. For reasons of Coulomb repulsion it is not well suited for positron analysis. As one suspects from contemplating the fingers, an "up" spinning electron approaching "straight ahead" a nucleus of (positive) charge Ze should prefer to scatter to the right rather than to the left because of the force $\nabla\boldsymbol{\sigma}\cdot(\mathbf{v}\times\mathbf{E})$ implied by its magnetic moment moving

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

in the steeply graded field $\mathbf{B}'=\mathbf{E}\times\mathbf{v}$. The quantum mechanical results, first estimated by Mott and more recently computed by Sherman (S56), predict generally large right-left asymmetry in the scattered intensity. The azimuthal variation of the scattered intensity at angle ϕ is $\sin(\phi-\phi_0)$ for an incident electron polarized at azimuth ϕ_0. Conversely, the asymmetry in intensity between azimuth $\phi+90°$ and the conjugate azimuth $\phi-90°$, defined as

$$\delta_\theta(\phi)=\frac{I(\phi+90°)-I(\phi-90°)}{I(\phi+90°)+I(\phi-90°)} \tag{4}$$

is a measure of the transverse polarization at azimuth ϕ. A coefficient of proportionality relates the thing we presume to be measuring, the transverse polarization $P_s(\phi)$, and the observed δ. We call this coefficient S_θ following Sherman, and write $\delta_\theta(\phi)=S_\theta P_s(\phi)$.

For given energy, there is a best region in polar scattering angle θ at which to work, from the point of view of size of the asymmetry S_θ. Some of Sherman's results for the right-left asymmetry for an unscreened point scatterer ($Z=80$) are given in Table I. This shows at each of several speeds v/c, the maximum S_θ, the angle $\theta_{\max}$ at which it occurs, and the two adjacent angles called $\theta_{\frac{1}{2}}$ at which the asymmetry is down to one-half maximum value. At a certain angle θ ($\sim 60°$ at $v/c=0.4$ and shifting to $\sim 30°$ at $v/c=0.9$) the asymmetry S_θ becomes zero and changes sign. To avoid ambiguous factors of two, note that $S=+0.4$, for example, means that the intensity to the right (see beginning of this subsection for orientation) exceeds that to the left for an up-spinning electron incident, the ratio of intensities being 1.4/0.6.

What is not shown in Table I, but which could be very important when considering possibilities of systematic error in an actual experiment, is the variation with θ of the ordinary differential cross section. This gradient turns out to be quite steep at angles of experimental interest. A representative value, for the speeds shown in Table I, is 150% change in differential cross section per radian at $\theta=90°$. The gradient at $\theta_{\max}$ ranges from roughly 70% per radian for $v/c=0.4$ to about 150% per radian for $v/c=0.9$.

Also important is the fractional change in ordinary differential cross section for given fractional change in energy. At $\theta=90°$ this amounts to about 1.6, and would be somewhat larger if put in terms of fractional change in momentum.

TABLE I.

v/c	$S_{\max}$	$\theta_{\max}$	$\theta_{\frac{1}{2}}$	
0.9	0.51	150°	101°	170°
0.8	0.48	137°	90°	167°
0.7	0.45	130°	85°	165°
0.6	0.43	126°	83°	162°
0.5	0.40	123°	82°	161°
0.4	0.37	121°	85°	159°

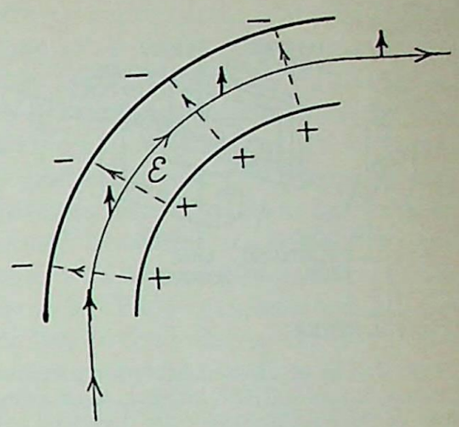

FIG. 1. Electrostatic spin-precessor due to Tolhoek and DeGroot (T51).

In the first successful detection of longitudinal polarization of beta particles from unpolarized nuclei by Frauenfelder and co-workers (Fa57), a means of first precessing the spin from longitudinal to transverse had to be employed in order to be in a position to use Mott scattering as the detector. A device originally proposed by Tolhoek and DeGroot (T51) was employed in order to "erect" the spins. Such a spin-precessor is shown in Fig. 1. It is essentially a nonrelativistic device and so the energies at which it works best are well matched to a Mott-scattering analyzer. Neglecting relativistic considerations, its action is simple and direct: The spin has no way to know that the electric field is continually changing the particle momentum $\mathbf{p}$, and thus the spin tends to retain its original direction in space, independent of sign or magnitude of the g value. (The device could more accurately be described as a momentum precessor.)

In the Frauenfelder experiment the Coulomb scattering act, (taking place in a thin gold foil) in analyzing the transverse polarization as the beam emerged from the spin erector, was measuring the longitudinal polarization that had entered the spin erector. Inasmuch as this spin precessor is a reversible device, that is, no information is lost through its use, we could classify this experiment as first order.

The angular aperture used was 95°–140°. A pair of end-window Geiger counters recorded the right- and left-scattered betas. The scattering foil was either 0.05 or 0.15 mg/cm² gold on a low-Z backing. The results of the first measurement, using a Co^{60} source, are well known: These negative betas were predominantly left-handed, the magnitude of the asymmetry obtained being taken to imply longitudinal polarization at emission of magnitude v/c, at least at sufficiently high beam energy that all the "dirt" effects that had at times plagued certain of the double-scattering experiments were probably not serious. There was a drop in apparent polarization of over a factor two on changing the mean v/c from 0.49 to 0.47, the decrease amounting to essentially two standard deviations.

We continue to introduce Coulomb scattering experiments in terms of the kind of spin precessor used, because the Mott scattering approach to polarization is

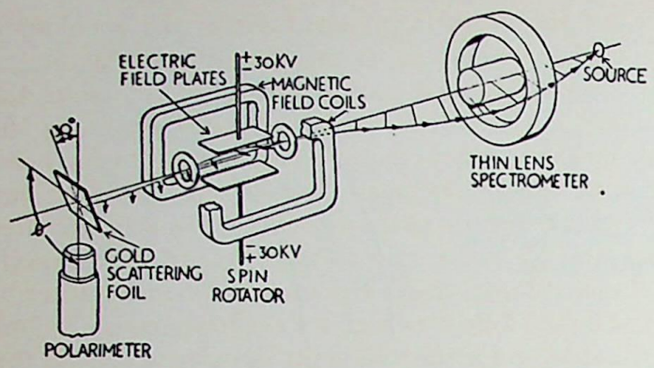

FIG. 2. Use of crossed-field spin-precessor. In the apparatus of Cavanagh *et al.* (CR57) original longitudinal spins entering at the right of the spin-precessor are precessed to emerge pointing downward. Polarimeter unit consists of scattering foil plus scintillation counter which can rotate about the beam axis.

scarcely new in the laboratory, and has been reviewed (T). Actual use of spin precessors is however quite new.

Another spin precessor is the crossed-field device. The beam is arranged to travel at right angles to an electric field **E** and a magnetic field **B** which are themselves at right angles. In the type to be described the fields are homogeneous over a certain region (it may be clearer to say that the geometry is rectangular). The crossed fields define a speed $\beta_0 = E/B$. If one arranges $0 < \beta_0 < 1$, then in the moving system characterized by speed β_0 in the laboratory, there is no electric field, and the magnetic field is $B' = B(1-\beta_0^2)^{\frac{1}{2}}$. A Dirac particle at rest (for example) in this moving system has its spin precessed at angular speed $\omega' = eB'/m_0c$, the sense depending on the sign of the g value. In the laboratory system this means that a particle that has traveled a distance $z = 2\pi\rho_0(1-\beta_0^2)^{-\frac{1}{2}}$ has its spin precessed through an angle $\theta = 2\pi$. Here, $B\rho_0$ stands for laboratory momentum of the central ray. For distances in the laboratory Δz, differing from integral multiples of the distance just cited, the precession angle of a general ray may deviate somewhat from that of the central ray, which remains $\Delta\theta = (1-\beta_0^2)^{\frac{1}{2}}\Delta z/\rho_0$. But such deviations are readily computed.

A crossed-field device with suitable slit system can be a mass spectrometer,‡‡ and not simply a "velocity-filter." It might be possible to make practical use of this fact in dealing with polarized particle beams.

Cavanagh and co-workers (CR57) have used a crossed-field device as a spin-erector. The beta energy was preselected by means of a magnetic lens (Fig. 2). This lens does nothing to alter P_p since $\boldsymbol{\sigma}\cdot\mathbf{v}$ in a region where $\mathbf{E}=0$ is a constant of the motion. Next the crossed-field precessor interchanges longitudinal and transverse polarization components in the beam. Finally, Mott scattering at nominal $\theta = 90°$ is used to analyze for transverse polarization. The scintillation detector (of size characterized by 0.3 radian) plus the thin gold scattering foil form a unit, the polarimeter unit, which may be rotated in azimuth ϕ. The results show the expected right-left asymmetry [the observed δ as in Eq. (1) being as large as 20%], but in addition a curious and hard to explain up-down asymmetry presumably of instrumental origin. It was possible by reversing fields to split off this latter (orthogonal) asymmetry from the desired one. In the first experiments Co^{60} and Au^{198} negative betas were shown to have longitudinal polarization consistent with $-v/c$. Alikhanov *et al.* have also used a crossed-field spin precessor (A58).

Regarding attenuation of the sought-for asymmetry due to the scattering foil having finite thickness, Fig. 3 shows an extrapolation against foil thickness. This gives a graphic demonstration of how finite foil thickness, presumably through plural scattering and possibly depolarization, reduces the observed asymmetry.

A third device for transferring polarization information from longitudinal to transverse (or vice versa) has been used specifically to prepare a beta beam for Mott scattering analysis. This we call a "spin reprojector." It consists in scattering the original beam by atoms, whether singly or multiply does not matter to a first approximation. The transverse polarization of the electrons after scattering at $\theta = 90°$ represents the input longitudinal polarization, to the extent that the original spin direction is unchanged on scattering.§§ The action is similar to that of the macroscopic electrostatic spin precessor.

The resulting transverse polarization lies in the plane of the scattering. Even taking into account the fact that the spin-orbit effect may not be entirely negligible, this cannot lead to any polarization in this plane. The spin-orbit effect and any helicity memory act only in competition to dilute and dull somewhat the transfer efficiency of interest, since the sum of the squares of

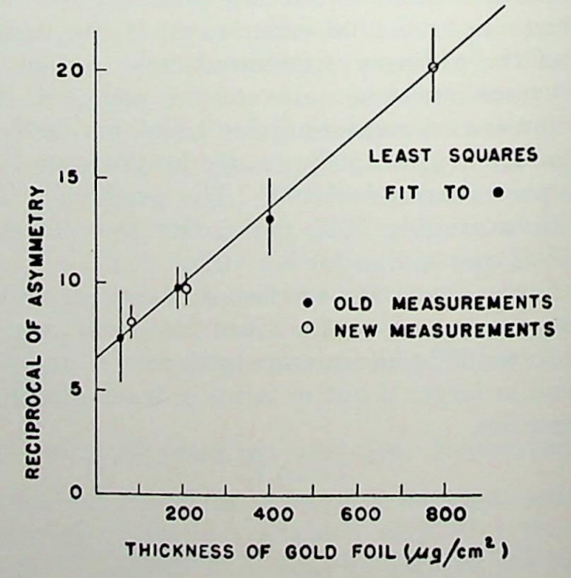

FIG. 3. Effect of scattering foil thickness on the measured asymmetry, from Cavanagh *et al.* (CR57).

‡‡ Compare the nonrelativistic applications by Bleakney and Hipple (B38).

§§ Bernardini, *et al.* (B58) treat this matter quantitatively. They show that there can be considerable helicity memory in a Coulomb scattering event.

three mutually complementary polarizations cannot exceed unity. A fairly low-Z scattering material is preferable from this point of view.

Spin erection by means of this reprojection method has been used by Pond (Po57) on P^{32} electrons. It has been used in a very nice geometry by Deshalit and coworkers (De57). Their apparatus is shown in Fig 4. The spin reprojector is in the form of a sheet of aluminum (denoted by symbol σ_1) forming an arc of a circle. From the geometry of the circle one may then have (for point source and point second-scatterer) constant "total" scattering angle θ, in this case 90°, over a large range of emission angle at the source. This affords a gain in intensity which is needed in a second-order experiment. The resulting asymmetry for P^{32} electrons of energy exceeding 900 kev, at nominal second-scattering angle $\theta=75°$, was 5%. This was interpreted as compatible with full v/c polarization.

Spin erection by means of Coulomb scattering was suggested independently also by Tassie (Ta57). Another possibility for spin erection is based on Møller scattering [see Sec. III D (1)].

A high-energy precession effect relating to the anomalous magnetic moment has been computed by Mendlowitz and Case (M55). A spin precessor based on such an effect, used in conjunction with a Mott scattering analyzer might suffer from a limitation due to energy mismatch. To illustrate with a simple situation where a Dirac particle travels normal to a magnetic field, if the g value were simply two, this would cause the preservation of spin polarization projected onto the velocity vector. In terms of "time dilation," the zero-energy value of the cyclotron frequency (the frequency of rotation of the velocity vector) and the spin precession frequency are each multiplied by the same factor, $(1-\beta^2)^{\frac{1}{2}}$. The two quantities, velocity and spin direction, then stay in phase for a hypothetical Dirac particle. Otherwise said, $\boldsymbol{\sigma}\cdot\mathbf{v}=\boldsymbol{\sigma}\cdot(\mathbf{p}-e\mathbf{A})$ is a constant of the motion because it commutes with the Dirac Hamiltonian. The interesting result of the Mendlowitz and Case calculation is that the additive "Schwinger part" of the magnetic moment (or of the g value) is predicted to be immune to this time-dilation factor.

If the velocity of the particle is effectively along the magnetic field (so that we might transform along the field, find the particle moving only normal to the field, but with practically nonrelativistic energy) then the spin ought to precess at the rate of $\omega_{cyc}(1+\alpha/2\pi)$. Higher terms are not mentioned because free-particle experiments are still concerned with the first||| non-Dirac term. It would then take the order of 137 cyclotron revolutions for the spin vector relative to the velocity vector (in the moving system) to change by one radian. However, for the case of primary interest here, where the particle with substantial energy moves normal to the magnetic field, it would require *only* about $137/E$ cyclotron revolutions to precess the spin one radian further than the velocity vector. Here E is the total energy of the particle in units of its rest energy.

This computation has recently been done again by Carrassi (C58) using a somewhat different approach, with the same result obtained by Mendlowitz and Case. Such an effect would be of interest for itself, independent of any "practical" use. For de-erecting transverse polarization of highly relativistic particles it could possibly be useful, since P_s becomes increasingly difficult to measure directly as kinetic energy increases above the rest energy.

To return to the Mott scattering method itself. It would seem that the effect of the screening of the nuclear charge by the atomic electrons will have to be understood quantitatively, as will plural and multiple scattering effects in finite scattering foils, before precision polarization numbers can be obtained with confidence. These matters are under active scrutiny in a number of laboratories, and therefore after a time a good understanding of this useful method must emerge.¶¶

C. Energy Term $\boldsymbol{\sigma}\cdot\mathbf{H}$

The Pauli energy term $\boldsymbol{\sigma}\cdot\mathbf{H}(e\hbar/2mc)$ affords a means of determining whether the spin $\boldsymbol{\sigma}$ is parallel or antiparallel to an applied magnetic field $\mathbf{H}$. For measuring σ_z of free beta particles it has so far not been employed.*** Niels Bohr showed that a Stern-Gerlach experiment on bare electrons is not a good way to go about such a measurement. This has been discussed thoroughly by Mott and Massey (MM).

One may however capture the particle of interest into a bound system (see again the discussion by Mott and Massey) and then measure $\boldsymbol{\sigma}\cdot\mathbf{H}$. Concerning the preservation of the spin direction during capture, one notices that it is the charge e of the particle and not its

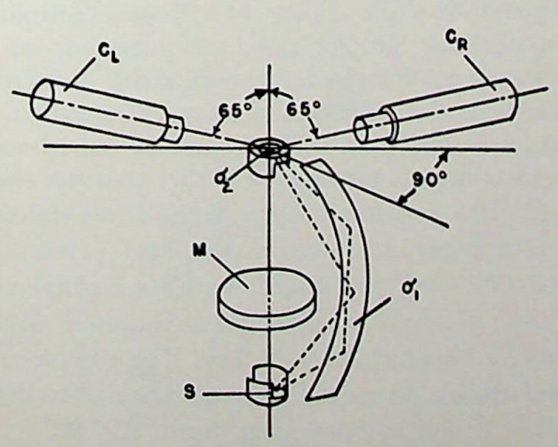

FIG. 4. Apparatus of DeShalit *et al.* (De57), illustrating "spin reprojection" by a first scattering of the betas from source S in the curved aluminum sheet, σ_1. Analysis of transverse polarization lying in the plane of $S-\sigma_1-\sigma_2$ is effected by Mott scattering at σ_2.

||| *Note added in proof.*—However, see recent precision results for g factor of a free electron obtained by the University of Michigan group, Bull. Am. Phys. Soc. Ser. II, 4, 250 (1959).

¶¶ It will then (by definition) be possible to perform a double-scattering experiment to high precision, with no anomalies.

*** A resonance experiment on free electrons has been performed by Dehmelt (D58).

magnetic moment that makes the process go. Hence, so long as the energy transfers involved (usually tens of volts only) are small with respect to m_0c^2 of the particle, there is no spin-flipping *mechanism* during the act of capture.

Let us specialize to formation of ground-state positronium since this has been employed for polarization measurement. Here an "up" positron allowed to form positronium (say by radiative capture with an effectively free electron) will not leave electron holes more "up" than "down." The fine structure of the resulting positronium is too small to cause selective capture to singlet rather than to triplet states (the former being bound more tightly by ΔE of only about 10^{-3} ev). It is necessary to examine a little more closely to find out where the original positron polarization information goes.

Consider still a free "up" polarized positron (that is with its spin along $+z$) which eventually is captured by one of a group of electrons which as a whole had no spin preference with respect to the z direction. Suppose there are no applied fields. On a time scale, the triplet-singlet energy difference ΔE is by no means inconsequential: ΔE corresponds to $\sim 10^{-12}$ sec. Thus at a time later than capture of the order of 10^{-12} sec, a (resonably adiabatic) inquiry whether the positronium state is singlet or triplet makes physical sense. This arises spontaneously in the process of decay by annihilation into two or three photons, respectively. At this stage, having allowed singlet and triplet state amplitudes to have lost their relative phase, the original spin information is largely lost: To be sure it could be partially retrieved if one looked only at certain kinematically special triplet (three-quantum) annihilation events, measuring photon helicity—rather difficult experimentally. For singlet annihilation (into two photons) there is no information that can be traced back to the original positron polarization, either in the angular correlation with respect to the $z=0$ plane, or in the helicities of the photons, the parent state being $J=0$ [see, for example, Yang's paper on dematerialization, (Y50)]. In the case of the singlet state, the original polarization has not actually been lost, but resides in the sign of the hole where the captured electron was, with complete preservation of information. For the three triplet substates as a whole the information resides 67% in the helicity of the residual photons, and 33% in the sign of the hole.††† The important point is that by examining only the two-photon residue, no information remains. This is in contrast to higher energy direct annihilation where quite large retention of polarization information is possible [see Sec. D (5)].

If the positronium is formed in the presence of an applied magnetic field, along z, say, then in effect some phase coherence between singlet and triplet states (of same J_z, thus only $M=0$ states are affected) can be "frozen in" until the annihilation takes place, and not only for the 10^{-12} sec permitted by the triplet-singlet energy difference. Under these circumstances some polarization information will now be retained. We should recall how the Zeeman splitting goes for ground-state positronium [see the positronium review articles (D53) and (D54)]. Here, J is no longer a good quantum number in the presence of the field $\mathbf{H}$, but only its projection along the field. Let us use an arrow for up or down positron spin, and likewise for the electron spin. Let the positron's spin state stand first. The state $\uparrow\uparrow$ and the state $\downarrow\downarrow$ are each unperturbed by the applied field. The $M=0$ part of the Hamiltonian, normally diagonal, now has, in virtue of the $\boldsymbol{\sigma}\cdot\mathbf{H}$ energy, part of which belongs to the positron and part to the electron, matrix elements connecting triplet and singlet. On rediagonalizing the Hamiltonian, the *nominal* triplet state is $(\uparrow\downarrow+\downarrow\uparrow)-\epsilon(\uparrow\downarrow-\downarrow\uparrow)$, and the nominal singlet state is $\epsilon(\uparrow\downarrow+\downarrow\uparrow)+(\uparrow\downarrow-\downarrow\uparrow)$. The mixing amplitude ϵ is practically linear with H, below 20 kilogauss, and becomes unity at extremely high field. The signs are such that positive H_z means positive ϵ.

In the high field limit, the two states of interest become (for positive H_z) $\downarrow\uparrow$ for triplet and $\uparrow\downarrow$ for singlet, indicating complete spin memory. Even at modest field values, say about 15 kilogauss, the disparity in $\langle\sigma_z\rangle$ for the positron (or the electron) between triplet and singlet is about a factor two. We can think of this as a capture efficiency $\epsilon_{cap}=-0.33$. This means that initial positron polarization (called P_z) would be 33% preserved in the capture act, residing finally in the asymmetry between the population of triplet and singlet states. As explained earlier, capture to $M=1$ states becomes generally a three-quantum annihilation problem and is not considered.

The discussion now divides according to whether the positronium is formed in a gas or in condensed material.

Positronium in gases.—At a field strength of 15 kilogauss about 0.97 of the triplet ($M=0$) states annihilate via two photons, and for practical purposes, *all* the singlet states do. Except for a peculiarity relating to the kinetics of the positronium atom just formed, the polarization information (all but some 3% of it) would now be lost, since it was agreed earlier that we should not attempt to measure helicity of the three quantum events. The triplet state has at this field value a lifetime $\sim 3\times 10^{-9}$ sec, the singlet state its normal value $\sim 10^{-10}$ sec. Nascent positronium in argon is known to have recoil energies of 1 or 2 ev. The magnetically quenched triplet states yield two photons observed to have such strong angular correlation at 180°, when suitable slowing (thermalizing) agents are present in the gas, that undoubtedly the positronium has lost essentially all its original recoil energy in 3×10^{-9} sec.

††† Thus two-thirds of the time, J, $M_J=1$, $+1$, and one-third of the time 1, 0, restricting to final $J=1$. The transfer efficiency from initial positron polarization to hole polarization is thus one-third.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

This behavior was known some time before polarization became of interest (H56, He57).

One may judge from the observed mutual angular correlation for the two-photon events whether the parent state was nominal triplet or singlet, the connection between an observable and the original positron spin direction being thereby completed. With reasonably narrow slits (about 1×10^{-3} radian of projected angle) the former states can be counted about five times as efficiently as the latter, at first glance implying the large efficiency for this stage of the operations of 0.67. However, inasmuch as there are many competing annihilations recorded (about five times as many positrons as we have just discussed are at the same time making competing direct annihilations in the gas sample) the effective efficiency because of the diluting action of such events drops to about 0.20.

To summarize: Let a hemisphere of positive betas emitted in the general z direction come to rest in a gaseous annihilator without depolarization. The geometrical efficiency (for projecting any longitudinal polarization P_p onto the z direction, calling the latter polarization P_z) is then 0.5. The capture efficiency ϵ_{cap} to ground-state positronium as discussed earlier would be 0.3 (at 15 kilogauss), the detector efficiency as discussed immediately above could be typically 0.2. The expected δ (on reversing **H**) is then $2\times0.5\times0.3\times0.2\times P_p = 0.06P_p$. In the initial experiment of Page and Heinberg (PH57) it was found that Na^{22} positrons characterized by v/c at emission of 0.75 were polarized with $P_p > +0.30$, the lower limit being considered conservative in that no backscattering corrections from the gold backing nor depolarization estimates were made (Fig. 5). The detector efficiency was purposely overestimated.

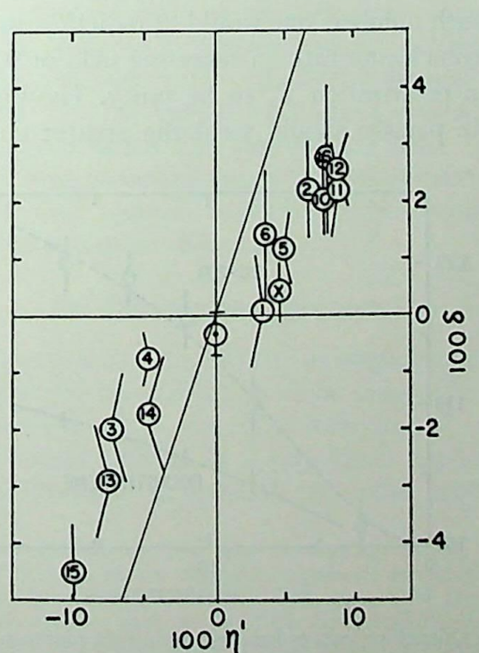

FIG. 5. Use of positronium in a gas as polarization detector (PH57). For longitudinal positron polarization at emission of +0.75, measured δ would follow oblique line whose slope is proportional to polarization.

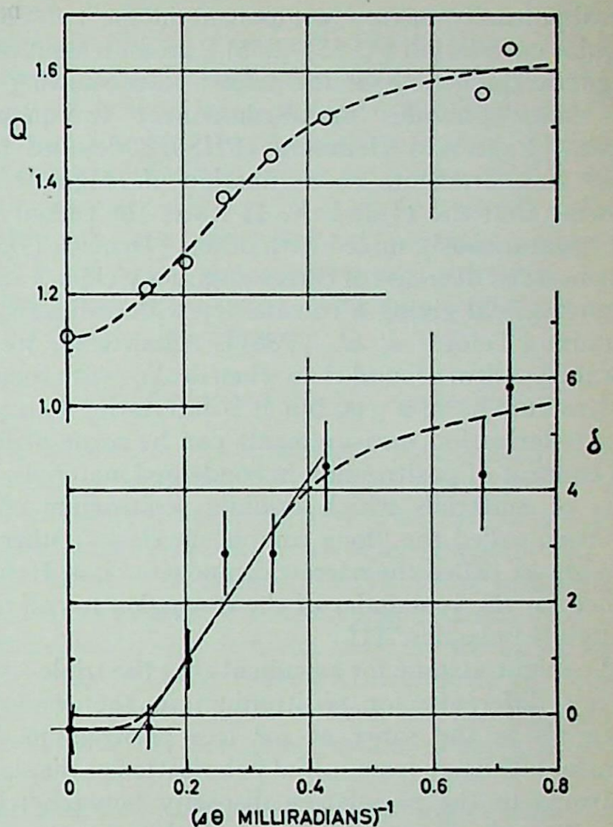

FIG. 6. Positronium in a gas (PO58). Lower curve: extrapolation of measured δ to zero effectively yields a measure of width of singlet contribution to the two-photon angular correlation. Upper curve: quenching ratio Q at infinite slit width yields fractional positronium formation in gas sample. Variation of Q with slit width yields width of triplet events.

Later data (Fig. 6), where effectively this latter efficiency is measured for the particular gas sample in use, by extrapolating measured δ against reciprocal angular resolution, gave $P_z=0.25$. This implies a lower limit on P_p of +0.50. The low-Z source-backing in the latter experiment (quartz) improved matters somewhat. Detailed angular correlation measurements (PO58) showed clearly the transfer from "broad component" to "narrow component" when the H field was changed from parallel to the positron momentum to antiparallel.

In a sense this kind of experiment is a comparison one: between the sign of $\langle\boldsymbol{\sigma}\rangle\cdot\mathbf{H}$ and the theoretical sign of the triplet-singlet energy difference for ground-state positronium. Here it was of practical concern for the first time which lay higher in energy, the triplet or singlet states.

Positronium in condensed materials.—Since the time when DeBenedetti and Richings (D52) found positrons to live longer in certain dense materials (specific gravity unity or more) than free positrons should, a number of diverse experimental results have been in accord with the hypothesis that positronium may exist in a certain class of substances. We mention the detailed measurement of these long lifetimes (Bell and Graham B53), the measurement of the abnormally high three-quantum yield [Pond (P54), Graham and Stewart (G54)], of

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

the abnormally narrow component in the two-photon angular correlation [(P55) (S55)], measurement of the magnetic quenching of the triplet state showing that this state provides broad-component two-quantum events [Page and Heinberg (PH56)], detailed time-delay measurements as a function of magnetic field showing that the ↑↑ and the ↓↓ states (in Teflon) were not spontaneously mixed with others [Deutsch (D56)], the observed decrease of three-quantum yield in a strong magnetic field giving a consistency with ordinary positronium [Telegdi *et al.* (T56)]. Admittedly, we are now on less firm ground than when dealing with *bona fide* positronium as in a gas, but it is interesting that positron polarization measurements can be made utilizing the concept of positronium in condensed materials. The class of materials which exhibits positronium effects has been called the "long component class." Otherwise it might be called the narrow component class. It might suffice for the remainder of the discussion to call these materials "plastics."‡‡‡

We might assume for argument that the triple-singlet energy difference for positronium in the condensed materials is the same as for free positronium. The transfer efficiency from initial polarization of the slowed positrons to the population disparity between triplet ($M=0$) and singlet states would then be the same figure at the same magnetic field as for free positronium. From this point on, the picture is quite different.

For our purposes, each positron which comes to rest in the annihilator gives two photons. Ignoring polarization for the moment, let us discuss a typical "plastic" such as fused quartz. The original conjecture was that the narrow component occurred in parallel§§§ with the delayed component (P55). If we retain this view, and also pretend that all measurement is ideally precise, we shall have the singlet states giving only narrow component, denoted N, the triplet states in absence of applied field giving only broad component, denoted B, with nonpositronium events giving also a broad angular distribution, B'. In actual measurement, B' has never been distinguished from B. Discussion is now restricted to the two $M=0$ states, singlet and triplet, unless otherwise stated.

Application of a strong field H, strong enough to compete successfully with the rather fast (one or two by 10^{-9} sec lifetime) "pickoff annihilation," causes a detailed transfer of events from B to N [(Pa55) (PH56) (W57)]. Fields of 10 to 20 kilogauss are typically required. If an angular correlation apparatus is set to accept only 180° events, within about 10^{-3} radian, the coincidence rate increases with H, as in the so-called quenching curves of Fig. 7. Here the detector is perhaps four times as efficient for N events as for B events.

Regarding the possibility of positron polarization measurement, the situation in one respect is not as fortunate as with positronium in gases: "up" positrons in an "up" field ought to form more singlet states than triplet, the singlet states give only N events, but the triplet states instead of giving only B events (as at zero applied field) now might divide 0.6 of the time into B and 0.4 of the time into N, for example. In other words the H field which is required to furnish the initial "capture efficiency" acts unfortunately to dull the action of the detector from distinguishing triplet from singlet events.

In order to see what response to expect for plastics let us supply some rather rough numbers, and assume that the field is such that one-third of the triplet ($M=0$) decays appear as N events. For orientation, at $H=0$, one has 0.5 of the positrons of interest forming singlet states and 0.5 triplet ($M=0$) states. The fraction f_N of these yielding N events is thus 0.50. For unpolarized input positrons, at $H=H_{\frac{1}{2}}$, one has still the equal division into singlet *versus* triplet states, but f_N becomes now 0.67. For completely polarized stopped positrons, at $H=H_{\frac{1}{2}}$, the capture efficiency for keeping the polarization information might be 0.33 (depending indirectly on the lifetime of the delayed component). Thus, for field **H** parallel to the spins, a singlet/triplet population ratio of 0.67/0.33 is implied, and f_N is computed as 0.78. For the opposite field setting one gets $f_N=0.55$. In order to arrive at a final number, suppose that 0.35 of *all* incident positrons go into ($M=0$) positronium, and that the detector response $N:B$ is 4:1. Using such numbers one would "predict" a measured δ in the coincidence rate on reversing field of 0.14, given positron polarization P_z to be unity. Having field **H** and spin parallel should yield the greater coincidence

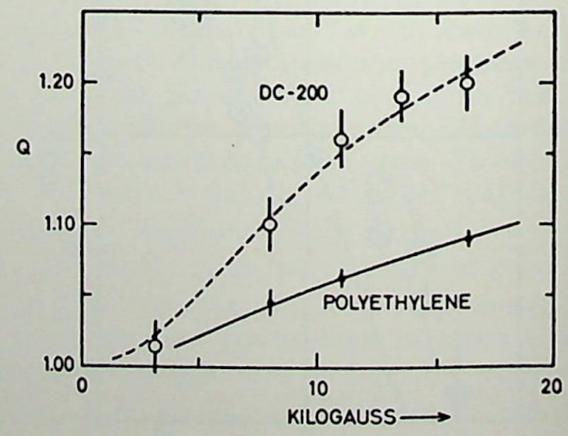

FIG. 7. Quenching curves for positronium in plastics. Fractional increase in two-photon coincidence rate within 1.5 milliradians of 180°, as a function of applied field H, corrected for focusing effects. Actual transfer from broad B component to narrow N component on applying field is less than one-fourth of $Q-1$. From Page and Heinberg (PH56).

‡‡‡ Inasmuch as whether or not the material tends to harbor positronium seems to connect with whether or not it is crystalline, some one has facetiously suggested the following nomenclature: materials not having positronium effects shall be Xtals, materials having them shall be Ytals. (This would save the term Xtal from extinction in the physical journals.)

§§§ Thus a positronium annihilation event is either narrow or it is delayed (at $H=0$). Attributing the delayed events to triplet positronium, one expects from statistical weights three times as many delayed events as narrow events.

CC-0. Central Kangri University Haridwar Collection. Digitized by eGangotri Foundation USA

rate, which is opposite to the response in the gas experiments just described.

The magnitude of the response of plastics to polarized positrons is next to impossible to estimate *a priori* because so many essentially unknown numerical factors enter. But the *sign* of the response may be traced back to one hypothesis, that the normal fate of the triplet states is broad annihilation (a half-width like 10×10^{-3} radian), and the normal fate of the singlet states is narrow annihilation (half-width less than 3×10^{-3} radian).

To come finally to an actual experiment, Page and Obenshain (PO57) used a hemisphere of Na^{22} positrons (gold-backed) which impinged on the plastic sample. The δ in the coincidence rate at 180° with angular resolution 1.5×10^{-3} radian was measured on reversing **H**. Only for the narrow-component materials was a nonzero δ found, and its sign agree always with that anticipated in the foregoing discussion. With no absorber between source and sample, and running typically at $H=13$ kilogauss, δ was measured for fused quartz, polystyrene, DC-200 high viscosity silicone oil, polyethylene, and Teflon. Expressed in percent the results in order were 1.7 ± 0.5, 1.7 ± 0.7, 1.3 ± 0.6, 1.3 ± 0.4, and 1.9 ± 0.5. With an interposed absorber of 0.0005-in. tantalum, the Teflon response increased to $4.8\pm1.1\%$, while a (low Z) Mylar foil of like density in mg/cm² increased the Teflon response to $4.5\pm0.9\%$. The very roughly estimated response quoted above would yield 7% expected δ for a hemisphere of fully (longitudinally) polarized positrons, neglecting back reflection.

Hanna and Preston (Ha58) have checked the sign of the response of polyethylene against the "iron detector." Page and Obenshain have checked the sign of the iron detector against the plastics [see Sec. III D (2)].

The fact that plastics in general give a detectible response to positron polarization must be taken as evidence that depolarization on slowing is small (even in tantalum, $Z=73$) and as supporting evidence that something very much like positronium must exist in this class of materials, and finally that the separation‖‖‖‖ into broad and narrow components for triplet and singlet states is rather clear-cut.

D. Comparison Methods

As discussed earlier (Sec. III A) a comparison method is one where the spin direction to be analyzed is compared somehow with the spin direction of atomic electrons already known. It is sometimes implied that comparison methods in general are rather inefficient. However, if one is discussing the particular physical act which is the heart of a given method, then it often turns out that efficiencies are closer to unity than to zero. It is best to keep separate the physics of the analysis act from the question of what degree of (reference) polarization might be achieved in practice for the average electron in a typical "iron" foil for example. In the discussion of several comparison methods, efficiency means efficiency per unit degree of polarization of the target electron, unless some statement is made to the contrary.

(1) *Møller and Bhabha Scattering*

The most direct and intimate comparison of spin directions is afforded by the electron-electron and positron-electron scattering processes, which we label "Møller" and "Bhabha" scattering respectively. The matrix element of Møller (M32), from which have stemmed the well-known Møller and Bhabha scattering formulas, has within it much polarization information which, prior to about 1957, was not much considered. Bincer (Bi57) seems to have been the first to publish computations on the polarization aspects of such scattering.

Speaking first about electron-electron collisions, and in the nonrelativistic limit, elementary quantum mechanics tells us that if a pair of identical spin-½ fermions are to undergo mutual scattering (letting all spins be random), one-half of the time the spins are antiparallel, the particles therefore distinguishable after the collision (they are always distinguishable before the collision) and the scattering cross section has its classical value at all angles in that there are now no interference (exchange) effects. For the other half of the time the spins are parallel, in which case we have indistinguishability after the collision, interference effects come into play, and, for 90° scattering in the center-of-mass system in particular, there can be no scattering. On the whole there is a progressive shift from the classical cross section at small angles to one-half of the classical value in the large angle limit, 90°.

The alternative view (which is not particularly useful for polarization discussions) is that three-fourths of the time the pair of spins form a triplet state, nullifying the scattering at 90°, while the remaining one-fourth of the time they are in a singlet state, now with constructive interference for fermions which doubles the cross section at 90°. The same numerical result is obtained at any angle as with the previous view. This result hinges on there being no spin-flips during the collision and again no spin sensitive forces in the scattering "force," which guarantees the first proviso.

Longitudinal polarization analysis.—For the relativistic discussion, let us focus attention on helicities. Writing the appropriate free particle spinors for definite initial and final helicities, then applying the Møller interaction and subtracting Feynman diagrams,

‖‖‖‖ Further results by Bell and co-workers (GB57) on the fraction of positrons in the delayed component for fused quartz in particular (now reported to be 0.51 instead of the earlier estimate of about 0.3) have removed the numerical disparity that existed for some time between fractional narrow component and fractional delayed component. The recent polarization applications however, being based on a balance method, might be argued to lend strong support to the contention that this separation is clear-cut.

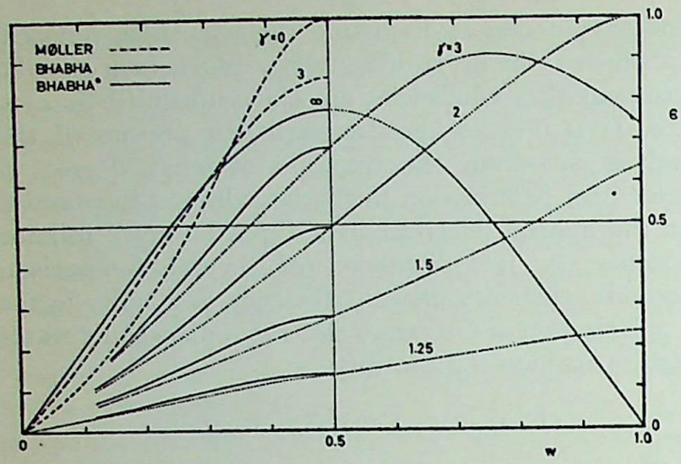

FIG. 8. Differential Møller and Bhabha scattering. For a completely polarized target electron, the efficiency ϵ for detecting longitudinal polarization of e^- or e^+ respectively, is plotted against fractional energy transfer w. Total energy of incident particle is γm_0c^2. Møller and Bhabha expressions coalesce as $\gamma \to \infty$. Solid curves, labeled Bhabha,* apply if final e^+ and e^- are *not* distinguished by the apparatus. Inasmuch as cross section generally changes rapidly with w, partial areas under curves may have but limited practical significance. Curves have been plotted from the formulas of Bincer (Bi57).

that is, writing down the Møller matrix element, the following facts emerge. We refer mostly to 90° scattering in the center-of-mass system where those polarization effects which arise entirely from the subtraction of diagrams are generally a maximum.

In the first place, single flips of helicity are taken out by the interference (at 90° scattering angle). In the second place, particle helicity tends to be better conserved as the energy increases.¶¶¶ We are not referring to the more trivial effect where at small angle the helicity naturally is well preserved. The helicity of one of the input particles would be in fact 80% conserved at only 0.6-Mev laboratory energy, in the sense that either of the output particles viewed in the center-of-mass system preserves 0.8 of the input helicity (for 90° scattering). This fact is used later. In the third place, and this is the important point upon which the polarization experiments have been based, the relative cross section (at 90°) between input spins parallel and antiparallel, for *longitudinal* polarization only, which was zero in the low energy limit climbs only to $\frac{1}{8}$ in the high-energy limit, the corresponding efficiency being therefore 7/9. The complete expression for this cross-section ratio as given by Bincer (Bi57) is

$$\frac{\sigma_p}{\sigma_a}=\frac{2x^2+\beta^2(3x^2+x^4)+\beta^4(1+x^2)}{1+x^2+\beta^2(2+3x^2-x^4)+\beta^4(5-4x^2+x^4)}, \quad (4)$$

where β is the speed of either particle in the center-of-mass system and $x=\cos\theta$ where θ is the center-of-mass angle of scattering. This result is shown in Fig. 8, now put in terms of analyzing efficiency ϵ for a longitudinally polarized target electron. The abscissa is the conventional fractional energy transfer, $w=\frac{1}{2}(1-\cos\theta)$. The two dashed curves labeled "Møller" and the limiting shape at high energy labeled ∞ apply here.

Bincer has also computed the companion expression for Bhabha scattering (Bi57). A few curves computed from these results are also shown in Fig. 8. These are the dotted curves labeled "Bhabha." At first glance, the e^+ and the e^- are distinguishable and thus one expects no polarization sensitivity in the sense of a correlation between positron and electron helicities for a given probability of scattering (of course, both initial and final e^+ helicity tend to be correlated, and the same applies for the e^-, on any simple theory). The point here is that there exists the virtual annihilation process, and this accounts for a good part of the ordinary (unpolarized) positron-electron scattering cross section (A54). This process is represented by one of the Feynman diagrams. It manifests itself now in making possible the polarization effect shown in Fig. 8. The effect dies out at quite low energy, where the annihilation amplitude has diminished.

Inasmuch as the Bhabha polarization efficiency ϵ as a function of w gives a rather unrealistic picture of how an experiment might be designed (because the differential cross section typically changes by a factor 30 between $w=0.25$ and $w=0.75$), we show also some modified Bhabha curves. These efficiency curves, labeled Bhabha,* would apply if the two particle detectors, operated in coincidence (or a single detector, if such an experiment were done), were completely insensitive to whether the counted particle is a final e^+ or a final e^-.

To summarize the picture presented in Fig. 8, the Møller method for longitudinal polarization measurement could be classed as a low-energy method, based on symmetry (Pauli principle)—the fact that a high efficiency persists to all energies can be regarded as good fortune. As for the Bhabha method, which again rests on symmetry, high energy is required to provide sufficient annihilation amplitude that the symmetry may come into play, so it is essentially a high-energy method. The left half of Fig. 8 clearly shows these energy trends. Another view is that at high energies the two methods are just the same (the infinity curve), but that at lower energies different details appear, simply because the forbidden zone of width $2m_0c^2$ is no longer negligible.

The Møller scattering method for the purpose of polarization detection was first employed by Frauenfelder and co-workers (Fb57) on negative betas from P^{32} and from Pr^{144} with the result that both beta groups were left-handed, and by an amount consistent with v/c at emission. Their apparatus is shown in Fig. 9. For reasons of impingement of beam, the scattering foil is inclined to the beam direction, so the efficiency has to be multiplied by the cosine of the small relevant angle. What is measured here is not an absolute differential cross section, or relative cross section against angle of

¶¶¶ This is not surprising since γ_5 does commute with the Møller interaction, but we remember that neither particle at finite energy can be in a pure eigenstate of γ_5.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

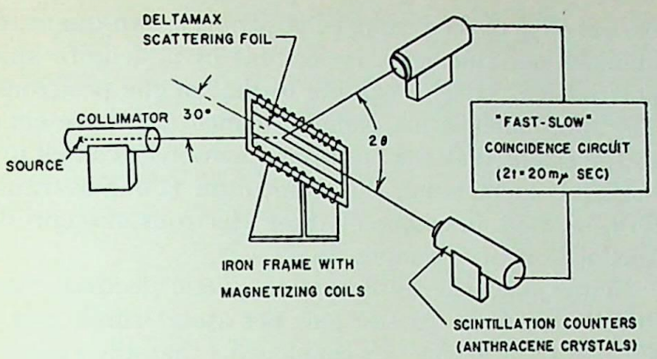

FIG. 9. Møller scattering setup of Frauenfelder and co-workers (Fb57).

collision, but only a comparison of a coincidence rate *proportional to* cross section between the two opposite states of magnetization of the scattering foil. For this reason the apparatus need not be especially elaborate.

The full definition of a true Møller event is that (i) $\mathbf{p}_1+\mathbf{p}_2=\mathbf{p}_0$. That is, momentum of particle No. 1 and particle No. 2 (labeled by which counter they enter) shall add up to the incident momentum. (ii) $K_1+K_2=K_0$. The kinetic energies likewise shall add up to the original kinetic energy. Coincidence detection of Møller events has been effected in the past by requiring for example that $(\mathbf{p}_1+\mathbf{p}_2)\cdot\mathbf{p}_0=p_0^2$ (P51), (A54), which is a compromise between complete rigidity of definition and counting rate. At energies of say 0.5 to 2.0 Mev, at the fairly high fractional energy transfers, say $0.4<w<0.5$, both $\mathbf{p}_1$ and $\mathbf{p}_2$ make sufficiently large angles with $\mathbf{p}_0$ that this simple criterion rules out multiple or plural scattering in the target foil, particularly after the Møller event, as well as against energy loss on the part of either particle No. 0, 1, or 2. Thus by setting (besides p_0) a certain value of $\mathbf{p}_1\cdot\mathbf{p}_0$, coincidences are found only at the expected value of $\mathbf{p}_2\cdot\mathbf{p}_0$ if the experiment is clean. See in this connection "coherence curves" (A54).

Returning to the experimental setup of Fig. 9, where a considerable spread was accepted in the incident energy K_0, typically a factor two or three, one would lose essentially all opportunity to check for "coherence" between K_1 and K_2. There does still remain the possibility for an "angular coherence" check, which however due to the relativistic narrowing is sharpest only for fixed K_1+K_2.

For the isotope Au^{198}, results obtained with the setup of Fig. 9 were interpreted (Fc57) as implying negligible longitudinal polarization for these particular negative betas (some seven standard deviations less than the expected v/c value). The Møller method was subsequently proven, for the case of Au^{198}, by Benczer-Koller *et al.* (BW58). The apparatus used by the latter group did not differ in essential details from that in Fig. 9. A magnetic lens system was used to bring the beam into the apparatus and focus it on the "iron" foil. It has been pointed out (W58) that precautions were taken in the latter experiment to discriminate against true time-coincident Compton electrons (due to the accompanying Au^{198} gammas) which could otherwise produce false Møller events, and that these precautions could probably account for the difference between the two results. The latter result was v/c polarization to seven standard deviations, and left-handed.

Use of the Bhabha method for longitudinal polarization measurement was first attempted by Frauenfelder and collaborators (Fd57) on the high-energy positron group from Ga^{66}. The results were interpreted as meaning that these positrons were probably not polarized (a matter of about three standard deviations below the expected v/c value). However, three different methods [see Sec. III D (2), (3), and (5)] applied to these same betas have since yielded large (right-handed) helicity. Since we know there is nothing wrong with the ordinary Bhabha differential cross section (A54) which itself is highly sensitive to whether one takes into account the interference effects, it must be presumed that the Bhabha polarization method is intrinsically sound.

Transverse polarization analysis.—It is interesting to contrast the possibilities for transverse polarization analysis with the longitudinal case just discussed. Specific discussion is for the electron-electron case. One may examine again the basic Møller matrix element, and restrict again to 90° scattering angle in the center-of-mass system where the algebra is easiest and the physics most meaningful for our purposes. For the efficiency of a transversely polarized target electron we have the nonrelativistic value unity at sufficiently low energy. With increasing energy, the efficiency falls off very rapidly compared to the longitudinal case just described: if we average over azimuth of the plane of collision the efficiency ϵ is down to 0.5 at only 0.65-Mev laboratory energy, 0.3 at 1.25 Mev, 0.1 at about 3.4 Mev and ultimately becomes zero. If, instead, the plane of the collision is restricted to include the initial "spin vectors" involved (to include the spin vector of the polarized target electron will suffice) then the efficiency falls off almost as fast with energy, but does have a nonzero residue in the high-energy limit of $+0.11$. Or, if the plane of collision is required to be at right angles to this direction, ϵ saturates at -0.11 in the high-energy limit, having passed through zero at about 3-Mev laboratory energy.

For practical purposes, the transverse Møller method does not compare favorably with the longitudinal Møller method. The details for the transverse Bhabha method can be had by inspecting the matrix element again. A paper by Stehle (St58) lists in convenient form both Møller and Bhabha matrix elements.

Spin erection.—A further comment on Møller scattering relates to its hypothetical use as a spin erector (compare the electrostatic spin-precessor and the reprojection spin erector discussed in Sec. III B). The helicity memory through the Møller event can be rather large: given an incident longitudinal particle,

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

let it make a single collision in an unpolarized target. Then either of the offcoming particles, as viewed in the center-of-mass system will have a certain memory of the original helicity. Speaking as usual of 90° scattering, this efficiency for retention of helicity is +0.6 at 0.25 Mev, +0.8 at 0.6 Mev, and +0.9 at 2 Mev in the laboratory. The high-energy limit is 8/9. If then we transform either of the final electrons to the laboratory system we find that the over-all efficiency for transfer of longitudinal polarization P_p into transverse polarization P_s(lab) departs from zero $\sim 0.71E$, reaches the value 0.4 at 0.25 Mev and 0.5 at 1.0 Mev. It then falls with increasing laboratory energy E, approximately as $0.89(E+2\text{ Mev})^{-\frac{1}{2}}$, decreasing to 0.25 at 10 Mev. The direction of the resulting P_s is clear from the description—it points away from the line of collision for right-handed input. Longitudinal target polarization likewise could be transferred to P_s(lab) using the same numbers, given an unpolarized incident beam. Again, the transfer of polarization from P_p to P_p(lab) can be had from the transfer efficiencies just quoted by multiplying in each case by $(E+1\text{ Mev})^{\frac{1}{2}}$.

If one asks now for the transfer efficiency from P_s to P_p(lab) in a 90° Møller scattering act from an unpolarized target, which is the inverse of spin erection, one finds quite different numbers from the spin erection case. Thus in contrast to the spin-erectors already described: macroscopic electrostatic device, crossed fields device, or the use of atomic scattering for spin reprojection, this is an illustration of a nonreversible device. For $P_p \rightarrow P_s$(lab), the spin direction of the participating target electron and also of the conjugate recoil electron are (individually) about 90% certain. For $P_s \rightarrow P_p$(lab) these spin directions are about 90% uncertain, except at very low energy.

As for use of Bhabha scattering for spin erection or de-erection, the various transfer efficiencies at high energies will be nearly the same as for the Møller case. For low energies, even for 90° scattering some memory of "which one is the positron" will persist through the collision, and at very low energy the various transfer efficiencies at any angle will be apparent from the geometry of the collision. The discussion has by now become quite academic. For positrons, or indeed electrons, except at quite high energy one would generally be better off to use single, plural or multiple Coulomb scattering for de-erection of spin.

Finally, neither Møller nor Bhabha formulas show any right-left asymmetry as there is in Mott scattering, even allowing both target and beam to be (transversely) polarized.

(2) *Annihilation of Slow Positrons in a Ferromagnet*

Suppose that initially polarized positrons could be brought to rest (that is to essentially thermal energies) in a ferromagnetic material, and still retain some of the original polarization, so that finally $\langle\sigma_z\rangle \neq 0$. We consider complete polarization for simplicity. The ultimate fate of over 99% of these stopped positrons is two-quantum annihilation, and against electrons of a definite spin polarization, namely opposite to that of the positrons. The total annihilation gamma momentum represents, to the extent that the positrons themselves contribute negligible momentum, the momentum (Fourier transform of wave function) of those electrons susceptible annihilation (for example, La57).

In iron, one believes that the magnetic electrons (the "two" out of the 26 electrons per atom) surely must have different momentum components than the average electron. Thus, quite aside from positron polarization, there would have to be some correlation between amount of departure from collinearity of the two annihilation photons and whether or not a "magnetic electron" had been annihilated. Since the deeper bound electrons, which are not polarized, also are presumably not very accessible to a slow positron for annihilation, this may tend to enhance the correlation. What could be measured in the two-quantum angular correlation is the relative abundance of the higher momentum portion (thus, in the wings of the curve, say from 5 to 10×10^{-3} radians away from 180°) for the two analyzer settings: magnetization along $+z$ and along $-z$. Thus if $\langle\sigma_z\rangle$ for the positrons were positive, then + magnetization must yield more of the higher momentum events than − magnetization, *providing* the magnetic electrons tend to have higher momentum than the average electron with which a positron may annihilate.

This method was devised and used successfully by Hanna and Preston (Ha57). Their first polarization results showed (accepting that the magnetic electrons have generally higher momentum) that Cu^{64} positrons are right-handed. In later work (Hb57, Ha58) various ferromagnetic materials and a number of different positron emitters have been compared. Figure 10 shows the apparatus used in certain of the experiments of Hanna and Preston. Instead of using the more standard

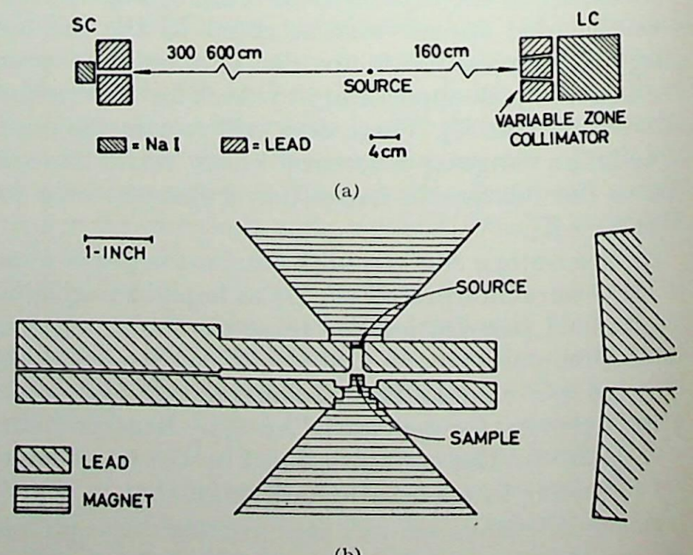

FIG. 10. Angular correlation apparatus of Hanna and Preston (Ha58) for measuring two-photon angular correlation from polarized positrons annihilating in a ferromagnet.

momentum measurer as originally introduced by De-Benedetti and collaborators (D50) which essentially defines projected angle between photon momenta $-\mathbf{k}_1$ and $\mathbf{k}_2$, they used an annular detector slit located opposite to a point detector so that the actual angle θ between $-\mathbf{k}_1$ and $\mathbf{k}_2$ is defined. The particular choice of geometry for the gamma detection is not crucial for making polarization measurements however. If this technique eventually makes contact with any anisotropy of the momentum of the polarized electrons (with respect to crystal axes) then choice of detector geometry can be quite important.

The measured δ on reversing the state of magnetization, as obtained by Hanna and Preston, range from 5% to 10% depending on controllable circumstances, such as inserting absorbers between source and iron analyzer to "clean up" the positron beam.

There is no reason to suppose that the positrons on slowing have partaken of the polarization of the ambient electrons to any extent. To consider how annihilation-in-flight competes with the ordinary energy loss processes, the fact that a positron has survived so as to finally appear within tens of milliradians of 180° in the angular correlation predisposes it to be polarized, by a fraction of a percent, and parallel to the predominant electron spins. However, such added polarization would be the same for both states of magnetization (if referred to the magnetizing field direction) and therefore could not influence the measured δ to first order (and to any order, no matter how large such added polarization might be, it could not give a false sign to the measured δ).

As with analysis of positron polarization by means of positronium in the "plastics," absolute polarization measurement by the present technique awaits further development. But relative polarization measurement is feasible now.

The sign of the response of annihilation-at-rest in iron, the sign of the response of positronium in plastics, and the sign of the response of positronium in gases, are mutually consistent (the iron method has, for entirely different reasons, the same sign as for gases; the method using plastics has the opposite sign). Figure 11 shows a comparison plot between measured δ for iron (mild steel) and for a plastic (Teflon), run in the same apparatus at the same angular resolution. The resolution chosen (4×10^{-3} radian) seemed to be suited to the iron, but is known to be too small for optimum response in Teflon (III C). In any case the opposite response to the same positrons is evident. Hanna and Preston have checked (using Cu^{64} positrons) the response of polyethylene with respect to iron and it was opposite (Ha58).

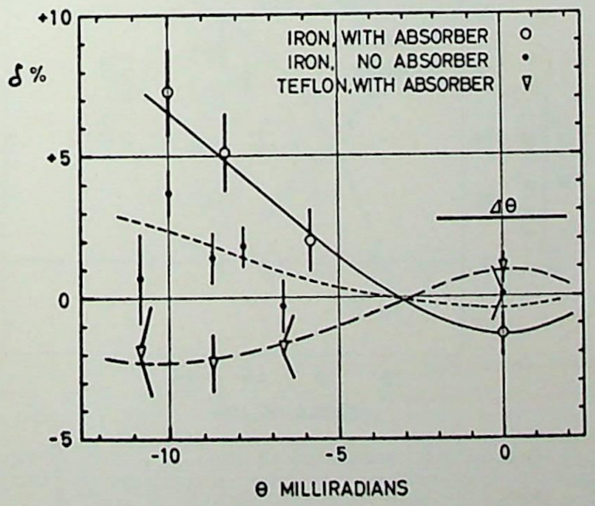

FIG. 11. Response of iron annihilator to polarized sodium-22 positrons compared to response of a plastic, both run at same resolution $\Delta\theta$ in same apparatus. Measured δ on reversing magnetic field is opposite in sign for the two materials. Positive δ means higher coincidence rate for H parallel to positron spins. (PO58).

The function of the absorber, which has been applied both at Argonne Laboratory and at Pittsburgh, is simply to enhance the measured δ, by selecting the higher energy portion of the actual positron spectrum which emerges from the source material plus the source backing. Thus, over and above the obvious fact that the effective v/c is slightly higher, clearly one is selecting particles of better polarization in the z direction. Depolarization of a positron beam in flight appears not to be a very serious matter.

A further comment on the three annihilation-at-rest methods for positron polarization measurement, is that it is generally quite difficult to join on in series a spin erector or de-erector, or an energy analyzer, principally because of the large ambient magnetic field in the immediate vicinity of the active region. For transverse polarization measurement, the annihilation-at-rest in a ferromagnet would clearly be the most easily adapted, since the magnetic field strength just outside the active sample need not be objectionably large.

(3) *Annihilation-in-Flight in Polarized Electron Target*

A method which is intrinsically nonrelativistic, but which can be used at fairly high energy nonetheless, is based primarily on the fact that at rather low energies, positron and electron helicities must be the same for two-quantum annihilation in flight to take place (three-quantum annihilation-in-flight is smaller by $\sim1/137$ and does not concern us here). There is, however, a strong departure from the nonrelativistic situation as regards efficiency for a longitudinally polarized analyzer to detect longitudinal beam polarization, at least assuming any and all two-quantum events to be recorded. This behavior is shown in Fig. 12, the solid curve. A crossover in sign of response occurs at about 4-Mev beam energy, so that at higher energies annihilation takes place more readily with spins parallel (positive efficiency ϵ).

However, as was realized by Frankel and co-workers (Fr57), the low-energy behavior (that is, $\epsilon=-1$) can be retained at any beam energy provided that the line-of-annihilation (in the center-of-mass system the two photons define a line of annihilation) lies exactly along the line of collision. In practice one chooses a sufficiently

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

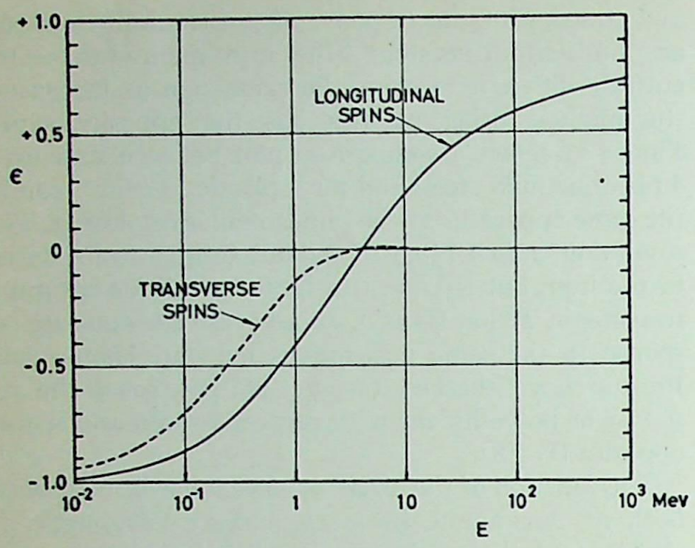

FIG. 12. Total cross section for annihilation-in-flight. Efficiency per polarized electron in target for analysis of longitudinal positron polarization (solid curve). Efficiency for transverse polarization analysis (dashed curve). Positive ϵ means parallel spins are favored to annihilate. From (P57).

narrow cone in the center-of-mass system that the high relativistic type events (those tending to make $\epsilon=+1$) are partially excluded from being counted. Thus, by a judicious choice between loss of efficiency for too large a cone and loss of counting rate for too narrow, a first-order experiment can be done on rather high-energy positrons. Frankel *et al.* used Ga^{66} (energies up to 4 Mev) with the result that these positrons are quite highly polarized, and right-handed, in line with the result of Deutsch *et al.* using another method [Sec. III D (5)]. In this type of experiment one necessarily runs into the oblique foil situation as in the Møller experiments (compare Fig. 9).

For energies much above 4 Mev, say 40 Mev, one would probably be better off to accept all annihilation events.

Transverse polarization.—The analog of the longitudinal case just discussed is mentioned briefly, for completeness sake, by examining the cross section for total annihilation-in-flight for a transversely magnetized foil. The efficiency per polarized electron is shown in Fig. 12 (as the dashed curve) as a function of positron energy in the laboratory. It is down to 0.5 by about 0.25 Mev and is essentially zero by about 3 Mev. Even restricting to the line of annihilation parallel to the line of collision, the efficiency falls off equally fast with increasing beam energy.

If the line of annihilation is restricted to be at right angles to the line of collision, the azimuthal dependence of the photon intensity becomes essentially $\cos^2\theta$ or $\sin^2\theta$ at high energy, depending on whether the input spins are parallel or antiparallel. This effect is about 50% efficient at 3 Mev and 90% efficient at 30 Mev (P57). Regarding counting rate such an approach would be expensive for two reasons: restricting the azimuth, and by restricting to cross-wise annihilation events, which unfortunately are fewer than the others (the ordinary Dirac differential annihilation cross section varies with beam energy so that a factor two is lost at 6 Mev, and a factor three at 20 Mev).

A second-order (hypothetical) method for transverse positron polarization analysis using annihilation-in-flight is discussed in context in Sec. III D (5).

(4) *Polarized Bremsstrahlung*

Longitudinal.—A spectacular and useful method for analyzing longitudinal polarization of energetic e^- and e^+ was devised largely intuitively by Goldhaber, Grodzins, and Sunyar. The method is to extract the longitudinal particle polarization information from the beam by means of the usual "forward" bremsstrahlung. This affords a natural, convenient, and (by polarization standards) copious source of circularly polarized photons. The secondary beam of photons is analyzed by comparison with atomic electrons (see Appendix C on the Compton method for photon helicity measurements).

Figure 13 shows the δ obtained by Goldhaber *et al.* (G57) on reversing the (transmission type) Compton analyzer through which the bremsstrahlung spectrum from Y^{90} betas was counted. These photons were found to be highly polarized. The Compton analyzer was here throwing in no spurious δ since the crossover in sign of the response is observed to come almost exactly where it should according to the Compton formulas, at 0.64 Mev.

Early calculations by McVoy (M57) showed that the transfer efficiency P_p to photon circular polarization P_k should be $\sim$0.95 at least for the truly forward photons, and near the tip of the bremsstrahlung spectrum. One of McVoy's curves (M57) implied**** that

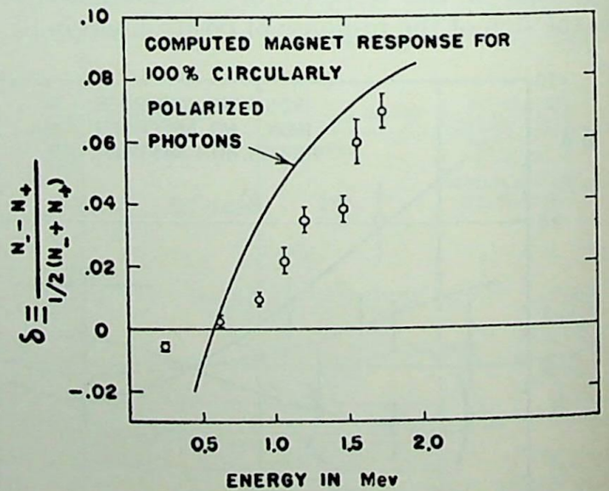

FIG. 13. Polarized bremsstrahlung from Y^{90} betas. Measured δ on reversing transmission type Compton analyzer as function of photon energy accepted. From Goldhaber *et al.* (G57).

**** See corrected curve (Mc58). The main effect in correcting the curve is that as $k/(E_1-1)$ decreases from unity the transfer efficiency begins to fall off considerably sooner than was at first believed, with the result that typically one should expect somewhat

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

such high efficiency should persist over a rather wide range of fractional photon energy, $k/(E_1-1)$. Later, bremsstrahlung computations were made over a range of photon angle as well as fractional photon energy by Fronsdal and Überall (F58). Computation on this problem has also been done by Claesson (C57) and by Böbel (B57). The problem of particle depolarization during such slowing as takes place before the bremsstrahlung act seems not to be an all-important problem, but must ultimately be faced.

On the basis of the first curve of McVoy (M57) some precise measurement of longitudinal particle polarization has been reported. For example, P^{32} betas were measured somewhat in the nature of a by-product in a series of experiments by Boehm and Wapstra (Bo58). Here the implied longitudinal polarization was -0.97 ± 0.06 of v/c. Until such time as (i) the bremsstrahlung method has been seriously checked, experiment *versus* theory, and (ii) the number of polarized electrons/cm^3 in a given ferromagnetic material under given conditions is truly known, polarization measurement by this method to absolute precision approaching 5% should be considered as somewhat on the optimistic side. As matters stand, item (i) cannot be divorced from item (ii), since the former is currently based upon the latter.

Aside from their intrinsic interest, bremsstrahlung sources are being widely used as calibrators for photon-

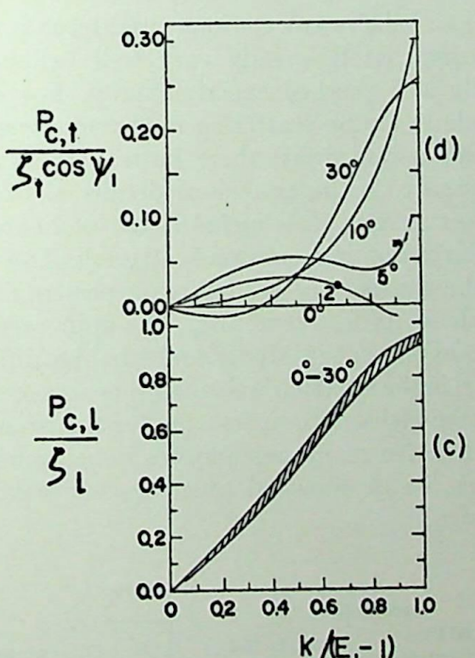

FIG. 14. Bremsstrahlung calculations. Theoretical transfer efficiency from longitudinal electron polarization to circular polarization of photon (lower curves) as function of fractional photon energy. Transfer from transverse particle polarization to photon helicity (upper curves). Photon emission angle θ is shown. Incident electron energy is 2.5 Mev. From Fronsdal and Überall (F58), with some details omitted.

less circular polarization, by perhaps 10 to 15%, unless the conditions correspond to the tips of both the beta spectrum and the bremsstrahlung spectrum (which is scarcely practical).

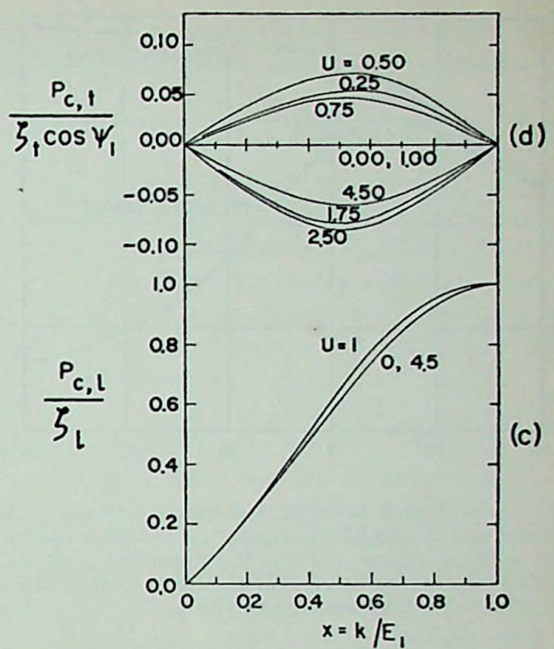

FIG. 15. Bremsstrahlung calculations. See also Fig. 14. Incident beam energy is 52 Mev. Photon emission angle in radians given by $U=103\theta$. From (F58).

helicity measuring devices. The bremsstrahlung process occupies a strategic position among the various polarized sources and measuring devices which eventually must come to be well understood.

Circular polarization of bremsstrahlung was the method used in the first successful helicity measurement of betas from muon decay. The experiment of Culligan *et al.* (Cu57) which yielded right-handed positrons, was the first suggestion that came from a *helicity* measurement that either lepton conservation or the tensor interaction in certain beta-decay processes would have to be given up. Since then, bremsstrahlung measurements on the helicity of both the negative and the positive betas from decay of the negative and positive muon, respectively, has been performed (Ma58). Both signs turn out to be the same as for the corresponding beta from nuclear beta decay, and the sign obtained by Culligan is thereby confirmed.††††

Typical results from the computation by Fronsdal and Überall (F58) are given in Figs. 14 and 15.‡‡‡‡ To a first approximation, all of the forward cone of bremsstrahlung has about the same transfer efficiency (from P_p to P_k) at a given fractional photon energy.

Transverse polarization.—The transfer efficiency from P_s to photon helicity P_k has been computed by Claesson (C57), by Böbel (B57), and by Fronsdal and Überall (F58). The efficiency here is considerably diminished from the longitudinal case, $P_p \rightarrow P_k$, as may be seen from the upper curves in both Figs. 14 and 15.

†††† See also Culligan, Frank, and Holt, Proc. Phys. Soc. (London) 73, 169 (1959) for further work.

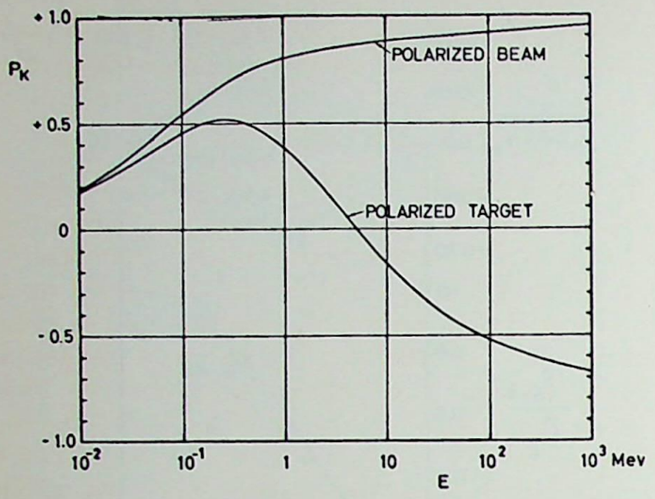

FIG. 16. Annihilation-in-flight. Computed transfer of helicity from positron to the annihilation quantum of higher energy in the laboratory system (upper curve). Right-handed positron yields right-handed photon (positive P_k). If target, instead of beam, is polarized, lower curve applies. From (P57).

(5) *Circular Polarization of Annihilation Photons*

As has been stressed before, there is no helicity information in the photons from nonrelativistic annihilation of positrons (nor is there in the photons which lie strictly along the line of collision, at any beam energy). However, for annihilation in flight at quite modest energies, the photon in the "opposite hemisphere" to whichever of the particles is longitudinally polarized takes on to some extent the same helicity as that particle had. This transfer efficiency is implied by the upper curve of Fig. 16, which specifically gives the circular polarization of the *higher* energy member of the pair of photons, per unit polarization of the beam. The target is assumed to be unpolarized. In actual circumstances, depending on geometry and energy discrimination in the photon detector, one may effectively accept only photons at center-of-mass angle $0<\theta<\theta_{\max}$, and usually with varying efficiency as a function of θ. What is shown here is simply the situation where all photons $0<\theta<90°$, and only those, are presumed to be analyzed (all counted and analyzed with equal efficiency). The process here is typically relativistic, and thus the higher the beam energy the more convenient the method becomes (with regard to energy discrimination, and geometrically). This may be compared with the experimental situation in Sec. III D (3), where a balance had to be maintained between competing effects.

The case where the target and not the beam is polarized is also indicated in Fig. 16, but is of no particular concern to us here. One sees however how the crossover in sign at 4 Mev relates to the similar crossover in the solid curve of Fig. 12.

Deutsch and collaborators (DS57) have used annihilation-in-flight in an unpolarized converter (Lucite) to measure the helicity of the positrons from Ga^{66} (the high-energy group has 4-Mev end point). Their apparatus is shown in Fig. 17. A selected portion of the beta spectrum is focused onto the converter, the high-energy (forward) photons being then analyzed for circular polarization in the transmission Compton analyzer shown. The computed δ, based on fully polarized (right-handed) positrons compared with the measured δ as a function of photon laboratory energy (for given input beta energy) implied essentially 100% longitudinal polarization. The measured values of δ ranged to 8%.

This second-order method has been used without preselecting the energy of the positrons by Boehm *et al.* (Bo57).

Transverse polarization.—For the process just considered (annihilation-in-flight against an unpolarized target) there is generally a nonzero transfer from any P_s in the particle beam to P_k of the annihilation radiation. This is a maximum at center-of-mass angle 90°, that is when the line of annihilation lies crosswise to the line of collision (P58). The magnitude of this efficiency generally exceeds the analogous transfer term for the bremsstrahlung process. At 3 Mev the transfer efficiency is a maximum of 0.55, and it is rather symmetric about 3 Mev on logarithmic energy scale, falling to half of this value at 0.3 Mev or at 60 Mev. This hypothetical method suffers from intensity limitations for the same two reasons mentioned in Sec. III D (3).

IV. CONCLUDING REMARKS

A. On Calculations

So far, all helicity calculations cited have proceeded from theory that is already very well believed, and reasonably well checked experimentally. For example (to include Compton scattering for completeness), the "spin effects" were always there, both theoretically and experimentally, in the nonhelical details of the differential cross section. This includes loss of definition of plane polarization in Compton scattering. The same is true of the existence of ground-state positronium and the details of its fine structure. The spin terms were known to be present in Møller and Bhabha differential scattering, in the annihilation-in-flight cross section, and in the Bethe-Heitler approximation for the bremsstrahlung process. No really new physics is being used here in making use of standard processes for polarization measurement.

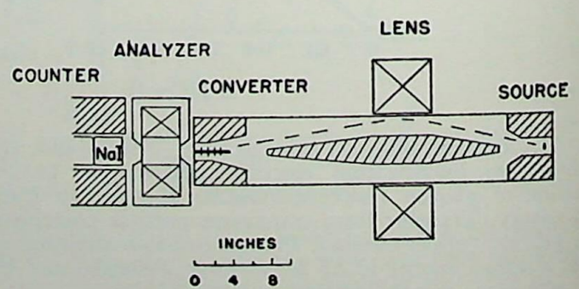

FIG. 17. Experiment to measure positron helicity by transferring polarization information to annihilation (in flight) photon, which is analyzed for helicity in Compton analyzer. From Deutsch and colloborators (DS57).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

In order to make practical use of these spin effects, lists of matrix elements (transition amplitudes) from fully specified state to fully specified state are good things to have accessible. Then none of the polarization implications in the original theory are averaged out until the people devising a particular experiment are ready to do so.

For fast particles, transverse polarization is generally less amenable to measurement than is longitudinal polarization. Perhaps it is not too early to begin looking beyond those polarization effects which are already in the extant theory. Under this heading would come an enquiry into the possibilities of right-left asymmetry in bremsstrahlung intensity from transversely polarized particles. Here one would have to go beyond the Bethe-Heitler approximation, reminiscent of how, in Coulomb scattering without radiation, one has to go beyond the first Born approximation in order to find any polarization effects other than "reprojection" of spin.

B. On Experiment

Of great assistance in succeeding with the experiments discussed here has been the fact that all the methods are really *null* methods. In these experiments, a large number of parameters such as solid angle, energy straggle, backgrounds, are arranged to be *the same* for both "states" of the analyzer. By and large it is nowadays as easy to demonstrate spin-helicity effects, using the large input polarizations now known to be available from beta decay, as it is to demonstrate in a nonpolarization experiment some relativistic feature of a differential cross section, or to measure an absolute cross section, to compare with Dirac theory. The reason is that none of these latter experiments can be made into a null method. In exploring details of a differential cross section there is always some important parameter that changes: the energy of a photon, an angle of obliquity in a scattering foil, signal-to-noise ratio. These things that matter will change always in a systematic way with the independent variable of the particular experiment. Hopefully, these systematic changes are computable, measurable or otherwise understood. As for absolute cross-section determinations (except perhaps for total Compton cross section), these are notorious for having many factors which must be controlled.

With the labor and care necessary for say a 10% measurement of differential cross section, one now gets typically a 1% measurement on a change in counting rate which relates linearly to the polarization being measured. The intrinsic reliablity and power of the balancing or null approach makes this possible. Suppose the polarization effect causes a 10% change in counting rate, then one would have a measurement of polarization good to 10%. For smaller output asymmetries, one must try to balance more thoroughly. In any case, it appears that the potential power of the null methods needs to be stressed, especially in telling of polarization measurement to persons outside the immediate field.

C. On Calibration

We look forward to the time when a number of standard (that is, reproducible) beta and bremsstrahlung sources and analyzers are available. Numbers will have to be attached, these numbers will have to be cross-checked with each other somehow, and of course "theory" and the numbers will have to be compatible.

Aside from precision "numerical" calibration which is the course presently being followed, there is a different approach which might be mentioned. Just as an unpolarized beam has no polarized part, a fully polarized beam has no unpolarized part. This is not trivial: It should be recalled that if the problem were to demonstrate that a certain beam is unpolarized to within an infinitesimal, perhaps 0.5%, then a polarization analyzer whose efficiency is known only crudely (say within a factor two) might suffice—one performs a null experiment. In dealing with degrees of polarization P which are much closer to unity than to zero, it might be worthwhile to consider possibilities for measuring $1-|P|$, instead of P itself. Thus, if $|P|$ were ~ 0.97, a measurement on $1-|P|$ good to only 30% is equivalent to a measurement on $|P|$ good to one percent. The sign of P would of course be known before one embarked on this hypothetical precision experiment. Admittedly, such experiments would have to be of second order and therefore quite difficult. Yet, it would be aesthetically pleasing to have proof of, say, 100% polarization presented in the form of a null experiment, to complement the more traditional approach which would hinge upon a chain of calibration numbers.

V. ACKNOWLEDGMENTS

The major part of this paper was written at the Institute of Physics, Uppsala. The author thanks Professor Kai Siegbahn for the hospitality of the Institute. A number of general discussions with Professor Mael Melvin at Uppsala have been appreciated. Association in past years with Professor Philip Stehle of Pittsburgh has laid some basis toward understanding of polarization problems.

The John Simon Guggenheim Memorial Foundation is thanked for a fellowship, and the further support provided by the Office of Ordnance Research, U. S. Army, is acknowledged.

APPENDIX A. BETA DECAY AND POLARIZATION

Allowed Fermi Decay

The connection between neutrino polarization and beta polarization can be illustrated in simple sketches (Fig. 18). We assume a pure V (vector) interaction, and let a positron be emitted for illustration. The other

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

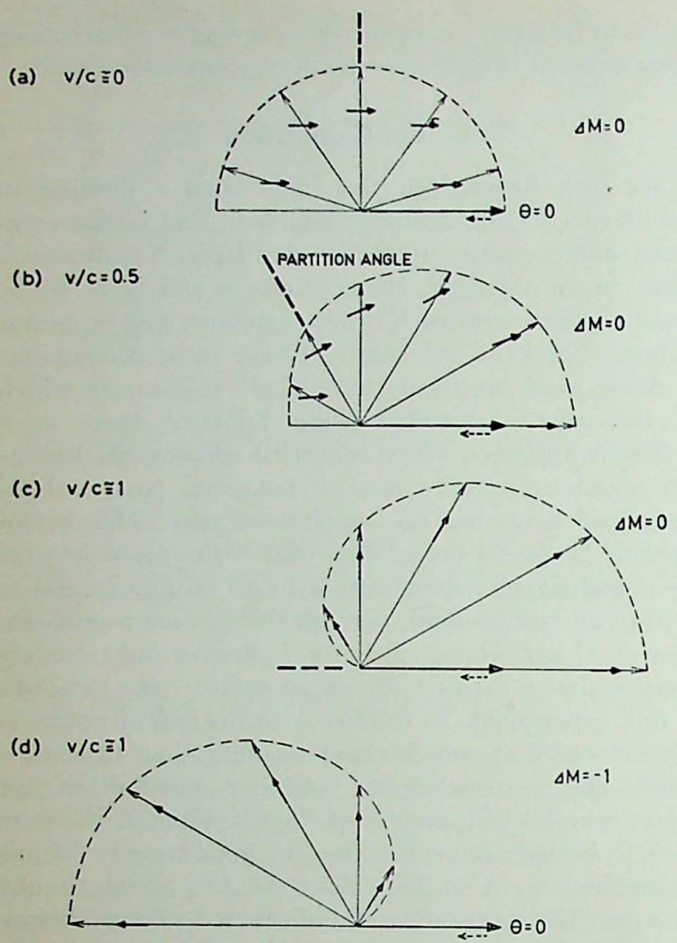

FIG. 18. Relations between polarization vectors and momentum vectors. The emitted neutrino momentum **q** defines direction $\theta=0$. Length of a given radius vector to the dotted envelope is proportional to the probability that the beta momentum **p** shall be in that direction. Spin-polarization vectors are shown by short arrows. Beta-polarization arrows (each representing degree of polarization unity) generally have meaning only in the rest system of the beta particle. Neutrino helicity -1 is used for illustration. Sketches apply for pure V or pure A interaction.

particle emitted is called a neutrino and not an anti-neutrino. In sketches (a), (b), and (c) the neutrino proceeds along the line $\theta=0$, to our right. Suppose it is left-handed. The sketches show (i) the angular correlation of the beta momentum **p**, with respect to neutrino momentum **q** (the envelope drawn is the relative probability of beta emission for given angle of emission, to be multiplied by d^3p); (ii) the polarization vector in the *rest system* of the beta particle, where the magnitude of the polarization is always unity since in this situation no degree of freedom remains.

These sketches rest on the fact that the *amplitude* for the beta to be at angle θ and to be right-handed is $(1+b)\cos(\theta/2)$, while the (coherent amplitude for it to be left-handed is $(1-b)\sin(\theta/2)$, where $b=p/(\gamma+1)$ and γ means total energy of the beta. It follows that the beta-neutrino correlation (unpolarized) is

$$W(\theta)=1+\frac{2b}{1+b^2}\cos\theta=1+\frac{v}{c}\cos\theta. \qquad \text{(A1)}$$

Alternatively from these amplitudes, the longitudinal polarization is

$$P_p(\theta)=\frac{(v/c)+\cos\theta}{1+(v/c)\cos\theta}. \qquad \text{(A2)}$$

Beginning again with these amplitudes, the longitudinal polarization, *independent of* θ is $+v/c$. We could have reversed the roles of beta and neutrino by requiring say a right-handed beta, then the angular correlation of the neutrino with this beta is just $(1+\cos\theta)$. A neutrino of zero rest mass is taken here.

Expression (A2) shows there is a "partition angle" at which the beta polarization is exactly transverse. This angle, defined by $(v/c)+\cos\theta=0$, moves closer to 180° as v/c increases. The drawings show how P_p tends to unity in the high-energy limit.

To pass from pure V interaction to pure S (scalar) interaction, one may reverse **q** and the neutrino helicity and otherwise keep the same patterns as sketched in (a), (b), and (c) of Fig. 18.

Nowhere in this discussion was anything said about nonconservation of parity: We could argue that what was plotted or given in the foregoing expressions was intended to represent only *half* of the Einstein-Podolsky situation. Then, by supplying the recipe for the *other* helicity of the neutrino, which says to reverse all polarization vectors, the picture would be completed. [Expression (A1) would be unchanged.]

It seems that only one-half of the picture occurs in nature, but this need have nothing to do with our trying to illustrate the connection between the momenta and helicities. It does supply the motive and explains our choice of *longitudinally* polarized neutrino in these figures.

Allowed Gamow-Teller Decay

In the foregoing section, although we pretended to be discussing only the pure Fermi case, drawings (a), (b), and (c) apply equally well to pure GT—to the $\Delta M=0$ part at least. For the A (axial-vector) interaction we may keep the drawings as they stand, for pure T (tensor) interaction we can reverse **q** and the neutrino helicity. To depict the situation for an offgoing right-handed neutrino, reverse all polarization vectors. To complete the picture for GT, a $\Delta M=-1$ transition is sketched as part (d) of Fig. 18, only the high-energy limit being shown for illustration. A $\Delta M=+1$ transition would be represented by reflecting picture (d) in the plane $\theta=90°$ (including the polarization arrows). Throughout we have been taking the axis of quantization for J to be along $\theta=0$.

As regards the unpolarized angular correlation, we now have competing parts: the angular correlation for a picture like (b) is $1+v/c\cos\theta$, and for a picture like (d) is $1-v/c\cos\theta$. However, transition (d) occurs twice as often as (b), at least for unpolarized initial and final nucleus. By not forcing a definite helicity on the neutrino, $|\Delta M|=1$ transitions occur twice as often as

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

$\Delta M=0$ transitions, as required by spectroscopic stability. Or, requiring definite helicity for the neutrino, picture (b) represents "half" of a triplet $M=0$ state (of neutrino plus beta). Thus, either way we look at it, the angular correlation is the same,

$$W(\theta)=1-\frac{v}{c}\cos\theta. \tag{A3}$$

Picture (a) and a nonrelativistic version of (d) are what apply in a pure GT K-capture event. With respect to $\mathbf{q}$, the ΔM imparted to the nucleus is either -1 or zero (for a left-handed neutrino emitted), the former transition occuring with twice the probability of the latter.

Now if we require, for the first time, a given "ΔM" in the laboratory, the neutrino will seldom proceed along the axis of quantization, and simple sketches such as these are no longer feasible. So many important experiments are related to J_z in the laboratory that the discussion should be pursued a little further. Inspection of equation (1) of Jackson *et al.* (J57) shows, for pure A interaction, say, that the $\Delta M=0$ transition has angular correlation (z axis fixed in the laboratory)

$$1-\frac{\mathbf{p}\cdot\mathbf{q}}{E_eE_\nu}+2\frac{p_zq_z}{E_eE_\nu}. \tag{A4}$$

Of course, $\mathbf{p}$ and $\mathbf{q}$ *separately* are isotropic in the laboratory since one cannot "align" a spin-$\frac{1}{2}$ particle but can only polarize it. From (A4) the correlation between $\mathbf{p}$ and $\mathbf{q}$ can be readily worked out to be $1-\mathbf{p}\cdot\mathbf{q}/3E_eE_\nu$, which is the same as (A3).

For comparison the $\Delta M=-1$ correlation [again from (J57)] is

$$\left(1-\frac{p_z}{E_e}\right)\left(1+\frac{q_z}{E_\nu}\right) \tag{A5}$$

and, although $\mathbf{p}$ and $\mathbf{q}$ are now each tied closely to the z axis, the correlation between them is the same as for the $\Delta M=0$ case just treated.

If we had the simple case J, $M=1$, -1, making a transition to $J=0$, the neutrino (taken to be left-handed) would be emitted as $1+\cos\theta$, the beta (independently) as $1-v/c\cos\theta$, the factor $\frac{1}{3}$ being now absent since only one possibility for ΔM has been allowed. On the other hand, if we ask for the polarization of daughter nucleus (let us now go from $J=0$ to $J=1$ for illustration) having found a beta along z, then the $\Delta M=0$ contribution is again in competition with $|\Delta M|=1$, and the factor $\frac{1}{3}$ often associated with GT transitions reappears. The beta—circularly polarized gamma correlation is treated in detail by Alder *et al.* (A57) for example.

APPENDIX B. SHORT COMPENDIUM OF HELICITY SIGNS

The experiment of Wu *et al.* (Wu57) showed that the negative beta particles from polarized Co^{60} nuclei come off predominantly opposed to the field H. Thus these betas as predominantly opposed to the direction of the original nuclear spin, because ground-state Co^{60} has a positive g value (W55). This decay has a decreasing spin change ($5\rightarrow 4$) and therefore the beta and the emitted antineutrino jointly carry off angular momentum parallel to the original nuclear spin, unless we suppose that conservation of angular momentum is in question. Since none of this angular momentum carried off is orbital (this is an allowed transition) it has to be carried entirely by the spins of the two particles. Suppose, for argument, that the original nuclear polarization were complete. Then the two particles must carry off one unit of angular momentum referred to the z axis, the field axis. They are both spin-$\frac{1}{2}$ particles and so must "aid each other." The Wu result implies then that the betas from Co^{60} have to be predominantly left-handed. To summarize, granting the sign of g, the sense of the spin sequence here, and granting the conservation of angular momentum, the "sign" that emerges from the Wu experiment is just the helicity of those betas.

Soon after the Wu experiment, the left-handed helicity of the Co^{60} betas was checked by Frauenfelder and collaborators (Fa57) by means of Mott scattering. Page and Heinberg found that positrons from Na^{22} were predominantly right-handed (PH57). Simultaneously Schopper (S57) showed that Na^{22} and Co^{60} (both having the same sense in the spin sequence) emitted photons of opposite handedness, when measured at nominal 180° to the line of the emitted beta, the sign for Co^{60} being in accord with the Wu experiment. Ga^{66} believed to decay via a pure Fermi transition was shown by Deutsch and co-workers (DS57) to give highly polarized right-handed positrons. [No attempt is made to record many of the early polarization experiments which quickly extended the list to include, for example, mixed (F and GT) transitions, forbidden transitions, etc.]

Strictly, none of these experiments shows anything about neutrino helicity (that is, whether it is left or right), since the neutrino direction is not measured. What is measured in the three kinds of experiment just mentioned, Wu experiment, polarized beta experiment, and beta—circularly polarized gamma experiment, is a a sense of circulation and coincidentally a *beta* direction, nothing more.

The helicity of the neutrino emitted in K capture (presumably the same particle as the one emitted together with a positive beta) was measured *directly* by Goldhaber *et al.* (G58) and found to be left-handed.§§§§ One concedes again conservation of angular momentum and certain j values of the levels involved.

§§§§ The sign and order of magnitude of the neutrino helicity for the decay used by Goldhaber ($Eu^{152m}\rightarrow Sm^{152*}$) has now been checked at Uppsala (M58).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

To review further would lead into the status of beta-decay theory. The algebraic signs relating to a small and specific set of decays are given, signs which have not been in jeopardy and presumably will stand. This is done for the benefit of any person who may have had the notion that all had been confusion with regard to helicity measurement.

APPENDIX C. COMPTON ANALYSIS OF PHOTON HELICITY

The use of a Compton analyzer for circularly polarized radiation rests on a spin-helicity correlation present in the matrix element of Klein and Nishina. Details‖‖‖‖‖‖ of the spin-helicity part of differential or total cross section are given in (G53), or see the review article (T). The Compton analyzers may be divided into two types as indicated in the following.

Transmission Type

Here the spin-polarization sensitivity of the *total* Compton cross section is utilized. The analyzing efficiency, per polarized "iron" electron, has a faint unexplored maximum of 0.06 at about 0.2 Mev, and is zero at 0.64 Mev. From this energy to 14 Mev, where the efficiency is 0.4, it increases almost as the logarithm of $E/0.64$ Mev, and at very high energy becomes unity. Before helicity measurement became of general interest, this type was used in second order (that is, the two sets of spins in an iron analyzer acted as the polarizer-analyzer combination to verify that the spin-helicity term could be seen experimentally). A transmission analyzer was first used in first order, to measure degree (and sense) of polarization in a beam, by Trumpy (T57). This was a "nonparity" experiment, as it used capture gamma rays produced by prepolarized slow neutrons. The first application of this analyzer in a "parity" experiment was by Goldhaber *et al.* (G57), to demonstrate and measure the polarization of bremsstrahlung by Y^{90} beta rays. Lundby and co-workers have used it in beta—circularly polarized gamma correlation work (L57).

Owing to the inescapable null in the efficiency curve at 0.64 Mev, the transmission analyzer is best suited for rather high energy work, but has been used successfully on a gamma line as low as 0.9 Mev (G58).¶¶¶¶ Normally, a gamma ray is not seriously degraded in energy in passing through the iron absorber. Finally, this type of analyzer has zero sensitivity to any competing *plane* polarization in the photon beam.

Differential Type

In this type one counts, at a certain angle, photons scattered by polarized electrons. Some years before parity work, the differential analyzer was proven at Leyden (W55) on the Ni^{60} gamma rays following the beta decay of polarized Co^{60}. The method has since been revived by Schopper (S57) and by Boehm and Wapstra (BW57) for use in beta—circularly polarized gamma correlation measurements. Scattering at very large angles has recently been employed by Bernardini *et al.* (Be58) to measure the helicity of inner-bremsstrahlung. Unless one is prepared to make absolute scattering measurements (which are quite out of the question, compare Sec. IV B) a differential analyzer is quite sensitive to *plane* polarization,***** this sensitivity being independent of spin direction. Therefore, for a given geometry of source, scatterer and photon detector, a flat statement of "circular polarization efficiency" in terms of *fractional* change in intensity of scattered photons on reversing magnetization cannot strictly be given, unless some proviso is made regarding ellipticity (or planeness). This feature was at once recognized by the Leyden group, but appears to have largely escaped mention since.

Owing to counting rate considerations the scattering geometry is often such that any lines in the incident gamma spectrum are quite spread in energy as seen by the detector.

Invited Papers from the Conference on Weak Interactions Held at Gatlinburg, Tennessee, October 27-29, 1958

Introductory Note

SOMEWHAT more than two years have passed since the realization came to physicists that the reflection law known as the conservation of parity possesses limits in the generality of its application. A paradox in the decay of the τ mesons had led to some daring theoretical speculation, promoting direct laboratory tests which led in crucial experiments of rare, illuminating character to a re-direction of thought concerning those interactions which we call "weak." For these physicists, the assumption of conservation of parity suddenly lost its sacredness. The result was a flurry of action; experiments of new types were started, and theoretical channels were explored along new lines. Last summer, new observations were being reported in abundance, and it occurred to members of the Physics Division of the Oak Ridge National Laboratory that a meeting of those involved and interested in the subject might be of profit. A local conference committee was established,* the American Physical Society was approached and granted its endorsement and help in the welcome form of two additional members for the Committee,† and the conference took place at Gatlinburg, Tennessee, on October 27, 28, and 29, 1958.

The conference comprised twelve sessions, in which the guidance of the following experienced contributors to the field, acting as chairmen, was a vitalizing influence: M. Goldhaber, M. Deutsch, M. E. Rose, J. M. Robson, E. J. Konopinski, E. C. G. Sudarshan, S. B. Treiman, H. L. Anderson, R. W. Thompson, R. G. Sachs, and E. P. Wigner. Abstracts of the contributed papers have been published in the *Bulletin of the American Physical Society* (January, 1959) and their position in the total conference can be gauged by their numbers in relation to the summary of sessions given below. The substance of the invited papers is set forth in the pages that follow.

ARTHUR H. SNELL
Chairman

Summary of the Conference Sessions

Session A.	Parity Experiments. *Invited paper by* C. S. WU.
Session B.	Polarization following Beta Decay. *Contributed papers.*
Session C.	Experimental Beta Decay. *Invited paper by* J. S. ALLEN; *contributed papers.*
Session D.	Beta Decay of the Free Neutron; Time Reversal. *Invited paper by* V. L. TELEGDI; *contributed papers.*
Session E.	Theoretical Beta Decay. *Invited paper by* R. P. FEYNMAN; *contributed papers.*
Session F.	Theoretical π and μ Decay and μ Capture. *Invited papers by* M. L. GOLDBERGER *and* H. PRIMAKOFF.
Session G.	π and μ Decay and μ Capture. *Contributed papers.*
Session GA.	Recent Observations of π-e Decay (unscheduled session).
Session H.	μ Mesons—Experimental. *Invited paper by* R. L. GARWIN; *contributed papers.*
Session J.	Strange Particles—Experimental. *Invited paper by* J. STEINBERGER; *contributed papers.*
Session K.	Strange Particles and Weak Interaction—Theoretical. *Invited paper by* R. H. DALITZ; *contributed papers.*
Session L.	Weak Interaction—Summary. *Invited paper by* M. GELL-MANN.

* Members: J. L. Fowler, A. I. Galonsky, M. E. Rose, A. H. Snell, T. A. Welton, and H. B. Willard.
† C. S. Wu and E. J. Konopinski.

REVIEWS OF MODERN PHYSICS VOLUME 31, NUMBER 3 JULY, 1959

Parity Experiments in Beta Decays*

C. S. Wu

Columbia University, New York, New York

INTRODUCTION

THE frontier of parity study has now advanced to the field of strange particles. The atmosphere in the field of beta decay appears unusually calm and quiet after the storm. I will try to piece together the jigsaw picture and to see what sorts of puzzles in beta decay have fallen into shape. Most urgent of all is the question, whether there are still any missing pieces, and if there are, what are they?

In principle, parity experiments are simply experiments designed to study the screw senses of particles, decay processes, or nuclear reactions. This all originated from our concept of left and right symmetry; that is, left and right are indiscernible.[1] To scientific minds, from the time of Leibniz to 1957, there was no inner difference, no polarity between left and right. The inner structure of space does not permit us, except by arbitrary choice, to distinguish a left from a right screw. However, a right screw or a right spinning particle shows up as a left screw or a left spinning particle in a mirror reflection. So from the right-left symmetry we arrived at the space-reflection symmetry. This symmetry implies that if a particle exists, the one obtained by reflecting it in a mirror must also exist. If a decay process can take place, the one seen in a mirror is also a possible one. The symmetry of space-reflection clearly requires that events or particles do not exhibit definite screw senses. That is why all parity experiments are concerned with the measuring of the screw senses. This screw sense is now christened with the elegant name of helicity and is defined as $\boldsymbol{\sigma}\cdot\mathbf{p}/|p|$, the spin along p.

The first parity experiment[2] using polarized Co^{60} was designed to test whether there are any screw senses in beta decay. The essence of the experiment was to line up the spins of the Co^{60} nuclei along the same axis and then to determine whether the beta particles were emitted preferentially in one direction or the other along the axis. The results showed that the electrons were emitted preferentially in the direction opposite to that of nuclear spin and therefore conclusively proved that the beta decay of Co^{60} behaves like a lefthanded screw or possesses a negative helicity. So parity is not conserved in beta decay.

Moreover, the asymmetry observed is as large as possible. In the electron angular distribution $I(\theta)=1+A\langle J_z\rangle/J(v/c)\cos\theta$ (where θ is the angle between the nuclear spin and electron momentum direction), the measured asymmetry parameter A is nearly equal to -1. This implies that the parity interference effects are about as large as they could be. So this first experiment on parity tells us not only that parity and charge conjugation are not conserved in beta decay but points to something even more drastic and significant.

TWO-COMPONENT THEORY OF THE NEUTRINO

When the experimental value of the asymmetry parameter ($A\cong-1$) in Co^{60} beta decay was made known to Lee and Yang, they immediately realized that here one had to consider an extremely simple and appealing theory of the neutrino.[3] This theory requires that the spin of a neutrino always be either parallel or antiparallel to its momentum and the helicity of an antineutrino be opposite to that of a neutrino. Incidentally, this theory requires also the rigorous masslessness of the particle. If there were any mass associated with the particle, the particle could therefore be at rest or with momentum $\mathbf{P}$ reversed in a certain frame of reference. In that case, it is rather meaningless to impose the necessary requirement of alignment of spin $\boldsymbol{\sigma}$ and momentum $\mathbf{P}$ for such a particle. From experimental evidence, the mass of the neutrino is indeed vanishingly small. The most sensitive method of estimating the mass of the neutrino is to investigate the slope of the upper end of a beta spectrum. The low-energy beta spectrum of H^3 has been investigated for this purpose by many laboratories.[4] The upper limit of the mass of the neutrino m_ν is around 250 ev ($\sim 1/2000\, m_e$) and the evidence is also not inconsistent with mass m_ν equal to zero.

All through the years, theoretical physicists had entertained the idea of associating such unique properties with a massless neutrino. It had to be abandoned lest the law of parity be violated. Clearly, the two-component theory of the neutrino violates P and C invariance separately. A left-handed neutrino looks into a mirror and finds a right-handed neutrino, but according to the two-component theory of the neutrino, there is no such possible state. The charge conjugate of a neutrino is an antineutrino; one behaves like a left

spinning particle, the other like a right spinning particle. This is a clear-cut violation of invariance of charge conjugation. In 1929, Weyl[5] proposed the mathematical possibility of such a particle, but it was discarded because it violated the law of parity and therefore could not be a physical reality! Landau[6] and Salam[7] reinvestigated this possibility shortly before the discovery of parity nonconservation. With the removal of both of these obstacles, interest in this theory was suddenly revived.

So in the first parity experiment of beta decay of polarized Co^{60}, not only was the screw sense in beta decay found, but even more dramatic was the realization of the possible existence of the two intrinsic opposite screws associated with the neutrino and antineutrino. The success of the two-component theory of the neutrino greatly facilitated our understanding of many phenomena in weak interactions.

LAW OF CONSERVATION OF LEPTONS

At this point, we should review another important conservation law known as the law of conservation of leptons which was suggested by Konopinski and Mahmoud[8] to explain the nonoccurrence of certain decay processes. The law states that if a leptonic number is assigned to each particle, then the sum of leptonic numbers must be conserved in all reactions. The assignments generally agreed upon are

lepton l=same (say +1)	for e^-, μ^-, ν
$l=-1$	for e^+, μ^+, $\bar{\nu}$
$l=0$	for π, γ, K and all heavy particles.

The ν or $\bar{\nu}$ expected in various decays are shown in the following equations:

$$n \rightarrow p+e^-+\bar{\nu} \qquad p \rightarrow n+e^++\nu \tag{1}$$

$$\pi^+ \rightarrow \mu^++\nu; \qquad \pi^- \rightarrow \mu^-+\bar{\nu} \tag{2}$$

$$\mu^+ \rightarrow e^++\nu+\bar{\nu}; \qquad \mu^- \rightarrow e^-+\nu+\bar{\nu} \tag{3}$$

$$\mu^-+p \rightarrow n+\nu; \qquad \mu^++n \rightarrow p+\bar{\nu} \tag{4}$$

$$K^+ \rightarrow \mu^++\nu; \qquad K^- \rightarrow \mu^-+\bar{\nu} \tag{5}$$

$$\pi^+ \rightarrow e^++\nu; \qquad \pi^- \rightarrow e^-+\bar{\nu}. \tag{6}$$

The confirmation of the assignments given by these decays should constitute a strong proof of the law of conservation of leptons. Particularly if the helicities of these two neutrinos are opposite, then the predictions of these decay processes become unique.

[5] The possibility of a two component relativistic theory of a spin 1/2 particle was first discussed by H. Weyl, Z. Physik **56**, 330 (1929). It was rejected on the ground of parity violation. See W. Pauli, *Handbuch der Physik* (Verlag Julius Springer, Berlin, 1933), Vol. 24, pp. 226–227.

EVIDENCE OF TWO-COMPONENT NEUTRINOS AND LEPTON CONSERVATION OBTAINED FROM PARITY EXPERIMENTS

I. From Nuclear Beta Decays

In the nuclear beta decay as shown in (1), an antineutrino is expected to be associated with β^- decay and a neutrino with β^+ decay. Furthermore, if the two-component theory of the neutrino is valid, then there are several unique phenomena predicted theoretically. The validity of the two-component theory and lepton conservation depends largely on the closeness of the agreement between the experimental evidence and the theoretical predictions. Suppose now we examine each phenomenon separately.

(A) *Beta Asymmetry from Polarized Nuclei*[2]

The beta asymmetry of allowed transitions from polarized nuclei can be expressed in the following form:

$$\begin{aligned} A=\Big\{&\lambda_{JJ'}\Big[\pm\mathrm{Re}(C_T{}^*C_{T'}-C_A{}^*C_{A'}) \\ &-\frac{Ze^2}{\hbar cp}\,\mathrm{Im}(C_T{}^*C_{A'}+C_{T'}{}^*C_A)\Big]|M_{GT}|^2 \\ &+\delta_{JJ'}\left(\frac{J}{J+1}\right)^{\frac{1}{2}}\Big[\mathrm{Re}(C_T{}^*C_{S'}+C_{T'}{}^*C_S-C_A{}^*C_{V'} \\ &-C_{A'}{}^*C_V)\pm\frac{Ze^2}{\hbar cp}\,\mathrm{Im}(C_A{}^*C_{S'}+C_{A'}{}^*C_S-C_T{}^*C_{V'} \\ &-C_{T'}{}^*C_V)\Big]|M_F|\cdot|M_{GT}|\Big\}\times\frac{2}{\xi(1+b/W)} \end{aligned} \tag{7}$$

$$\xi=(|C_S{}^2|+|C_V{}^2|+|C_{S'}{}^2|+|C_{V'}{}^2|)|M_F|^2 +(|C_T{}^2|+|C_A{}^2|+|C_{T'}{}^2|+|C_{A'}{}^2|)|M_{GT}|^2$$

$$\xi b=\pm 2\gamma\,\mathrm{Re}[(C_SC_V{}^*+C_S{}'C_{V'}{}^*)|M_F|^2 +(C_TC_A{}^*+C_T{}'C_{A'}{}^*)|M_{GT}|^2],$$

where C_i and C_i' are the even and odd beta coupling constants. This measurement gives unique information about the pure G-T interaction. Neglecting the imaginary term for the time being and setting the Fierz term $b/W=0$, then one can obtain a simple relation for "A" for the $J \rightarrow J'=J-1$ transition,

$$A(\beta_\pm)=\pm 2[\mathrm{Re}(C_T{}^*C_{T'}-C_A{}^*C_{A'})]/ |C_T{}^2|+|C_A{}^2|+|C_T{}'|^2+|C_A{}'^2|.$$

Furthermore, for the two-component neutrinos the even and odd beta coupling constants are related by $C_T=-C_{T'}$ (left-handed antineutrino) or $C_A=C_{A'}$ (right-handed antineutrino). Therefore, $A(\beta_\pm)=\mp 1$ for the above pure G-T transition. As we all know, the β^- asymmetry A of polarized Co^{60} where the spin and

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

parity change is $5^+ \rightarrow 4^+$ is indeed nearly -1 to within a systematic uncertainty not larger than 20%. This is the first strong evidence of the possible existence of the two-component neutrino. On the other hand, what evidence do we have of the β^+ asymmetry in a pure G-T transition of β^+ decay? Unfortunately, with the present technique of nuclear alignment, the nuclei which can be substantially polarized belong to a very exclusive club. In order to obtain the same type of information which can be extracted from polarized nuclei, we have to resort to an indirect method which is easier to apply although far less sensitive. This is shown in the following.

(B) β-γ (*Circular Polarization*) *Correlation*

It is quite obvious from the observed beta-asymmetry distribution of polarized nuclei that the β decay should leave the nucleus partly polarized with respect to the direction in which the β particle is detected. If a γ ray follows immediately after the β decay, it should have circular polarization proportional to the cosine of the angle between the β particle and γ ray. The circular polarization of the γ ray can be analyzed with a cylindrical electromagnet which could be magnetized to saturation either parallel or anti-parallel to the photon direction. The principle of this analysis is based on the existence of a spin dependent part of the Compton cross section of circularly polarized photons and is treated in detail by Gunst and Page.[9] The correlation for the most frequent decay sequence such as

$$J \xrightarrow[\beta \text{ transition}]{\text{allowed}} J' \xrightarrow{2^L \text{ pole } \gamma} J''=J'-L$$

can be expressed by

$$W(\theta)=1+A\frac{v}{c}\cos\theta,$$

where

$$A+\frac{1}{L+1}\Big\{\mu_{JJ'}\Big[\pm\mathrm{Re}(C_T{}^*C_T'-C_A{}^*C_A')-\frac{\dot{Z}e^2}{\hbar cp}\,\mathrm{Im}(C_T{}^*C_A'+C_T'{}^*C_A)\Big]|M_{GT}|^2+\delta_{JJ'}\Big(\frac{J+1}{1}\Big)^{\frac{1}{2}}\Big[\mathrm{Re}(C_T{}^*C_S'+C_T'{}^*C_S-C_A{}^*C_V'-C_A'{}^*C_V)\pm\frac{Ze^2}{\hbar cp}\,\mathrm{Im}(C_A{}^*C_S'+C_A'{}^*C_S-C_T{}^*C_V'-C_T'{}^*C_V)\Big]|M_F|\cdot|M_{GT}|\Big\}\frac{2}{\xi(1+b/W)}. \quad (8)$$

Schopper[10] first applied this β-γ (circular) correlation method to Co^{60} and obtained the parameter $A\cong-\frac{1}{3}$. This is in excellent agreement with the conclusion derived from the polarized Co^{60} experiment, that is, $C_T=-C_T'$ or $C_A=C_A'$. When this method was applied to Na^{22}, which is a pure G-T positron emitter ($3^+ \rightarrow 2^+$), the sign of the circular polarization was found to be opposite to that of the electron emitter Co^{60} as theoretically predicted. However, none of these experiments[11] has an accuracy of much better than 20%.

(C) *Longitudinal Polarization of β Rays*[12]

Since parity is not conserved, the pseudoscalar term $(\sigma\cdot p_e)$ formed from the measured spin and momentum vector of electrons may occur. In other words, the decay electrons from unpolarized nuclei can be longitudinally polarized. The general expression of the $\beta^\pm$ polarization is

$$P(\beta^\mp)=\pm\frac{v}{c}\frac{2\,\mathrm{Re}[(C_SC_S'{}^*-C_VC_V'{}^*)|M_F|^2+(C_TC_T'{}^*-C_AC_A'{}^*)|M_{GT}|^2}{(|C_S{}^2|+|C_V{}^2|+|C_S'{}^2|+|C_V'{}^2|)|M_F|^2+(|C_T{}^2|+|C_A{}^2|+|C_A'{}^2|+|C_T'{}^2|)|M_{GT}|^2}. \quad (9)$$

If we assign $C_S=-C_S'$; $C_T=-C_T'$ (for left-handed antineutrino) or $C_V=C_V'$; $C_A=C_A'$ (for right-handed antineutrino) then $P(\beta^\mp)=\mp v/c$. First to observe this polarization was the Frauenfelder group. There are, at present, three major methods being used for the determination of electron polarization. They are: (1) Coulomb scattering from heavy nuclei (Mott scattering); (2) circular polarization of forward Bremsstrahlung or annihilation radiation; and (3) free electron-electron scattering (Møller or Bhabha scattering). The results are startling and simple, and all agree that β^- particles emitted in radioactive decay behave like left-handed screws and all β^+ particles behave like right-handed screws. For relativistic energy $v/c\cong1$, we have practically completely polarized elec-

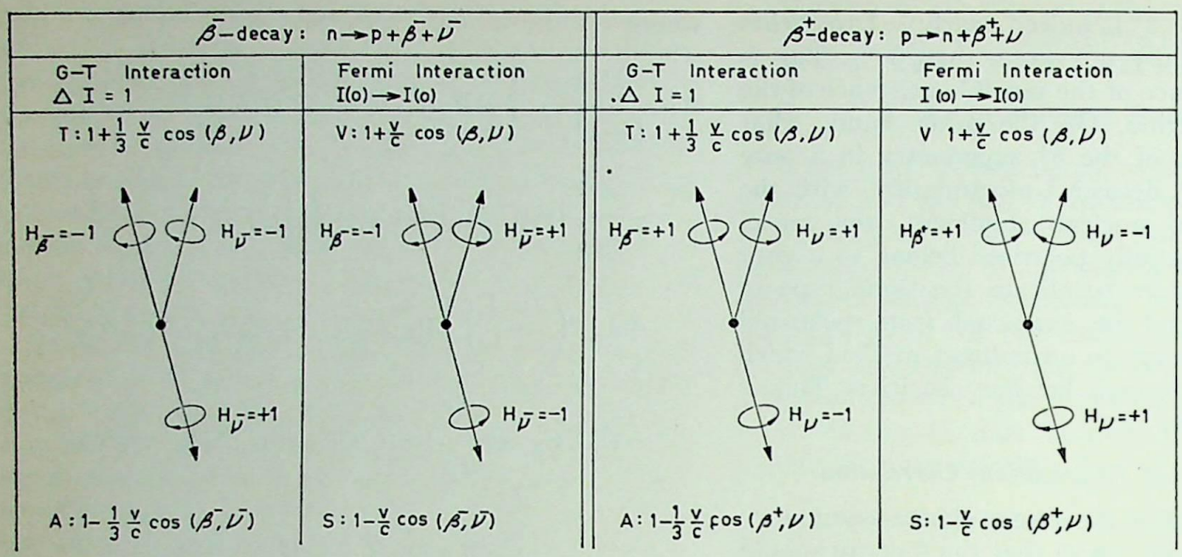

FIG. 1. Correlations of neutrino helicities and β interactions.

tron or positron beams. We have been working with the polarized beam of β particles for the past sixty years, yet we were completely unaware of it because of the faultiness of our left-right symmetry conception. However, many systematic uncertainties in the measurements, such as the backscattering effect, depolarization effect, instrumental asymmetry, and the screen correction factor, etc., are rather difficult to assess or to estimate. Probably it is fair to say that in the high-energy region of $v/c \geq 0.6$, the polarization is nearly v/c with an accuracy of not better than 10%. Below $v/c=0.6$ very few results have been reported and the picture in that region is not clear.[13]

(D) *Correlations between the Helicities of Leptons and Beta Interactions*

The helicity of the neutrino can be correlated to the electron polarization and the form of beta interaction as shown in Fig. 1.

In a G-T β^- interaction, the angular momentum carried away by the leptons is one unit. In the tensor interaction, both leptons are emitted preferentially in the same direction. Since the electron is found to possess negative helicity (left-handed screw), the antineutrino must have the same helicity. On the other hand, in the axial vector interaction, the electron and the antineutrino are emitted preferentially in opposite directions; so positive helicity is predicted for the antineutrino and negative helicity for the neutrino. The helicity of the neutrino[14] observed in the electron capture process of Eu^{152*} is indeed negative and therefore supports the axial-vector interaction. In a similar manner, one can figure out the helicity of the antineutrino for scalar and vector interactions. The relations between the helicities of various leptons in different beta interactions are shown in Table I. This table also points out two more significant conclusions: First, the much used Fierz interference term between S and V expressed as $(C_S C_V{}^* + C_S{}' C_V{}'^*)$ and A and T such as $(C_T C_A{}^* + C_T{}' C_A{}'^*)$ now automatically vanishes because the neutrino or antineutrino associated with S and T or V and A has opposite helicity. Therefore, no interference occurs. Secondly, for the same reason, combinations of (V and T) and (S and A) will not result in interference between Fermi and Gamow-Teller terms.

Many beautiful β-γ (circular polarization) correlation studies[15] on the mixed (G-T and Fermi) transitions such as Sc^{46}, Au^{198}, etc., showed nearly maximum amount of interference between G-T and Fermi interactions. This evidence strongly ruled out a pure VT or SA combination. Incidentally, this conclusion had been reached also by Mahmoud and Konopinski[16] by the study of the first forbidden beta spectra alone in the pre-parity era.

TABLE I. Helicities of ν, $\bar{\nu}$, β^-, and β^+. Helicity: $\boldsymbol{\sigma}\cdot\mathbf{p}/|p|$.

Helicities	ν	$\bar{\nu}$	β^-	β^+
S, T	$+1$	-1	$-\frac{v}{c}$	$+\frac{v}{c}$
V, A	-1	$+1$	$-\frac{v}{c}$	$+\frac{v}{c}$

(E) *Inverse Beta Decays and the Double Beta Decays*

There are also three experiments, initiated long before the parity crisis, which originally had no bearing on the parity question. However, it turns out now that they have important implications for the two-component neutrino and the conservation of leptons. As a matter of fact, a voice of dissension fron these investigations could cause serious troubles.

1. Capture cross section for the antineutrinos in the Cowan and Reines Experiments.[17]—$\bar{\nu}+p \rightarrow n+\beta^+$. For two-component neutrinos, the outgoing neutrinos from the reactor have only one spin state instead of the usual two. By a detailed balancing method, the absorption cross section will be twice as great as the old one. The latest experimental results[18] are no longer in disagreement with the two-component theory of the neutrino. The cross section per fission $\bar{\nu}$ (assuming 6.1 $\bar{\nu}$ per fission) for the inverse beta decay of the proton is

$$\sigma_{\text{exp}}=(11\pm4)\times10^{-44}\ \text{cm}^2,$$

which is comparable to the theoretical cross section calculated for the two-component theory of the neutrino and based on the antineutrino spectrum from the fission fragments.

$\sigma_{\text{theo}}=9.5\times10^{-44}$ Reines *et al.*[18]
$=12\times10^{-44}$ Muehlhause and Oleksa[18]
$=15\times10^{-44}$ King and Perkins.[18]

2. Capture process for the neutrino.—In the Davis experiment[19] $\nu+\text{Cl}^{37} \rightarrow \text{A}^{37}+\beta^-$. Here a neutrino, not an antineutrino, is required for the absorption process. The intensive flux of antineutrinos pouring out of a power nuclear reactor does not provide the right kind of neutrino for this process and therefore no A^{37} activity should be attributed to the reactor neutrinos. The very small A^{37} counts (0.3±3.4 counts per day) which Davis observed in his one thousand gallons of CCl_4 are equivalent to a cross section for neutrino capture of $(0.1\pm0.6)\times10^{-45}$ cm^2. This could be accounted for by the muon activation from the cosmic radiation, and no evidence for a positive effect from the reactor neutrinos exists at the present time. At least, there is no dissension about the two-component theory of the neutrino from the capture process of the neutrino.

3. Double beta-decay.[20a]—The theoretically calculated rates of double beta-decay depend on many assumptions concerning the properties of the neutrinos and whether one or both kinds of neutrinos are emitted in β^- decay. The existence of the conservation law of leptons, together with the two-component neutrino, limits the possible alternatives and demands that the rate of double beta decay be its minimum value. Experimentally no single electron line of discrete energy equal to the sum of the two disintegration energies has ever been observed. The observed upper limit of the rate of double beta decay also strongly rejects the short lifetime based on Majorana neutrinos and favors the longer time of Dirac neutrinos. For example, the predicted half-life of double beta decay of Ca^{48} (4.3±0.1 Mev) is 4×10^{15} yr for no neutrino emissions and 4×10^{18} yr for Dirac neutrinos. The observed decay rate of Ca^{48} is $>2\times10^{18}$ [20b] or 6×10^{18} yr.[20b] In the case of Nd^{150} (3.7±0.1 Mev), the observed decay rate is $>2\times10^{18}$ yr[20c] in comparison with that predicted for Dirac neutrinos of 2×10^{18} yr. However, it is desirable to increase the sensitivity of the detector so one can actually observe the Dirac type double beta decay.

So, all in all, the experimental evidence in favor of two-component neutrinos and the conservation law of leptons is overwhelming. Not even a faint voice of dissension has been raised. On the other hand, neither can a great accuracy be claimed. A greatly improved accuracy to strengthen its ultimate validity is much to be desired.

II. From $\pi-\mu-e$ Decays

Here we review briefly how successfully the two-component theory of the neutrino and the conservation of leptons can interpret the observed phenomena in $\pi-\mu-e$ decays. Particularly, we show that the observed helicities of the neutrino and the antineutrino in $\pi-\mu-e$ decays are the same as those found in nuclear beta decays.

(A) *Polarization of Muons and Electrons*

Consider the decay of a positive pion in its own rest frame [Fig. 2(a)]. Since π^+ is spinless, the neutrino angular momentum (its spin 1/2) about its direction of motion must be balanced by the muon angular momentum about its direction of motion. Now the neutrino in nuclear beta decay is found to possess a negative helicity, so negative helicity is predicted for the μ^+. So far no direct determination of μ^+ helicity has been reported.

However, the information may be inferred from the helicity of the decay electrons within the two-component theory. In the extreme case [Fig. 2(a)] when the neutrino and the antineutrino go in the same direction, the electron which goes in the opposite direction has to carry away the angular momentum of the muon. If μ^+ has a negative helicity, the decay e^+ must possess positive helicity. The experimental results on the polarization of the negative and positive electrons from

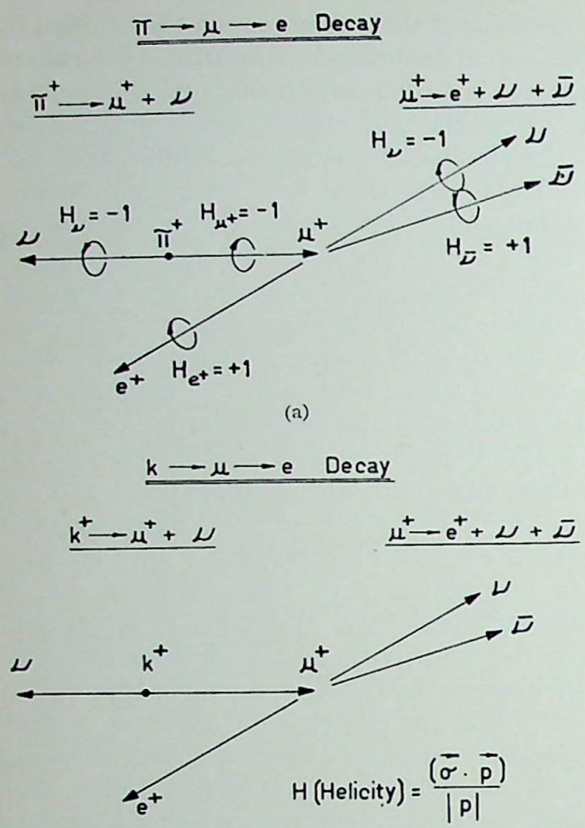

FIG. 2.

muon decays obtained by measuring the circular polarization of the bremsstrahlung and annihilation radiation[21] or by the Møller scattering method[22] conclusively show positive helicity for e^+ and negative helicity for e^-. Here the results on the helicities of the neutrinos in nuclear beta-decays and from $\pi-\mu-e$ decays are in excellent accord.

(B) *Michel Parameter "ρ"*

The shape of the energy spectrum of e^+ from μ^+ decay is characterized by a single parameter "ρ" discussed by Michel. In the two-component theory of the neutrino, ρ must equal zero if the electron is accompanied by two neutrinos or two antineutrinos, and equal 3/4 if one neutrino and one antineutrino are emitted. The present experimental values[23] of ρ vary from 0.68 to 0.72, which is close to 0.75, for one neutrino and one antineutrino emission, and confidently reject the assumption of two neutrinos or two antineutrinos in muon decay. The ultimate determination of the value of ρ is highly desirable because of its significant theoretical implications.

(C) *Energy Dependence of the Asymmetry Coefficient*[24]

The two-component theory of the neutrino predicts closely the energy dependence of the asymmetry coefficient of electron distribution in muon decay. In the high-energy end of the spectrum, the data are in good agreement with the theory. At the low-energy region, measurements are difficult and the accuracy has been poor. However, as a whole, the energy dependence of the asymmetry coefficient in μ^- decay agrees with the prediction of the two-component theory.

III. Muon Capture

The process of muon capture has been studied only in complex nuclei and very little information is available in the literature. At present one side of the Puppi triangle, which represents the muon capture process, is attracting much attention. Before the conference is over we will hear several interesting papers[25] and communications[25] on this topic.

IV. $K-\mu-e$ Decays[26]

The $K-\mu-e$ decay is analogous to $\pi-\mu-e$ decay [Fig. 2(b)]. If the conservation law of leptons holds, the same kind of neutrinos are expected in these two parallel cases. This should, therefore, result in the same asymmetry distribution of electrons with respect to the direction of μ motion. The observance of this predicted asymmetry in $K-\mu-e$ decay further strengthens the validity of lepton conservation.

V. $\pi-e$ Decays[27]

The existence of $\pi-e$ decays is finally confirmed by several laboratories, and the measured ratio R of $\pi \to e$ to $\pi \to \mu+\nu$ decay is very close to that predicted by a simple calculation which gives $R=(\pi-e)/(\pi-\mu)=1.36\times10^{-4}$. It is interesting to note that the helicity of the electron from $\pi-e$ decay should be opposite to that from $\mu-e$ decays.

So there is overwhelming evidence in favor of the two-component theory of the neutrino and the conservation of leptons in all the beta-decay phenomena. To establish firmly the validity of these two assumptions, more precision measurements are required.

INTERACTIONS RESPONSIBLE FOR BETA DECAY

I. From Classical Beta-Decay Experiments

Prior to the discovery of parity nonconservation in beta decay, the (S,T) combination had been the

favorite choice based mainly on $He^6(\beta\text{-}\nu)$ angular correlation results.[28] In fact, the $(\beta\text{-}\nu)$ angular correlation was the only means used to investigate the type of beta interaction in those days. But this type of experiment was known to be difficult. Wu and Schwarzschild[29] made a detailed examination of the old He^6 experiment and pointed out that the effective volume of the He^6 source in the hole of the pumping diaphragm was not correctly taken into account. Had this been done properly, the results of He^6 would not then have implied the tensor interaction. However, in spite of its many limitations, $\beta\text{-}\nu$ correlation is still an effective and powerful method in yielding information on the beta interactions. The first sign of warning against the (S,T) combination in beta interaction came in May of 1957 when Herrmannsfeldt *et al.*[30] published their $(\beta\text{-}\nu)$ correlation results on A^{35}, which decays mainly through Fermi interaction, and the results strongly supported the vector interaction instead of scalar as was once believed.

Recently,[31] this group has remeasured the $(\beta\text{-}\nu)$ correlation in He^6 with the same apparatus and obtained the correlation coefficient $\lambda=-0.39\pm0.02$, which certainly favors axial vector in He^6.

Meantime the $\beta\text{-}\nu$ angular correlation in

$$Li^8 \xrightarrow{\beta} Be^8 \longrightarrow 2\alpha$$

was reinvestigated with greatly improved technique at California Institute of Technology[32] and at Heidelberg University.[33] They measured either the angular distribution of the two α particles or the α spectra in coincidence with the β particles emitted at either 180° or 90° from the α direction. The results from Heidelberg strongly favor the axial vector, and the California Institute of Technology results are accurate enough to put the upper limit of tensor mixture in G-T interaction to less than 10%.

Thus the (V,A) combination is strongly favored from $(\beta\text{-}\nu)$ correlation experiments. Let us now look into the information on beta interactions obtained from parity experiments.

II. From Parity Experiments

(A) *Electron Capture Process in* Eu^{152*} [34]

In an electron capture process, a neutrino and the recoil nucleus are emitted in opposite directions $e^- + p \rightarrow n + \nu$. If the capture process is followed by the emission of a gamma ray and the spin and parity changes are favorable as shown in the following decay process

$$A(0^-) \xrightarrow{e^- \text{ capture}} B^*(1^-) \xrightarrow{\gamma \text{ ray}} B(0^+)$$

then, by applying the conservation laws of momentum and angular momentum, one can deduce a simple correlation that the helicity of the downward gamma ray will be the same as that of the upward neutrino. So the problem of determining the neutrino helicity becomes that of measuring the circular polarization of the gamma ray. However, to select only those downward gamma rays following the emission of the upward neutrinos, many conditions must be fulfilled. First, the gamma ray must have an energy comparable to that of the neutrino and the lifetime of the excited level B^* must be very short ($\sim 10^{-14}$ sec) in order to permit the use of solid material. Even then one has to detect only the resonantly scattered gamma ray.

The requirements were indeed strict, but the radioisotope Eu^{152*} seemed heaven-sent to do this job. Goldhaber, Grodzins, and Sunyar knew of this radioisotope Eu^{152*} from their previous investigations and it fulfills all the requirements stated above. By measuring the circular polarization of the gamma rays from Eu^{152*} which are resonantly scattered by Sm, they found that the helicity of the gamma ray is *negative*! ($H=-0.67\pm0.10$). From this result one concludes that the helicity of the neutrino in electron capture is negative and therefore the Gamow-Teller interaction in electron capture is dominantly "A" and not "T."

(B) *Beta Decay of Polarized Neutrons*[35]

Meanwhile, at the Argonne National Laboratory, a highly polarized neutron beam had been successfully completed since 1957. Burgy *et al.*[35] had been measuring two asymmetry coefficients from the beta decays of polarized neutrons. One is the coefficient "A," the β^- distribution asymmetry ($\langle J\rangle \cdot p_{e^-}$); the other is the coefficient "B," the $\langle\nu\rangle$ distribution asymmetry ($\langle J\rangle \cdot p_{\langle\nu\rangle}$). From the value $A=-0.11\pm0.02$ and $B=0.88\pm0.15$, they concluded that the interaction in β^- decay is dominantly V and A with opposite phase relations $(V-A)$.

Look back at the history of the theory of beta decay. It has been filled with surprises and excitement. Now, after a period of nearly sixty years of continuous investigation, finally along comes the nonconservation of parity. These two (classical beta theory and nonconservation of parity) joined forces in reaching the conclusion on the beta interaction.

However, we must be cautioned here that whether there is any small mixture of (S,T) in beta interaction is still unknown and is waiting to be proved.

III. Universal Fermi Interaction

The great similarity in the strength of the coupling constants in beta decay, μ decay and μ capture suggests that the interaction forms of the three decay processes may also be the same. When beta-decay coupling was concluded to be (S,T) and μ-decay coupling was deduced to be dominantly V and A from the negative sign of the asymmetry coefficient, this possibility of a universal Fermi interaction was naturally ruled out. Now that the interaction (V,A) has replaced (S,T) in beta decay, the situation is quite altered. This is particularly intriguing because this specific form of (V and A) has been prophesied independently by Marshak and Sudershan[36] and also by Feynmann and Gell-Mann[37] by different deductions. The interactions which are responsible for the muon capture process are now under intensive investigation.

CONCLUSION

We have come a long way since the overthrow of the law of parity in weak interactions. A great advance has been made in the theory of the neutrino. We have two-component neutrinos and the law of conservation of leptons. A vast amount of experimental data is accounted for by the $V-A$ theory, and therefore the idea of the universal $(V-A)$ Fermi interaction is again made acceptable.

However, there are still many questions unanswered. Is there any connection between the beta interactions and the gravitational forces? Why should the ratio of the coupling constants between G-T and Fermi interactions $|C_{GT}/C_F|^2$ be what was observed? Are there any possible theoretical explanations for this? The ratio of $|C_{GT}/C_F|^2$ calculated from the recent neutron half-life[38] of (11.7±0.3) min and the O^{14} ft value[39] is 1.42±0.08. The ratio of $|C_{GT}/C_F|^2$ from the asymmetry distribution of electrons from polarized neutrons is 1.56±0.14.[35] On the other hand, the ratio of $|C_{GT}/C_F|^2$ obtained from the analysis of the ft values of beta decays of mirror nuclei by the "B-X" diagram is only 1.16±0.05.[40] The last method relies largely on the evaluation of the matrix elements. Would this apparent discrepancy eventually show us a way to improve our evaluation of the matrix elements? We are all eagerly anticipating hearing many interesting discussions on these subjects at this conference.

Determination of the Beta-Decay Interaction from Electron-Neutrino Angular Correlation Experiments

JAMES S. ALLEN

Department of Physics, University of Illinois, Urbana, Illinois

INTRODUCTION

EXPERIMENTAL determination of the specific form of the interactions responsible for nuclear beta decay has remained a critical problem ever since the original formulation of the theory by Fermi.[1] Bloch and Moller[2] probably were the first to point out that the electron-neutrino angular correlation in nuclear beta decay depends on the type of light-particle-neutron interaction assumed in the Fermi theory. According to present ideas, a linear combination of five relativistically invariant expressions can be chosen for the interaction Hamiltonian. The individual interactions are the scalar, vector, tensor, axial-vector, and pseudoscalar interactions, denoted respectively S, V, T, A, and P. In the case of allowed transitions, the pseudoscalr interaction usually is small compared to the other forms and can be omitted.

During the past ten years we have been conducting a series of electron-neutrino angular correlation experiments on allowed beta decays in an attempt to obtain an unambiguous determination of the form of the beta-decay interaction. In general, these experiments have tended toward a procedure which requires only a direct measurement of the shape of the energy spectrum of the recoiling nuclei. This method has eliminated the difficulties inherent in the experiments which require an explicit measurement of either the angle between the electron and recoiling nucleus or the energy of the electron. Our present method does not require the detection of the recoiling nucleus and the decay electron in coincidence and, consequently, the counting rate is not limited by a decreasing true to chance rate.

This program finally has been completed with a series of measurements of the angular correlations in the allowed beta decay of He^6, Ne^{19}, Ne^{23} and A^{35}. Since the entire set of measurements was carried out in one spectrometer, the experimental results may be compared directly. The results prove that the dominant interactions are, vector for the Fermi type of decay, and axial-vector for the Gamow-Teller decays.

THEORY

In the usual theory of allowed beta decay the transition probability for the emission of an electron-neutrino pair is

$$P(W,\theta_{ev})\mp dW d\Omega_e=\frac{1}{(2\pi)^4}F(\pm Z,W)pW(W_0-W)^2\xi \times\left[1+\frac{b}{W}+\frac{\lambda p}{W}\cos\theta_{ev}\right]dW d\Omega_e, \quad (1)$$

where W and p, respectively, are the total energy and momentum of the electron. The angular correlation coefficient, expressed in terms of the coupling constants and nuclear matrix elements, is

$$\lambda\xi=(|C_V|^2+|C_V'|^2-|C_S|^2-|C_S'|^2)|\langle 1\rangle|^2 +\tfrac{1}{3}(|C_T|^2+|C_T'|^2-|C_A|^2-|C_A'|^2)|\langle\sigma\rangle|^2, \quad (2)$$

where

$$\xi=(|C_V|^2+|C_V'|^2+|C_S|^2+|C_S'|^2)|\langle 1\rangle|^2 +(|C_T|^2+|C_T'|^2+|C_A|^2+|C_A'|^2)|\langle\sigma\rangle|^2. \quad (3)$$

There is also a small additional term in λ which vanishes if time reversal is invariant. This term also is identically zero with the current choice of coupling constants, $C_{VA}=+C_{V'A'}$ and $C_{TS}=-C_{T'S'}$. It is interesting to note that the Fierz interference term b/W also is identically zero with this choice of coupling constants.

It is readily seen from (2) that λ assumes the values $+1$, -1, $+\frac{1}{3}$, and $-\frac{1}{3}$ for the pure V, S, T, and A interactions, respectively. Also, λ does not contain terms due to interference between the parity conserving and parity nonconserving interactions. Therefore, electron-neutrino angular correlation experiments of the type discussed here are not able to separate the primed and unprimed coupling constants. In other words, these experiments cannot show the degree of mixing of the parity conserving and nonconserving interactions.

The energy distribution function for the decay electrons is obtained by integrating $\cos\theta_{ev}$ in (1) over all values of θ_{ev}. Since $\cos\theta_{ev}$ is an odd function of the angle, the integral is zero and consequently the shape of the energy spectrum does not depend on λ. However, when the distribution in energy of the recoiling nuclei is measured, the integration is over values of θ_{ev} consistent with conservation of energy and linear momentum in the emission of the electron-neutrino pair. In this case the term containing λ does not vanish and therefore the shape of the energy spectrum depends on the form of the angular correlation.

In our most recent experiments we have measured

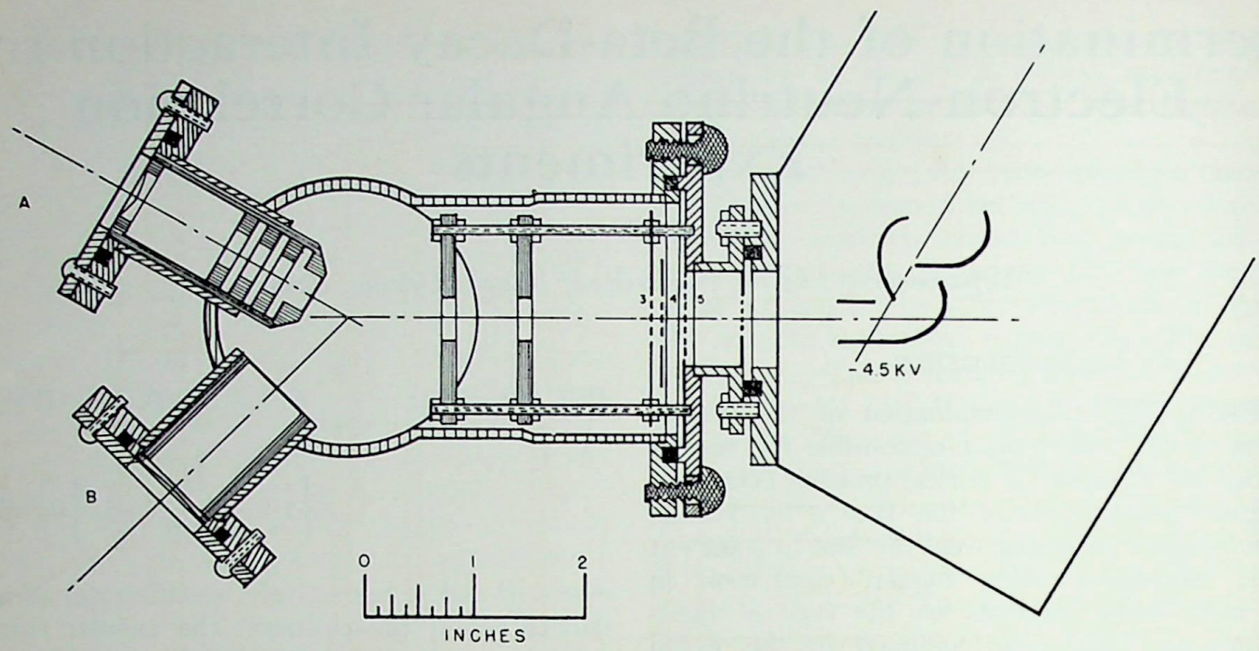

FIG. 1. The apparatus used for the first He^6 neutrino experiment. The recoil ions were counted by the electron multiplier and the electrons by a Geiger counter at window A or B. The energy spectrum of the recoil ions was measured by the retarding potential method.

the shape of the energy spectra of the recoiling nuclei and have deduced values of λ from comparisons of the experimental data with the theoretical distribution functions. The experimentally determined angular correlations have established the form of the dominant beta-decay interaction.

EARLY RECOIL EXPERIMENTS

The beta decay of He^6 can be represented by

$$He^6 \rightarrow Li^6 + e^- + \bar{\nu}, \quad \log ft = 2.91, \qquad (4)$$

with a spin change of $J=0$ to $J=1$, no change of nuclear parity. The maximum kinetic energy of the recoiling Li^6 ion is 1405 ev. The beta-decay process produces a singly charged positive ion. However, in about 10% of the decays, doubly charged ions are present as a result of ionization caused by the sudden change in the nuclear charge. The small value of ft indicates that the He^6 transition is allowed, and the spin change shows that this is a pure Gamow-Teller transition. The angular correlation factor will be either $+\frac{1}{3}$ for the tensor or $-\frac{1}{3}$ for the axial-vector interaction.

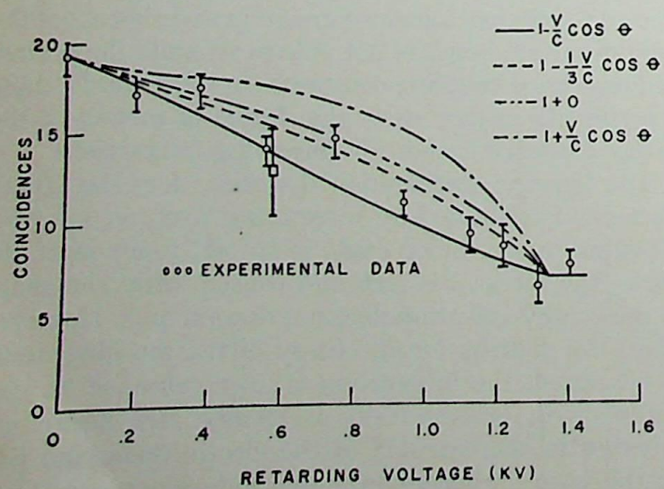

FIG. 2. Experimental and theoretical retarding potential curves for the recoil ions from the decay of He^6. The angle between the direction of emission of the electrons and the recoil ions was $162° \pm 8°$.

The first He^6 experiment was carried out by Allen, Paneth, and Morrish.[3] An attempt was made to obtain the recoil energy spectrum of the ions in coincidence with electrons emitted at angles of 135° and 162° with respect to the direction of the ions. A schematic of the apparatus is shown in Fig. 1. A retarding potential method was used for the analysis of the kinetic energy of the ions. The retarding voltage was applied to grid 4 located between the grounded grids 3 and 5.

The experimental data obtained with the Geiger counter at position A are shown in Fig. 2. Although the statistical accuracy is poor, most of the experimental points lie below the $\lambda=0$ curve and therefore suggest the axial-vector interaction.

The next experiment in our series represented an attempt to study the He^6 decay using a scintillation counter instead of a Geiger counter. A schematic diagram of the apparatus is shown in Fig. 3. The effective source volume was cylindrical in shape and was defined at one end by the scintillator and at the other end by the sliding gate A. This gate had an open and also a closed aperture. An aluminum foil covering the closed aperture was thick enough to stop the recoil ions, but also sufficiently thin to transmit the decay electrons without appreciable scattering or loss of energy. The difference between the counting rates observed with the gate open and closed represents the net rate produced by disintegrations occurring in the

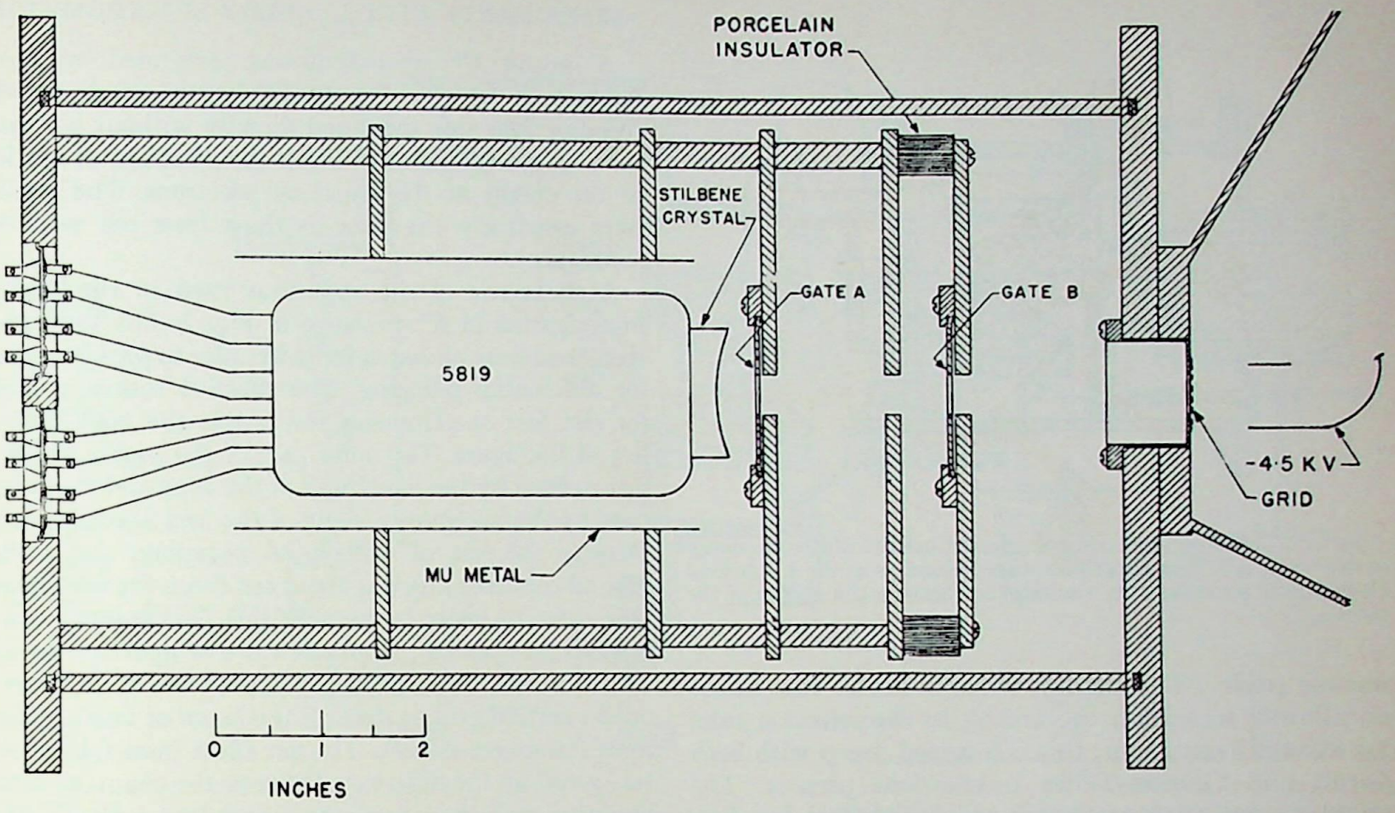

FIG. 3. The apparatus used for the second He^6 neutrino experiment. The effective source volume was cylindrical in shape and was defined at one end by the curved surface of the stillbene crystal and at the other end by the gate A. The velocity spectrum of the recoil ions was measured by the time-of-flight method. The sliding gate B supported an alpha-particle source used for testing the two detectors.

region between the gate and the scintillator. The experimentally determined time-of-flight spectrum is represented by the histogram of Fig. 4. In contrast to the results of our first He^6 experiment, the new data appeared to agree with the tensor rather than the axial-vector curve.

The results of the experiment of Rustad and Ruby[4] became available before the completion of our second He^6 experiment. These authors measured the electron-neutrino angular correlation in the decay of He^6 and their results clearly indicated that the interaction was tensor. Since the statistical accuracy of this experiment was much higher than that obtainable with our method, we decided to give up our work on He^6 and to concentrate our efforts on other allowed decays.

EXPERIMENTS WITH A SINGLE ELECTROSTATIC SPECTROMETER

A recoil apparatus with improved energy resolution and transmission designed by Maxson and Allen[5] is shown in Fig. 5. The disintegration electrons were detected in a hemispherical plastic scintillator and a spherical electrostatic spectrometer was used to measure the energy of the recoils. The front surface of the source volume was defined, as in our previous experiments, by means of a sliding gate. This single spectrometer was used in our studies of Ne^{19} and A^{35}.

Ne^{19} is a positron emitter which decays according to the scheme

$$Ne^{19} \rightarrow F^{19} + e^+ + \nu, \quad \log ft = 3.27, \tag{5}$$

with a spin change of $J=\frac{1}{2}$ to $J=\frac{1}{2}$, no change in

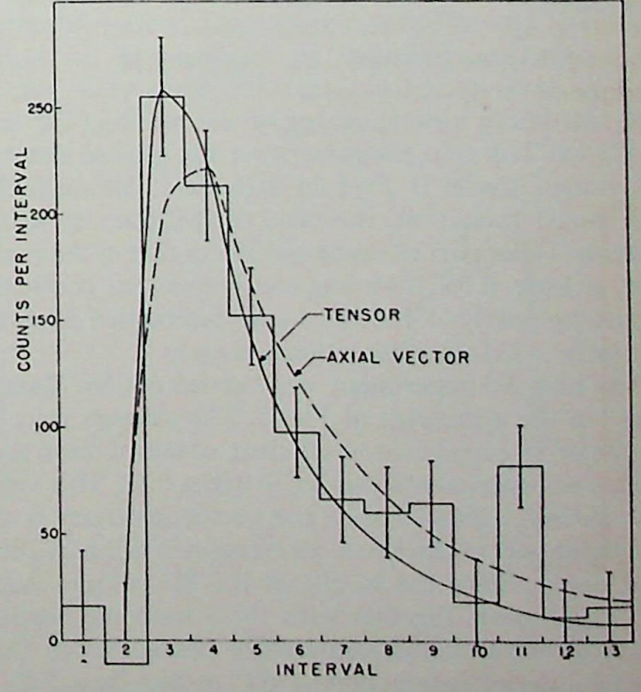

FIG. 4. The time-of-flight spectrum of the recoil ions from the decay of He^6. The angle between the directions of emission of the ions and the electrons varied from about 100° to 180°.

[4] B. M. Rustad and S. L. Ruby, Phys. Rev. **97**, 991 (1955).

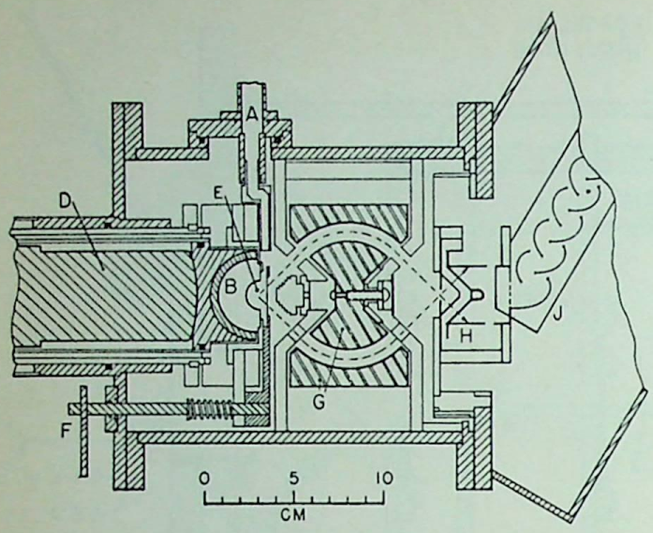

FIG. 5. The experimental arrangement used to study the decay of Ne^{19} and A^{35}. The effective source volume is at E. A spherical electrostatic spectrometer was used to measure the energy of the recoils.

nuclear parity. The small ft value indicates that this is an allowed transition. According to the selection rules for allowed transitions, this is a mixed decay with both Fermi and Gamow-Teller interactions present. The angular correlation coefficient computed from ft values is approximately -0.04 for the ST and $+0.04$ for the VA combination of interactions. The observed energy spectrum and several theoretical curves are shown in Fig. 6. A least squares fit of the theoretical curves to the experimental data yielded $\lambda=-0.21\pm0.08$, where the indicated error is statistical. This correlation was somewhat more negative than the value expected for the ST or VA interactions.

A^{35} is a positron emitter which decays according to the scheme

$$A^{35}\rightarrow Cl^{35}+e_{+}+\nu, \quad \log ft=3.79. \qquad (6)$$

The maximum kinetic energy of the recoiling Cl^{35} ions is 455 ev. The spin assignment for the ground states of the mirror nuclei is $J=\frac{3}{2}$ in each case. Although this is a mixed transition, the ratio of the intensity of the Gamow-Teller part of the transition to that of the Fermi part is only 0.05. The angular correlation coefficient should be nearly $+1$ if the Fermi interaction is vector or nearly -1 if the interaction is scalar.

The first A^{35} experiment was carried out by Maxson *et al.*[5] in the apparatus of Fig. 5. The average value of the angular correlation coefficient obtained from four groups of experiments was $\lambda=+0.85\pm0.12$. This value of λ clearly indicated that the vector invariant is the dominant part of the Fermi interaction in this particular beta decay. Since the results of the Rustad and Ruby He^{6} experiment, together with those from the neutron and Ne^{19} experiments, apparently demonstrated that the beta-decay interaction is ST rather than VT, a decision was made to repeat the A^{35} experiment with a new apparatus.

EXPERIMENTS WITH A DOUBLE SPECTROMETER

A second A^{35} experiment was performed by Herrmannsfeldt *et al.*[6] The energy distribution of the recoiling ions was measured directly without a simultaneous measurement of either the direction of motion or the energy of the associated electrons. The results were essentially the same as those from our first A^{35} experiment.

A schematic of the apparatus used in the second investigation of A^{35} is shown in Fig. 7. The two spectrometers were placed in series in order to provide space for differential pumping. The effective source volume for the first spectrometer was inside the cone at the left of the figure. The outer part of the source volume was defined by the metal wall of the cone and the inner part by the acceptance angle of the first spectrometer. Despite the use of differential pumping, the background counting rate was about ten times the maximum true rate. In order to measure this background, a set of grids was placed in front of the exit aperture of the source volume. A retarding potential could be placed on the second grid to shut off the beam of ions coming from the source volume. The net effect from the source was given by the difference between the counting rates observed with the retarding potential on and off. The intensity of the source was monitored by a scintillation counter viewing part of the source volume.

The experimental points and the theoretical recoil energy distributions for the decay of A^{35} are shown in Fig. 8. The experimental points correspond to an angular correlation factor of $\lambda=+0.97\pm0.14$ which is in excellent agreement with the value of $+0.98\pm0.08$ predicted for the AV interaction or the value of $+0.99\pm0.04$ expected for the TV interaction. In each case the predicted values of the angular correlation coefficient have been deduced from known ft values.

Since the results of our second A^{35} experiment con-

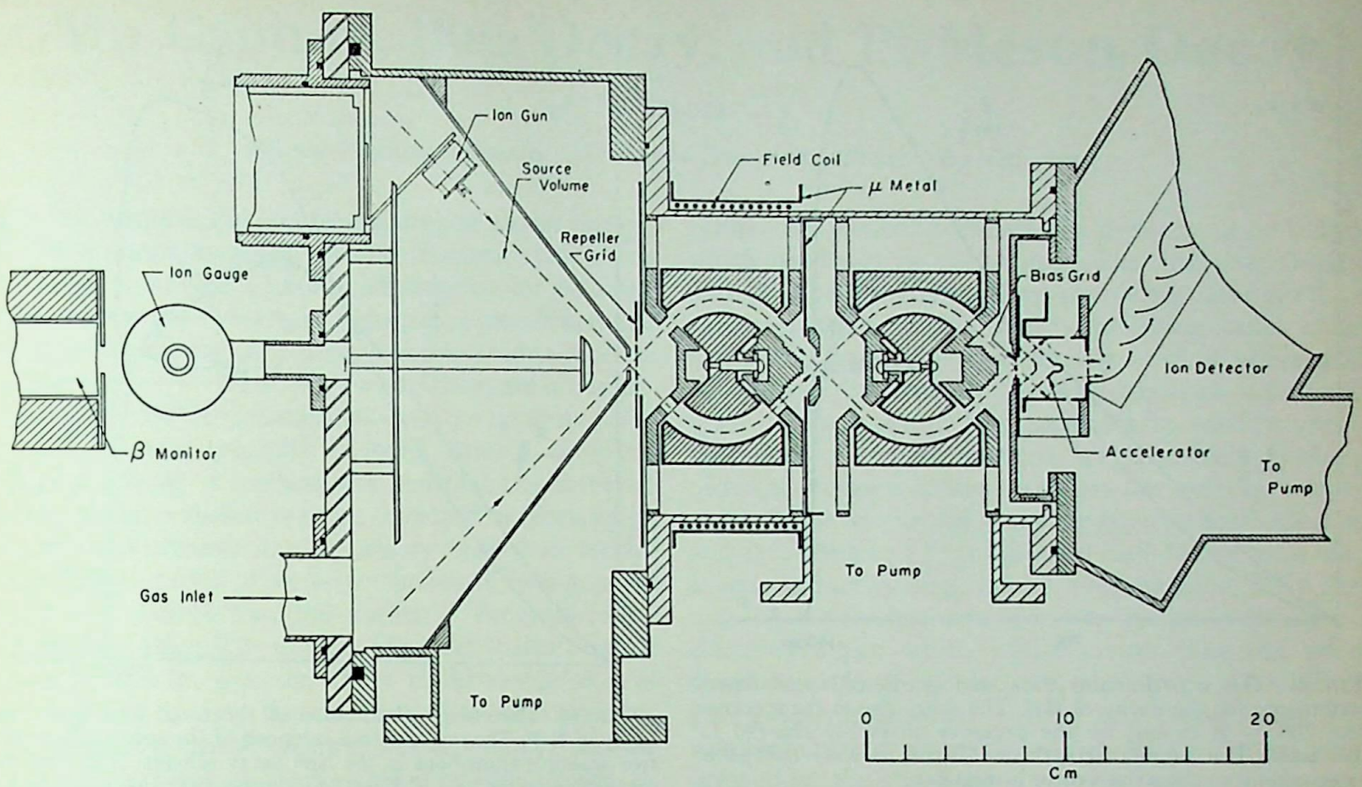

FIG. 7. A schematic of the double spectrometer used in the study of He^6, Ne^{19}, Ne^{23}, and A^{35}. The effective source volume is inside the cone at the left of the diagram. A retarding potential could be applied to a grid in front of the exit aperture of the source volume in order to separate the background from the true effect.

firmed those of the first, this was strong evidence for the VA interaction. Additional evidence for the axial-vector form appeared shortly after the completion of our second experiment. The most convincing evidence was supplied by Goldhaber *et al.*[7] who measured the helicity of the neutrino and found it to be left-handed. Their experiment clearly indicates that the Gamow-Teller interaction is axial-vector when it is supplemented by the information obtained from measurements of the longitudinal polarization of decay electrons. These developments suggested that a repetition of the He^6 experiment would be highly advisable.

A new He^6 experiment was carried out by Herrmannsfeldt *et al.*[8] using the double spectrometer of Fig. 7. The He^6 activity was produced through the $Be^9(n,\alpha)He^6$ reaction with fast neutrons inside the CP-5 reactor at the Argonne National Laboratory. The data from our latest He^6 experiment are shown in Fig. 9. The energy spectrum below one-half the maximum energy is distorted by the presence of doubly charged ions and cannot be used for a determination of λ. The angular correlation deduced from the data above 700 ev was $\lambda=-0.39\pm0.05$ corresponding to the axial-vector interaction.

This series of angular correlation experiments has been completed with a measurement of λ in the decay of Ne^{23}. This decay is complex with a 67% pure Gamow-Teller transition to the ground state of Na^{23} with $\Delta J=1$, no change of nuclear parity and a 32% transition to an excited state of Na^{23} with a probable spin change of $\Delta J=0$. Although this second transition is mixed, there are theoretical reasons for believing that the Fermi matrix element is very small. If this decay scheme is correct, the expected recoil energy spectrum should be a composite of two Gamow-Teller type spectra. Very weak transitions to higher levels of Na^{23}

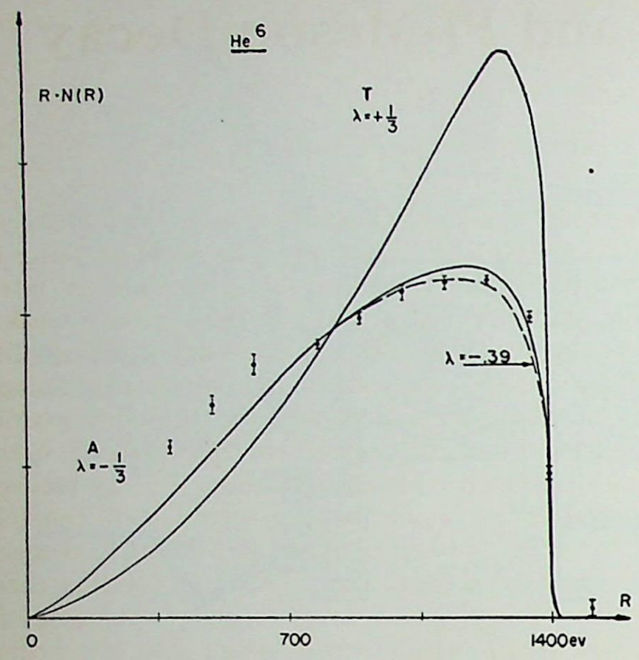

FIG. 9. The experimental data and predicted recoil energy distributions for the decay of He^6. The sharp rise in the spectrum below 700 ev is caused by the presence of doubly charged Li^6 recoil ions. The angular correlation factor is $\lambda=-0.39\pm0.05$ corresponding to the axial-vector interaction.

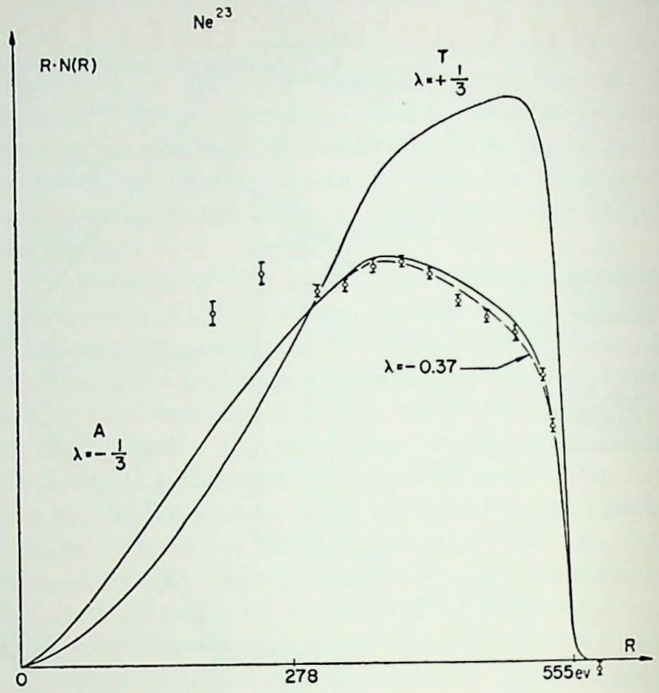

FIG. 10. The energy distribution of the recoil ions from the decay of Ne^{23}. The spectrum is a composit of the spectra from the two principle transitions in the Ne^{23} decay scheme. The angular correlation factor $\lambda=-0.37\pm0.04$ indicates that the axial-vector interaction is dominant in the Gamow-Teller type of decay.

can be neglected in the interpretation of this experiment. The measured spectrum is shown in Fig. 10. The angular correlation obtained from the upper one-half of the energy spectrum is $\lambda=-0.37\pm0.04$ where the indicated error is statistical.

The results of the Ne^{23} experiment can be interpreted in two different ways. If we assume that the $Ne^{23}-Na^{23}$ level scheme is correct, the experiment supplies additional evidence that the Gamow-Teller beta-decay interaction is axial-vector. The quoted uncertainty in the intensities of the two transitions[9] is sufficient to account for the observed deviation in λ from the value $-\frac{1}{3}$. Alternatively, we may consider the Gamow-Teller interaction to be predominantly axial-vector and in this case our experiment proves that the $Ne^{23}-Na^{23}$ level scheme is correct. Our results disagree with the value $\lambda=-0.05\pm0.10$ observed by Ridley.[10]

CONCLUSION

This series of experiments has removed most of the uncertainties concerning the nature of the beta-decay interaction which have been present for a number of years. We conclude that the dominant interaction form is *VA*. However, the present experiments do not exclude a possible tensor admixture of 10% or less. A scalar admixture of the same magnitude may also be present.

Mu Capture, Beta Decay, and Pi-Meson Decay

M. L. GOLDBERGER

Palmer Physical Laboratory, Princeton University, Princeton, New Jersey

IN the original Yukawa formulation of meson theory, the π meson (as we now believe Yukawa's particle to be) was to provide a natural explanation for β decay. The process $\pi \rightarrow e+\bar{\nu}$ was regarded as an elementary interaction and nuclear β decay was imagined to proceed by the route $n \rightarrow p+\pi \rightarrow \mu+e+\bar{\nu}$. There are a variety of reasons why this scheme fails. Just the opposite point of view is now generally adopted, namely, that the nuclear β decay is fundamental and that the observed decay of the π meson is to be explained in terms of it. We do not exclude the possibility that β decay be described in terms of an as yet unknown heavy intermediate. Nevertheless, the nuclear β decay is to be regarded as essentially primary. In order to describe the actual dominant π-meson decay mode $\pi \rightarrow \mu+\bar{\nu}$ it is necessary to assume the existence of another β decay like process, μ-meson capture. The elementary process may be described as $\mu+p \rightarrow n+\nu$, or equally well as $n+\bar{p} \rightarrow \mu+\bar{\nu}$; the first is the experimentally observed μ-meson absorption reaction, whereas, the second, the annihilation of a neutron and an antiproton, plays an important role in π-meson decay.

Since this is a conference on weak interactions, I shall not be able to say that one of the π mesons, the neutral one, decays into two gamma rays; electromagnetic interactions are too strong to be mentioned! Furthermore, I will not be able to point out that a theory of the π^0 decay can be given which is very similar to what we describe for charged pions.

During the past year or two the field of weak interactions has become a surprisingly orderly one. The two-component theory of the neutrino, as well as the principle of lepton conservation now both seem to be well established. Both nuclear β decay and μ-meson decay seem to be describable in terms of a vector (V) and axial vector (A) coupling. This statement has to be qualified somewhat in the case of nuclear β decay. There is the additional fact that in both β decay and μ decay the vector coupling constants are almost identical. Rather less is known of the coupling types for the μ-meson capture reaction, but the dominant couplings seem to have about the same strength as in β decay. This is discussed by Primakoff. We tentatively assume that the apparently universal (V,A) interaction extends also to this Fermi process.

Precisely what do we mean by a *universal* interaction? This can mean only that the basic interaction Lagrangian contains only these two coupling types. Given this basic definition let us see whether there is anything surprising in the observed decays. First, in μ decay the V and A couplings are forced to be equal if we adopt the two component neutrino theory. In β decay, $g_A = 1.25\ g_V$, which need not be disturbing. The amazing thing is, with β decay and μ capture involving strongly interacting particles and μ decay involving only weakly interacting ones, that there is any kind of universality whatsoever. One would expect the existence of pions and other strongly interacting particles to modify greatly the effective matrix element for transitions between physical nucleons as compared to the μ-decay process.

Insofar as the vector coupling is concerned, Gerstein and Zel'dorich and Feynman and Gell-Mann have made a very attractive suggestion: They propose that there may be a principle analogous to gauge invariance in electrodynamics which would insure that the vector coupling constant in β decay be the same even when the strong interactions are turned on. Recall that as a result of current conservation, or, if you prefer, gauge invariance, the charge of a bare and physical proton is the same. In order to achieve this goal the β decay "vector current density" $g_V\bar{\psi}\gamma_\mu\psi$ [ψ is a nucleon field operator] must be augmented by terms which ultimately couple leptons directly to pions, etc., and such that the total "current density" $j_\mu{}^V$ satisfies $\partial j_\mu{}^V/\partial x_\mu$. The difference between vector and axial vector couplings in β decay is attributed to renormalization of the axial vector interaction.

One troublesome point in connection with this proposal has been raised by Wightman, Telegdi, and Michel. When one computes the electromagnetic radiative corrections for μ decay and β decay, one finds that to lowest order in all couplings not a finite correction for μ decay, but a logarithmic divergence in β decay. One may argue that if the nucleons are "dressed" properly and the radiative corrections are then computed (something no one knows how to do exactly) the result will be convergent. Nevertheless, it is not clear why, even if the β-decay effect is made finite, the two radiatively-corrected vector coupling constants should continue to be equal.

Let us discuss in a systematic way the role of strong interactions in Fermi processes. The work to be reviewed was carried out by Treiman and me and has been, for the most part, published elsewhere. I apologize for this, but in order to talk about something new, I would have to make an obviously wrong new theory—the correct one already having been given.

We suppose that β decay and μ capture are described by the Lagrangian density,

$$\mathcal{L}_I = Z_2 f_A \bar{\psi}_\nu(1-\gamma_5) i\gamma_\lambda\gamma_5\psi_1(\psi_n i\gamma_\lambda\gamma_5\psi_p) + Z_2 f_V \bar{\psi}_\nu(1-\gamma_5)\gamma_\lambda\psi_1(\bar{\psi}_n\gamma_\lambda\psi_p) + \text{Hermitian conjugate}, \quad (1)$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

where f_A and f_V are the unrenormalized coupling constants, and Z_2 is the nucleon wave-function renormalization constant. The ψ's are field operators associated with the particles indicated by the subscripts; l stands for either an electron or a μ meson. There may be other interactions of leptons. Among these are the direct pion couplings of Feynman and Gell-Mann, or perhaps couplings to baryons other than nucleons. For the time being we do not consider such possibilities. We consider the processes $(e,\mu)+p\rightarrow n+\nu$. To lowest order in the weak interaction, the matrix element computed from (1) is given by

$$S=i(2\pi)^4\delta(n+p_\nu-p-p_l)M, \tag{2}$$

where n, p_ν, p, p_l are the four-momenta of the neutron, neutrino proton, and electron (or μ meson), and

$$M=\bar{u}_\nu(1-\gamma_5)i\gamma_\lambda\gamma_5 u_l\langle n|P_\lambda|p\rangle + \bar{u}_\nu(1-\gamma_5)\gamma_\lambda u_l\langle n|V_\lambda|p\rangle \tag{3}$$

$|n\rangle$ and $|p\rangle$ represent physical neutron and proton states and

$$P_\lambda=Z_2 f_A\bar{\psi}_n i\gamma_\lambda\gamma_5\psi_p, \quad V_\lambda=Z_2 f_V\bar{\psi}_n\gamma_\lambda\psi_p. \tag{4}$$

The lepton spinors have been normalized according to $\bar{u}_l\gamma_4 u_l=\bar{u}_\nu\gamma_4 u_\nu=1$.

In the Feynman-Gell-Mann theory, V_λ would have additional terms. We do not use the explicit forms of V_λ and P_λ.

The general forms of the matrix elements of P_λ, V_λ required for Eq. (3) may be deduced from invariance principles, and they are

$$\langle n|P_\lambda|p\rangle=\left(\frac{m^2}{n_0p_0}\right)^{\frac{1}{2}}\bar{u}(n)\{ai\gamma_\lambda\gamma_5-b(p-n)_\lambda\gamma_5\}u(p), \tag{5}$$

$$\langle n|V_\lambda|p\rangle=\left(\frac{m^2}{n_0p_0}\right)^{\frac{1}{2}}\bar{u}(n)\{c\gamma_\lambda-d\sigma_{\lambda\mu}(p-n)_\mu\}u(p). \tag{6}$$

In these formulas, m is the nucleon mass, and the spinors are normalized according to $\bar{u}u=1$. The fact that only the momentum combination $p-n$ appears above is a consequence of charge symmetry and time reversal invariance in the strong interactions. Finally, the coefficients a, b, c, and d are functions of $(n-p)^2$, the momentum transfer squared.

Substituting these matrix elements in Eq. (3) and using the Dirac equation for the leptons we find for M the result

$$M=\left(\frac{m^2}{p_0n_0}\right)^{\frac{1}{2}}\{a\bar{u}_\nu(1-\gamma_5)i\gamma_\nu\gamma_5 u_l\bar{u}_n i\gamma_\lambda\gamma_5 u_p + m_1b\bar{u}_\nu(1-\gamma_5)\gamma_5 u_l\bar{u}_n\gamma_5 u_p+c\bar{u}_\nu(1-\gamma_5)\gamma_\lambda u_l\bar{u}_n\gamma_\lambda u_p + d\bar{u}_\nu(1-\gamma_5)\gamma_\lambda(p_l-p_\nu)_\mu u_l\bar{u}_n\sigma_{\lambda\mu}u_p\}.$$

The first and third terms are in the form of the usual axial vector and vector interactions. The functions $a[(n-p)^2]$ and $c[(n-p)^2]$ are, for zero value of the momentum transfer, simply the coupling constants g_A and g_V of β decay. In μ capture $(n-p)^2\sim m_\mu^2$ but a and c do not deviate much from g_A and g_V over such an interval. The second term has the form of a conventional pseudoscalar interaction with an effective coupling constant m_lb. Barring strong dependence of b on momentum transfer, this term is relatively much less important in β decay than in μ capture. The last term is identical with what has been called weak magnetism by Gell-Mann and is present whether or not the conserved vector current of Feynman and Gell-Mann is assumed. The magnitude of d depends critically, however, on this assumption.

This is as far as one can go on more or less general grounds. What we have done is to study the four functions a, b, c, and d by dispersion techniques. It is not practical to discuss this investigation in detail, so we outline the elements that go into such a treatment and quote the relevant results. We wish to represent the functions in the following form:

$$a(\xi)=g_A-\frac{\xi}{\pi}\int_{(3m_\pi)^2}^{\infty}d\xi'\frac{\mathrm{Im}a(-\xi')}{\xi'(\xi'+\xi-i\epsilon)},$$

$$b(\xi)=\frac{1}{\pi}\int_{m_\pi^2}^{\infty}d\xi'\frac{\mathrm{Im}b(-\xi')}{\xi'+\xi-i\epsilon},$$

$$c(\xi)=g-\frac{\xi}{\pi}\int_{(2m_\pi)^2}^{\infty}d\xi'\frac{\mathrm{Im}c(-\xi')}{\xi'(\xi'+\xi-i\epsilon)},$$

$$d(\xi)=\frac{1}{\pi}\int_{(2m_\pi)^2}^{\infty}d\xi'\frac{\mathrm{Im}d(-\xi')}{\xi'+\xi-i\epsilon}.$$

We have written the dispersion relations explicitly in such a way that $a(0)=g_A$, $c(0)=g_V$ and make essentially no effort to relate the renormalized coupling constants g_A, g_V to the unrenormalized ones appearing in the original Lagrangian. The quantities Ima, etc., represent the imaginary parts of the various amplitudes (which are real for positive arguments) and these may be expressed in terms of the amplitudes for certain real physical processes.

Consider first the vertex $\langle n|P_\lambda|p\rangle$; it is slightly more convenient to study $\langle 0|P_\lambda|\bar{n}p,in\rangle$ which is related to our other amplitude according to

$$\left(\frac{p_0\bar{n}_0}{m^2}\right)^{\frac{1}{2}}\langle 0|P_\lambda|n,\bar{p},in\rangle=\bar{v}_{\bar{n}}[ai\gamma_\lambda\gamma_5-b(p+\bar{n})_\lambda\gamma_5]u(p),$$

where $v_{\bar{n}}$ is a negative energy spinor and a is now a function of $(p+\bar{n})^2$. This matrix element may be imagined as describing the annihilation of a proton-antineutron pair to produce leptons via the interaction P_λ. The dependence on the lepton variables may be factored out so that they no longer appear explicitly. The sort of things that can contribute to this matrix element are shown in Fig. 1.

CC-0. Panjab University Chandigarh. Digitized by eGangotri University Haridwar Collection. Digitized by S3 Foundation USA

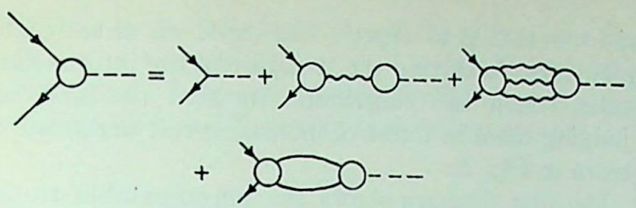

FIG. 1. The structure of the pseudoscalar matrix element $\langle 0|P_\lambda|n\bar{p}\rangle$ is pictured: The first "term" is effectively the bare interaction, the second shows a virtual transition to a π meson which decays into leptons, the third shows the reaction passing through a three pion state, and finally we have nucleon-antinucleon scattering followed by lepton emission.

The first element is essentially the bare interaction; in the second the pair annihilates to form a pion which then undergoes $\pi-\mu$ decay; the third diagram shows the pair annihilating into three pions, which ultimately combine to yield the lepton pair; the fourth diagram shows the pair undergoing a scattering interaction before annihilating to produce the leptons by the very matrix element we are studying. We are, thus, generating an integral equation. Needless to say, there are an infinite number of diagrams which we have not shown; we cannot even compute all of the ones we have. The intermediate state involving three pions is too hard for us to handle, but the remaining three are manageable and the integral equation for a and b can be easily solved.

The resulting solutions involve the ${}^3P_1$ and ${}^1S_0$ complex phase shifts for proton-antineutron scattering, the renormalized strong pion-nucleon coupling constant (G), the renormalized β-constant $[g_A=a(0)]$ and the experimental $\pi\rightarrow\mu+\nu$ lifetime. The latter enters via the one pion intermediate state which contributes only to the effective pseudoscalar interaction b. We find

$$a(\xi)=g_A\exp\left\{-\frac{\xi}{\pi}\int_{4m^2}^{\infty}dy\frac{\phi_1(y)}{y(y+\xi-i\epsilon)}\right\},$$

$$a-\frac{\xi}{2m}b=\left[g_A+\frac{\xi}{\xi+m_\pi{}^2}\frac{\sqrt{2}GF(-m_\pi{}^2)}{2m}\times\exp\left\{-\frac{m_\pi{}^2}{\pi}\int_{4m^2}^{\infty}dy\frac{\phi_0(y)}{y(y-m_\pi{}^2)}\right\}\right]\times\exp\left\{-\frac{\xi}{\pi}\int_{4m^2}^{\infty}dy\frac{\phi_0(y)}{y(y+\xi-i\epsilon)}\right\},$$

where $F(-m_\pi{}^2)$ may be related to the $\pi-\mu$ lifetime; ϕ_0 and ϕ_1 are related to the ${}^1S_0$ and ${}^3P_1$ phase shifts δ_0, δ_1 according to

$$\tan\phi=\frac{\mathrm{Re}e^{i\delta}\sin\delta}{1-\mathrm{Im}e^{i\delta}\sin\delta}.$$

We find, using the experimental value of the $\pi-\mu$ lifetime, $F=-0.115(\sqrt{2}Gmg_A/2\pi^2)$. Using this value and neglecting the contributions from the proton-antineutron scattering (i.e., set $\phi_0=\phi_1=0$) we find "g_p"$=m_\mu b(m_\mu{}^2)\approx 8g_A$ as the effective pseudoscalar coupling constant that would be effective in μ capture. The deviations of a from the value at $\xi=0$ are of order $m_\mu{}^2/m^2$; of course, the three pion intermediate state could cause slightly larger corrections but one would expect that for β decay or μ capture the leading terms

$$a\approx g_A,$$

$$b\approx-\frac{\sqrt{2}GF(-m_\pi{}^2)}{\xi+m_\pi{}^2},$$

are certainly adequate. In π decay, one needs a and b for values of $-\xi>4m^2$ in which case the neglect of the many less massive states (such as 3, $5\cdots$pions) could be much more serious. It is our feeling that since the leptons are coupled directly only to the nucleon pairs (or perhaps more generally to other baryon pairs) that such pair states are more important than the lighter pion states.

The effective vector interaction matrix element may be analyzed in a manner quite similar to our treatment of $\langle 0|P_\lambda|\bar{n}p,in\rangle$. We do not go into the analysis in much detail since the vector interaction plays no role in π decay. The matrix element $\langle 0|V_\lambda|\bar{n}p,in\rangle$ is identical in form to that encountered in the study of the electromagnetic structure of nucleons. If we follow Feynman and Gell-Mann we see that this parallel is essentially exact. As in the electromagnetic problem, the two-pion intermediate state is expected to play a dominant role for the relatively small values of $(\bar{n}+p)^2$, namely, about $m_\mu{}^2$ encountered in μ capture. In order to evaluate the two-pion contribution, we must know the matrix element for pair annihilation into two pions (even when the total energy extends into the unphysical region of total energy W, $4m^2>W^2>4\mu^2$) and also that for the pions to annihilate into a lepton pair. The latter process may also be analyzed by dispersion methods and we have done so in a rather crude fashion. For its evaluation one requires the matrix element for production of a proton-antineutron pair by two pions; the pair then annihilates via the original matrix element $\langle 0|V_\lambda|\bar{n}p,in\rangle$ (strictly speaking, there is a two pion intermediate state also which we neglect). We approximated all the matrix elements encountered in the problem by lowest order perturbation theory and found

$$c(\xi)=g_V\left[1+\frac{4}{9\pi}\frac{f^2}{4\pi}(0.24)\frac{\xi}{m_\pi{}^2}\right],$$

$$d(\xi)=1.7\frac{g_V}{2m}\times\frac{16}{3\pi}\frac{f^2}{4\pi}\left[1-\frac{0.12}{6}\frac{\xi}{m_\pi{}^2}\right],$$

where $f^2/4\pi=0.08$ is the effective pseudovector coupling constant of pion physics.

Adopting the Feynman—Gell-Mann theory, then, at least as far as the static terms (i.e., $\xi=0$) are concerned,

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

FIG. 2. Dispersion theoretic diagrams for π decay. The first shows a transition to an intermediate state with three pions, which we neglect; the second shows the usually contemplated transition through a nucleon-antinucleon pair.

the calculation can be carried out exactly. In their theory there is a complete analogy with the electromagnetic problem (except for slight numerical isotopic spin factors) so that we have without calculation,

$$c(0)\equiv g_V,$$
$$d(0)=(\mu_p-\mu_N)g_V/2m,$$

where μ_p, μ_N are the anomalous moments of proton and neutron in units of nucleon magnetons. Thus there is a clear-cut difference between the prediction of $d(0)$ made by the Feynman—Gell-Mann theory and the conventional theory: The value of d is about fifteen times larger in their case, and raises it out of the undetectable range.

An experiment to test the correctness of the Feynman—Gell-Mann proposal for conserved vector currents has been proposed by Gell-Mann. It is possible that the magnetic moment term, d, as well as the induced pseudoscalar interaction, b, may be detectable in certain μ-capture effects as discussed by Primakoff.

We turn now to a discussion of the decay of the π meson. It is some relief to be able to say that only the mode $\pi^-\to\mu^-+\bar{\nu}$ need be discussed. The correct branching ratio for the channel $\pi^-\to e^-+\bar{\nu}$ presumably then follows from our basic Lagrangian containing only vector and axial vector couplings. It is easy to see that the axial vector coupling alone plays any role in π decay. The leptons are assumed to emerge from a point (in the sense of an arbitrary Feynman diagram); hence there is only one momentum vector in the problem, say that of the pion, p_π. The pion is presumably a pseudoscalar and thus it is impossible to construct anything other than a pseudoscalar or a pseudovector to be coupled to the leptons. Formally, the S-matrix element for the transition is proportional to Λ where

$$\Lambda=\bar{u}(p_\mu)i\gamma_\lambda\gamma_5(1+\gamma_5)u(p_\nu)\langle 0|P_\lambda|\pi\rangle + \bar{u}(p_\mu)\gamma_\lambda(1+\gamma_5)u(p_\nu)\langle 0|V_\lambda|\pi\rangle$$

and the second term vanishes if one assumes parity is conserved in the strong interactions.

We concentrate attention, therefore, on $\langle 0|P_\lambda|\pi\rangle$ which we write as

$$\langle 0|P_\lambda|\pi\rangle=-i(p_\pi)_\lambda F(p_\pi{}^2)/(2p_{\pi 0})^{\frac{1}{2}}.$$

We can easily show that $F(p_\pi{}^2)$ satisfies a dispersion relation of the form

$$F(\xi)=\frac{1}{\pi}\int d\xi'\frac{\mathrm{Im}F(-\xi')}{\xi'+\xi-i\epsilon},$$

and our task is to express $\mathrm{Im}F$ in terms of calculable quantities. Analyzing the structure of the intermediate states which can contribute, we find the first few (judging them in terms of increasing rest mass) are as shown in Fig. 2.

The first diagram shows the uncomputable transition from one to three pions which ultimately combine to yield the leptons. There should then come states with 5, 7, $\cdots$ pions, perhaps followed by zero strangeness states involving K mesons and pions. Finally, one comes to the neutron-antiproton state. There are three reasons for concentrating attention on this state: (1) it is the one conventionally envisaged in a qualitative discussion of π-decay; (2) the leptons are directly coupled to nucleons, hence, such states might be expected to be of great importance; and (3) we can do quite a reasonable job of evaluating its contribution (and cannot calculate any of the others).

The individual pieces of our diagram are also treated by dispersion methods. We have already discussed the weak vertex in detail and so we now concentrate on the strong one, describing the virtual dissociation of the pion into a neutron-antiproton pair. In Fig. 3 the first diagram shows the "bare" interaction, the second, a three-pion state which by this time we neglect quite automatically, and, finally, the one we retain, namely, that involving a neutron-antiproton pair. This pair (in the rest system of the pion) is in a ${}^1S_0$ state (isotopic triplet) and to the indicated approximation can be characterized by a complex phase shift, δ_0.

For this vertex function, $K(\xi)$, say, one finds

$$K(\xi)=\sqrt{2}G\exp\left\{-\frac{\xi+m_\pi{}^2}{\pi}\int_{4m^2}^{\infty}d\xi'\frac{\phi_0(\xi')}{(\xi'-m_\pi{}^2)(\xi'+\xi-i\epsilon)}\right\},$$

where ϕ_0 is the same function introduced in connection with our previous discussion of $a-\xi b/2m$, the quantity arising from the weak vertex. Putting our dispersion pictures together, we find for $\mathrm{Im}F(\xi)$, neglecting small terms $\sim m_\pi{}^2/m^2$,

$$\mathrm{Im}F(\xi)=-\frac{\sqrt{2}G}{4\pi}\left[mg_A+\frac{\sqrt{2}GF(-m_\pi{}^2)\xi}{\xi+m_\pi{}^2}\right]\times\left[\frac{\xi+4m^2}{\xi}\right]^{\frac{1}{2}}H(\xi)$$
(for $-\xi>4m^2$, $=0$ otherwise),

where $H(\xi)$ is given by

$$H(\xi)=\exp\left\{-\frac{2(\xi+m_\pi{}^2)}{\pi}P\int_{4m^2}^{\infty}d\xi'\frac{\phi_0(\xi')}{(\xi'-m_\pi{}^2)(\xi'+\xi)}\right\},$$

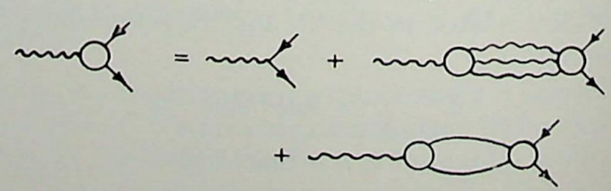

FIG. 3. Dispersion theoretic diagrams for the strong pion-nucleon vertex. The first one is the direct interaction, the second the uncomputable three pion state and finally the important state, the one involving a nucleon-antinucleon pair.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

and P means the principal value of the integral is to be taken at the singularity $\xi'=-\xi$. H is thus, aside from a factor, $|K(\xi)|^2$. On substituting $\mathrm{Im}F(\xi)$ into the dispersion relation for F, we find (neglecting m_π^2/m^2)

$$F(-m_\pi^2)\approx F(0)=-\frac{m\sqrt{2}}{4\pi}Gg_A\frac{J}{1+(G^2/4\pi)\cdot J},$$

where J is given by

$$J=\frac{1}{\pi}\int_{4m^2}^{\infty}d\xi\frac{(\xi-4m^2)^{\frac{1}{2}}}{\xi^3}H(-\xi).$$

If there were couplings to other baryon pairs (beside $\bar{p}n$) we would have

$$F(0)=-\frac{m}{4\pi}\sqrt{2}g_A\frac{\sum_i G_iJ_i}{1+(1/4\pi)\sum G_i^2J_i},$$

where the G_i are the strong coupling constants and the J_i are computed from H_i derived from the various ϕ_{0i}'s.

If we disregard the denominator and set the function H equal to unity, we get the familiar logarithmically-divergent result of perturbation theory. It has been conventional to say that if one puts the logarithm thus obtained equal to unity and computes the lifetime, the value of about sixty times the experimental one, which is found, is qualitative support for the correctness of the basic picture of π decay. The computation of the π-decay lifetime is really impossible for a person who believes seriously in the renormalization program based on perturbation theory. The π lifetime is a primitively divergent quantity whose presence must be accounted for by the existence of a so-called counter term which evidently then serves to remove the divergence and put in the observed decay rate by hand. One must prescribe the renormalized value of this divergent quantity. We obviously do not subscribe to this philosophy. Our feeling is that the function $H(\xi)$ plays a critical role and that the perturbation theoretical indications are irrelevant.

We obviously do not know enough about the complex $^1S_0$ phase shift for neutron-antiproton scattering to make a real quantitative study of J. What we have done, therefore, is to make a few simple models which have reasonable low energy behavior, and hope that they are not too insane at high energies. The reason that this may not be too unrealistic a procedure is that, provided only $H(\xi)\to 0$ however weakly for large ξ, the integral J exists. Furthermore, since it occurs in the denominator, multiplied by $G^2/4\pi\approx 15$, we see that if $J\gtrsim 1/15$ the J term dominates the denominator; neglecting the unity, then, J cancels out. This is a kind of strong coupling limit leading to $F(0)$ inversely proportional to G, instead of proportional to it, as would be given in weak coupling. In the case of several types of baryon loops there would evidently be a kind of mean value of $1/G$ defined by $\sum G_iJ_i/\sum G_i^2J_i$. In the global symmetry strong coupling limit ($G_i=G$) the earlier result continues to hold.

The models treated take for δ_0 the representation

$$\tan\delta_0=k(a+ib),\quad k=[(\xi/4)-m^2]^{\frac{1}{2}},$$

which leads to

$$\tan\phi_0=ka/(1+kb),$$

and we define $\delta_0(k=0)=0$. Various limiting cases of this expression have been studied ($a\gg b$, $b\gg a$) and in every case we find $J\gtrsim 0.7$. In a very unphysical case, namely, that of no absorption, $b=0$, all integrals may be evaluated analytically, and we find

$$J=-\frac{2}{\pi}\frac{ma+1}{ma-1}\{1-(m^2a^2-1)^{-\frac{1}{2}}\tan^{-1}(m^2a^2-1)^{\frac{1}{2}}\},$$

for the not unreasonable value of $ma\approx 3$ we find $J=0.7$.

Finally, making our strong coupling approximation, we obtain

$$F(0)=-(\sqrt{2}Gmg_A/\pi^2)[0.11],$$

using $G^2/4\pi=15$. This is to be compared with the experimental value given earlier, namely,

$$F(0)=-(\sqrt{2}Gmg_A/\pi^2)[0.115].$$

The agreement is rather impressive. It would be nice to hope that the neglect of all of the millions of states which we have made is contained in the 5% discrepancy. We are not quite so optimistic, but it is our feeling that the most important elements of the π-decay problem have been taken into account, and that a reasonable quantitative understanding of the process has been obtained.

Theory of Muon Capture*

H. PRIMAKOFF

Department of Physics, Washington University, St. Louis 5, Missouri

THE present paper deals with various aspects of the theory of muon capture with emphasis on the relation between theory and experiment. The theory is based on an effective Hamiltonian, $H_{\text{eff}}^{(\mu)}$, which describes muon capture with subsequent neutrino emission by an aggregate of A dressed nucleons:

$$\mu^- + \left\{\begin{matrix} Z \text{ protons} \\ A-Z \text{ neutrons} \end{matrix}\right\} \rightarrow \nu + \left\{\begin{matrix} Z-1 \text{ protons} \\ A-Z+1 \text{ neutrons} \end{matrix}\right\}.$$

The treatment is subdivided as follows:

1. Effective Hamiltonian.
2. Total Muon Capture Rate in Closure Approximation—"Isotope" Effect.
3. Comparison of Closure Approximation Expression for Total Muon Capture Rate with Experiment.
4. Muon Capture to Particular Final States of Daughter Nucleus.
5. "Hyperfine" Effect in Muon Capture Rate—Muon Capture in Hydrogen.
6. Radiative Muon Capture: Total Rate and Photon-Neutrino Angular Correlation.
7. Parity Non-conservation Effects:

(a) Angular Distribution of Recoil Nuclei in Capture of Polarized Muons.
(b) Angular Distribution of Photons in Radiative Capture of Polarized Muons.
(c) Polarization of Recoil Nuclei in Muon Capture.
(d) Polarization of Photons in Radiative Muon Capture.

1. EFFECTIVE HAMILTONIAN

The appropriate expression for $H_{\text{eff}}^{(\mu)}$, as discussed in some detail by Fujii and Primakoff,[1] is, in a configuration space representation,

$$H_{\text{eff}}^{(\mu)} = \frac{1}{\sqrt{2}} \tau^{(+)} \frac{(1-\boldsymbol{\sigma}\cdot\boldsymbol{\nu}_1)}{\sqrt{2}} \sum_{i=1}^{A} \tau_i^{(-)} \{ G_V^{(\mu)} 1\cdot 1_i + G_A^{(\mu)} \boldsymbol{\sigma}\cdot\boldsymbol{\sigma}_i - G_P^{(\mu)} \boldsymbol{\sigma}\cdot\boldsymbol{\nu}_1 \boldsymbol{\sigma}_i\cdot\boldsymbol{\nu}_1 \} \delta(\mathbf{r}-\mathbf{r}_i) \quad (1a)$$

with

$$G_V^{(\mu)} \equiv g_V^{(\mu)} \left(1+\frac{\nu}{2m_p}\right);$$

$$G_A^{(\mu)} \equiv g_A^{(\mu)} - g_V^{(\mu)} (1+\mu_p-\mu_n) \frac{\nu}{2m_p}; \quad (1b)$$

$$G_P^{(\mu)} \equiv [g_P^{(\mu)} - g_A^{(\mu)} - g_V^{(\mu)} (1+\mu_p-\mu_n)] \frac{\nu}{2m_p}$$

and

$$g_V^{(\mu)} \cong g_V^{(\beta)} \times 0.972; \quad g_A^{(\mu)} \cong g_A^{(\beta)} \times 0.999; \quad g_P^{(\mu)} \cong 8 g_A^{(\mu)} \cong 8 g_A^{(\beta)}. \quad (1c)$$

This $H_{\text{eff}}^{(\mu)}$ corresponds,[1] in a nonrelativistic approximation for the muon and for the nucleons, to the most general Lorentz covariant transition matrix element for the reaction $\mu^- + p \rightarrow \nu + n$ in a theory where the lepton-bare nucleon coupling is V and A, where the neutrinos are emitted with unit negative helicity, where time reversal invariance holds, and where any bare hyperon, bare kayon "currents" which interact with the lepton current, have the same transformation property under the charge symmetry operation as the bare nucleon, bare pion currents.[2,3] However we neglect in Eq. (1) "many body" terms in $H_{\text{eff}}^{(\mu)}$ arising from the possibility of exchange of virtual pions, kayons, etc., among the nucleons. Such many body terms depend on the relative space coordinates of pairs, triplets, . . ., of nucleons and are believed, on the basis of a rough analysis of the corresponding beta decay situation, to be relatively small.[1]

In Eqs. (1a) to (1c), $g_V^{(\mu)}$, $g_A^{(\mu)}$, and $g_P^{(\mu)}$ are vector, axial vector and "induced" pseudoscalar muon-dressed nucleon coupling constants effective in muon capture while $g_V^{(\beta)}$ and $g_A^{(\beta)}$ are electron-dressed nucleon vector and axial vector coupling constants effective in beta decay. The numerical relations in Eq. (1c) between $g_V^{(\mu)}$, $g_V^{(\beta)}$; $g_A^{(\mu)}$, $g_A^{(\beta)}$ arise from the assumption of "universality" between the V, A muon-bare nucleon and electron-bare nucleon coupling constants which implies that $g_V^{(\mu)}$, $g_A^{(\mu)}$ differ from $g_V^{(\beta)}$, $g_A^{(\beta)}$ only because of the differing nucleon four-momentum transfers in the muon capture and in the beta decay. The numerical relation in Eq. (1c) between $g_P^{(\mu)}$ and $g_A^{(\mu)}$, due to Goldberger and Treiman[3] and to Wolfenstein,[4] is based on the assumption that a reaction such as: $\mu^- + \pi^+ \rightarrow \nu$ takes place predominantly via the sequence of "steps": $\mu^- + \pi^+ \rightarrow \mu^- + p + \bar{n} \rightarrow \nu$ which implies the possibility of muon capture via the "four-step process": $\mu^- + p \rightarrow \mu^- + \pi^+ + n \rightarrow \mu^- + p + \bar{n} + n \rightarrow \nu + n$. The quantities $\mu_p = 1.793$, $\mu_n = -1.913$ are the proton, neutron (static) anomalous magnetic moments (in units of $e/2m_p$ with e, m_p proton charge, mass and $\hbar = 1$, $c = 1$); these appear in the interaction effective in muon capture [Eq. (1b)] as a consequence of the Gell-Mann–

Feynman assumption of a "conserved vector current" [5] which necessitates the existence, for example, of the reaction: $\mu^-+\pi^+\rightarrow\nu+\pi^0$ and hence implies the possibility of muon capture via the "three-step process": $\mu^-+p\rightarrow\mu^-+\pi^++n\rightarrow\nu+\pi^0+n\rightarrow\nu+n$. Also in Eqs. (1a) and (1b), $\mathbf{v}=\nu\mathbf{v}_1$ is the neutrino momentum; 1, 1_i and $\boldsymbol{\sigma}$, $\boldsymbol{\sigma}_i$ are 2×2 matrix unit operators and spin angular momentum operators for the lepton and the ith nucleon; $\mathbf{r}$ and $\mathbf{r}_i$ are space coordinates of the lepton and the ith nucleon; $\tau^{(+)}$, $\tau_i^{(-)}$ are isobaric-spin operators which transform a lepton muon state into a lepton neutrino state and an ith nucleon proton state into an ith nucleon neutron state; the factor $1/\sqrt{2}$ arises from the normalization of the neutrino relativistic wave function; the factor $(1-\boldsymbol{\sigma}\cdot\mathbf{v}_1)/\sqrt{2}$ is a consequence of the assumption of a maximum parity nonconserving two-component neutrino type muon-neutrino-nucleon coupling $(\sim(\psi_\nu{}^+[(1+\gamma_5)/\sqrt{2}]\gamma_4\gamma_\lambda\psi_\mu)\times(\psi_n{}^+\gamma_4\gamma_\lambda\psi_p)$, etc.). Though the muon and the nucleons are treated nonrelativistically in the derivation of $H_{\rm eff}{}^{(\mu)}$ all first-order nucleon recoil corrections, i.e., all terms in $H_{\rm eff}{}^{(\mu)}\sim\nu/m_p$, are nevertheless included.

2. TOTAL MUON CAPTURE RATE IN CLOSURE APPROXIMATION—"ISOTOPE" EFFECT

With the $H_{\rm eff}{}^{(\mu)}$ of Eqs. (1a) to (1c) we can obtain the square of the muon capture transition matrix element, $\langle|\text{M.E.}{}^{(\mu)}|^2\rangle$, summed over all spin orientations of the neutrino and averaged over all spin orientations of the muon. A straightforward calculation gives

$$\langle|\text{M.E.}{}^{(\mu)}|^2\rangle=\frac{1}{(2\pi)^3}\left[\frac{1}{\pi}\left(\frac{Zm_\mu{}'}{137}\right)^3\right]^{\frac{1}{2}}\cdot|\text{M.E.}_{\rm nucl}{}^{(\mu)}(a\rightarrow b)|^2, \quad (2a)$$

where $m_\mu{}'=m_\mu/[1+(m_\mu/Am_p)]$ is the muon reduced mass in the parent mu-mesic atom and the nuclear matrix element is expressed as

$$\begin{aligned}|\text{M.E.}_{\rm nucl}{}^{(\mu)}(a\rightarrow b)|^2&=(G_V{}^{(\mu)})^2|\langle b|\textstyle\sum_i\tau_i{}^{(-)}\exp(-i\nu_{ba}\cdot\mathbf{r}_i)\varphi(r_i)|a\rangle|^2\\&+(G_A{}^{(\mu)})^2|\langle b|\textstyle\sum_i\tau_i{}^{(-)}\exp(-i\nu_{ba}\cdot\mathbf{r}_i)\varphi(r_i)\boldsymbol{\sigma}_i|a\rangle|^2\\&+[(G_P{}^{(\mu)})^2-2G_A{}^{(\mu)}G_P{}^{(\mu)}]\\&\times|\langle b|\textstyle\sum_i\tau_i{}^{(-)}\exp(-i\nu_{ba}\cdot\mathbf{r}_i)\varphi(r_i)\boldsymbol{\sigma}_i\cdot\mathbf{v}_1|a\rangle|^2. \quad (2b)\end{aligned}$$

In Eqs. (2a) and (2b), $|a\rangle$, $|b\rangle$ represent wave functions of the two nuclear states involved in the capture process; the quantity $\varphi(r_i)$ is the muon space orbital wave function normalized in such a way that $\varphi(r_i)\rightarrow1$ as $Z\rightarrow0$, i.e., for small Z,

$$\varphi(r_i)\cong\exp(-Zm_\mu{}'r_i/137).$$

[5] R. P. Feynman and M. Gell-Mann, Phys. Rev. **109**, 193 (1958); M. Gell-Mann, Phys. Rev. **111**, 362 (1958); J. Bernstein and R. R. Lewis, Phys. Rev. **112**, 232 (1958).

The emitted neutrino momentum, ν_{ba}, is obtained from the energy and momentum conservation laws as

$$\nu_{ba}=m_\mu\left(1-\frac{\epsilon_a}{m_\mu}-\frac{(E_b-E_a)}{m_\mu}\right)\left(1-\frac{m_\mu}{2(m_\mu+Am_p)}\right), \quad (2c)$$

where ϵ_a is the binding energy of the muon in the lowest Bohr orbit of the mu-mesic atom and E_a, E_b are the energies of the nuclear states a, b. Thus, taking proper account of the density of final states available to the emitted neutrino, the total muon capture rate of the parent nucleus in the state $a|\rangle$, $\Lambda^{(\mu)}(a)$, is

$$\Lambda^{(\mu)}(a)=2\pi\cdot4\pi\sum_b\int\frac{d\mathbf{v}_1}{4\pi}\langle|\text{M.E.}{}^{(\mu)}|^2\rangle(\nu_{ba})^2\times[1+\nu_{ba}/[(\nu_{ba})^2+(Am_p)^2]^{\frac{1}{2}}]^{-1} \quad (3a)$$

so that using Eqs. (2a) to (2c)

$$\begin{aligned}\Lambda^{(\mu)}(a)=Z^3\frac{1}{2\pi^2}\frac{m_\mu{}^5}{(137)^3}\sum_b(\eta_{ba})^2\int\frac{d\mathbf{v}_1}{4\pi}&\times\{(G_V{}^{(\mu)})^2|\langle b|\textstyle\sum_i\tau_i{}^{(-)}\exp(-i\nu_{ba}\cdot\mathbf{r}_i)\varphi(r_i)|a\rangle|^2\\&+(G_A{}^{(\mu)})^2|\langle b|\textstyle\sum_i\tau_i{}^{(-)}\exp(-i\nu_{ba}\cdot\mathbf{r}_i)\varphi(r_i)\boldsymbol{\sigma}_i|a\rangle|^2\\&+[(G_P{}^{(\mu)})^2-2G_A{}^{(\mu)}G_P{}^{(\mu)}]\\&\times|\langle b|\textstyle\sum_i\tau_i{}^{(-)}\exp(-i\nu_{ba}\cdot\mathbf{r}_i)\varphi(r_i)\boldsymbol{\sigma}_i\cdot\mathbf{v}_1|a\rangle|^2\}\end{aligned} \quad (3b)$$

where

$$(\eta_{ba})^2\equiv\left(1-\frac{\epsilon_a}{m_\mu}-\frac{(E_b-E_a)}{m_\mu}\right)^2\left(1-\frac{m_\mu}{2(m_\mu+Am_p)}\right)^2\times[1+\nu_{ba}/[(\nu_{ba})^2+(Am_p)^2]^{\frac{1}{2}}]^{-1}\left(1+\frac{m_\mu}{Am_p}\right)^{-3}, \quad (3c)$$

or, dropping terms in m_μ/Am_p,

$$(\eta_{ba})^2\cong\left(1-\frac{\epsilon_a}{m_\mu}-\frac{(E_b-E_a)}{m_\mu}\right)^2\cong(\nu_{ba}/m_\mu)^2. \quad (3d)$$

The approximate expression for $(\eta_{ba})^2$ in Eq. (3d), involving neglect of the corrections for daughter nucleus recoil and parent mu-mesic atom reduced mass, holds to better than 5% for $A>12$.

The sum over b in Eqs. (3a) and (3b) runs over all energetically accessible states of the daughter nucleus, i.e., over all states b for which $E_b\leqq E_a+(m_\mu-\epsilon_a)$. Such energetically accessible states are very numerous since $m_\mu-\epsilon_\mu\approx100$ Mev and $(E_b)_{\text{ground state}}-E_a$ is normally ≈2–3 Mev and never exceeds 15 Mev; in addition, the matrix elements

$$\langle b|\textstyle\sum_i\tau_i{}^{(-)}\exp(-i\nu_{ba}\cdot\mathbf{r}_i)\varphi(r_i)|a\rangle,$$

$$\langle b|\textstyle\sum_i\tau_i{}^{(-)}\exp(-i\nu_{ba}\cdot\mathbf{r}_i)\varphi(r_i)\boldsymbol{\sigma}_i|a\rangle,$$

$$\langle b|\textstyle\sum_i\tau_i{}^{(-)}\exp(-i\nu_{ba}\cdot\mathbf{r}_i)\varphi(r_i)\boldsymbol{\sigma}_i\cdot\mathbf{v}_1|a\rangle$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

are largest for low lying states b. Thus one may have confidence in the accuracy of a closure approximation which extends the sum over all energetically accessible states b to a sum over all states b without restriction, and which replaces the explicitly E_b-dependent quantities, ν_{ba}, η_{ba}, by suitable averages $\langle\nu\rangle_a$, $\langle\eta\rangle_a$, which do not depend explicitly on E_b. Such a closure approximation applied to Eq. (3b) yields

$$\begin{aligned}\Lambda^{(\mu)}(a)=Z^3(\langle\eta\rangle_a)^2\frac{1}{2\pi^2}\frac{{m_\mu}^5}{(137)^3}\int\frac{d\boldsymbol{\nu}_1}{4\pi}\{&(G_V{}^{(\mu)})^2\langle a|\sum_{i,j}{}^{\cdot}\,\tau_i{}^{(+)}\tau_j{}^{(-)}\exp(i\langle\nu\rangle_a\boldsymbol{\nu}_1\cdot\mathbf{r}_{ij})\varphi^*(r_i)\varphi(r_j)|a\rangle\\&+(G_A{}^{(\mu)})^2\langle a|\sum_{i,j}\tau_i{}^{(+)}\tau_j{}^{(-)}\exp(i\langle\nu\rangle_a\boldsymbol{\nu}_1\cdot\mathbf{r}_{ij})\varphi^*(r_i)\varphi(r_j)\boldsymbol{\sigma}_i\cdot\boldsymbol{\sigma}_j|a\rangle\\&+((G_P{}^{(\mu)})^2-2G_P{}^{(\mu)}G_A{}^{(\mu)})\langle a|\sum_{i,j}\tau_i{}^{(+)}\tau_j{}^{(-)}\exp(i\langle\nu\rangle_a\boldsymbol{\nu}_1\cdot\mathbf{r}_{ij})\varphi^*(r_i)\varphi(r_j)\boldsymbol{\sigma}_i\cdot\boldsymbol{\nu}_1\boldsymbol{\sigma}_j\cdot\boldsymbol{\nu}_1|a\rangle\}\end{aligned}\tag{4a}$$

$$\begin{aligned}\cong Z^4(\langle\eta\rangle_a)^2\frac{1}{2\pi^2}\frac{{m_\mu}^5}{(137)^3}((G_V{}^{(\mu)})^2+3(\Gamma_A{}^{(\mu)})^2)\Bigg\{&\frac{\left\langle a\left|\sum_i\left(\frac{1+\tau_i{}^{(3)}}{2}\right)|\varphi(r_i)|^2\right|a\right\rangle}{\left\langle a\left|\sum_i\left(\frac{1+\tau_i{}^{(3)}}{2}\right)\right|a\right\rangle}\\&+\frac{\left\langle a\left|\sum_{i,j}{}'\left[\tfrac{1}{4}(\boldsymbol{\tau}_i\cdot\boldsymbol{\tau}_j-\tau_i{}^{(3)}\tau_j{}^{(3)})((G_V{}^{(\mu)})^2+(\Gamma_A{}^{(\mu)})^2\boldsymbol{\sigma}_i\cdot\boldsymbol{\sigma}_j)\right]\left[\frac{\sin(\langle\nu\rangle_a r_{ij})}{(\langle\nu\rangle_a r_{ij})}\varphi^*(r_i)\varphi(r_j)\right]\right|a\right\rangle}{Z((G_V{}^{(\mu)})^2+3(\Gamma_A{}^{(\mu)})^2)}\Bigg\}\end{aligned}$$

$$\begin{aligned}\equiv(Z_{\text{eff}})^4(\langle\eta\rangle_a)^2\frac{1}{2\pi^2}\frac{{m_\mu}^5}{(137)^3}&((G_V{}^{(\mu)})^2+3(\Gamma_A{}^{(\mu)})^2)\\\times\Bigg\{1+&\frac{\left\langle a\left|\sum_{i,j}{}'\left[\tfrac{1}{4}(\boldsymbol{\tau}_i\cdot\boldsymbol{\tau}_j-\tau_i{}^{(3)}\tau_j{}^{(3)})((G_V{}^{(\mu)})^2+(\Gamma_A{}^{(\mu)})^2\boldsymbol{\sigma}_i\cdot\boldsymbol{\sigma}_j)\right]\left[\frac{\sin(\langle\nu\rangle_a r_{ij})}{(\langle\nu\rangle_a r_{ij})}\varphi^*(r_i)\varphi(r_j)\right]\right|a\right\rangle}{Z((G_V{}^{(\mu)})^2+3(\Gamma_A{}^{(\mu)})^2)\left(\int|\varphi(r)|^2\mathfrak{D}_a(r)d\mathbf{r}\right)}\Bigg\},\end{aligned}$$

where

$$(\Gamma_A{}^{(\mu)})^2\equiv(G_A{}^{(\mu)})^2+\tfrac{1}{3}((G_P{}^{(\mu)})^2-2G_A{}^{(\mu)}G_P{}^{(\mu)});\quad\sum_{i,j}{}'\cdots\equiv\sum_{i,j;\,(i\neq j)}\cdots;\tag{4b}$$

$$(Z_{\text{eff}})^4\equiv Z^4\frac{\left\langle a\left|\sum_i\frac{1+\tau_i{}^{(3)}}{2}|\varphi(r_i)|^2\right|a\right\rangle}{\left\langle a\left|\sum_i\frac{1+\tau_i{}^{(3)}}{2}\right|a\right\rangle}=Z^4\int|\varphi(r)|^2\mathfrak{D}_a(r)d\mathbf{r}$$

with

$$\mathfrak{D}_a(r)\equiv\frac{1}{2J_a+1}\sum_{M_a}\frac{\left\langle E_a,J_a,M_a\left|\sum_i\left(\frac{1+\tau_i{}^{(3)}}{2}\right)\delta(\mathbf{r}-\mathbf{r}_i)\right|E_a,J_a,M_a\right\rangle}{\left\langle E_a,J_a,M_a\left|\sum_i\left(\frac{1+\tau_i{}^{(3)}}{2}\right)\right|E_a,J_a,M_a\right\rangle}.\tag{4c}$$

The approximate equality in Eq. (4a) refers to the replacement of

$$\int\frac{d\boldsymbol{\nu}_1}{4\pi}\left\langle a\left|\sum_{i,j}{}'\,\tau_i{}^{(+)}\tau_j{}^{(-)}\exp(i\langle\nu\rangle_a\boldsymbol{\nu}_1\mathbf{r}_{ij})\varphi^*(r_i)\varphi(r_j)\boldsymbol{\sigma}_i\cdot\boldsymbol{\nu}_1\boldsymbol{\sigma}_j\cdot\boldsymbol{\nu}_1\right|a\right\rangle\tag{4d}$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

by

$$\frac{1}{3}\int\frac{d\nu_1}{4\pi}\left\langle a\left|\sum_{i,j}{}'\,\tau_i^{(+)}\tau_j^{(-)}\frac{\sin(\langle\nu\rangle_a r_{ij})}{(\langle\nu\rangle_a r_{ij})}\varphi^*(r_i)\,\varphi(r_j)\boldsymbol{\sigma}_i\cdot\boldsymbol{\sigma}_j\right|a\right\rangle, \tag{4e}$$

a replacement which is justified since the d wave, g wave, $\cdots$ parts of $\exp(i\langle\nu\rangle_a\boldsymbol{\nu}_1\cdot\mathbf{r}_{ij})$ make a relatively small contribution to

$$\int\frac{d\nu_1}{4\pi}\left\langle a\left|\sum_{i,j}{}'\,\tau_i^{(+)}\tau_j^{(-)}\exp(i\langle\nu\rangle_a\boldsymbol{\nu}_1\cdot\mathbf{r}_{ij})\,\varphi^*(r_i)\,\varphi(r_j)\boldsymbol{\sigma}_i\cdot\boldsymbol{\nu}_1\boldsymbol{\sigma}_j\cdot\boldsymbol{\nu}_1\right|a\right\rangle.$$

The quantity $(Z_{\text{eff}})^4$, introduced by Wheeler in his original estimates of muon capture rates,[6] describes the variation of the muon space orbital wave function over the extent of the nucleus the quantity $\mathfrak{D}_a(r)$ being the (directionally-averaged-over) density function of the protons in the parent nucleus—the electrostatic potential appropriate to $\mathfrak{D}_a(r)$ enters into the muon energy eigenfunction-eigenvalue Dirac equation which determines ϵ_a and $\varphi(r)$. It is clear that $((Z_{\text{eff}})^4/Z^4)<1$, and $\to 1$ as $Z\to 0$.

Introducing the expression for the neutron decay rate,

$$\frac{\ln 2}{(\tau_{\frac{1}{2}})_{\text{neu}}}=\frac{1}{(2\pi)^3}m_e^5 f_{\text{neu}}\left[(g_V{}^{(\beta)})^2+3(g_A{}^{(\beta)})^2\right];\quad f_{\text{neu}}(\tau_{\frac{1}{2}})_{\text{neu}}=(1180\pm 35)\text{ sec},^7 \tag{5}$$

we have, from Eqs. (4a) to (4c) and (5),

$$\begin{aligned}\Lambda^{(\mu)}(a)&=(Z_{\text{eff}})^4(\langle\eta\rangle_a)^2\frac{(m_\mu/m_e)^5}{(137)^3}\frac{\pi(\ln 2)}{(f_{\text{neu}}(\tau_{\frac{1}{2}})_{\text{neu}})}\mathfrak{R}(1-\mathcal{g}_a)\\&=(Z_{\text{eff}})^4(\langle\eta\rangle_a)^2(272\text{ sec}^{-1})\mathfrak{R}(1-\mathcal{g}_a)\end{aligned} \tag{6a}$$

with

$$\mathfrak{R}\equiv\left[(G_V{}^{(\mu)})^2+3(\Gamma_A{}^{(\mu)})^2\right]/\left[(g_V{}^{(\beta)})^2+3(g_A{}^{(\beta)})^2\right], \tag{6b}$$

$$\mathcal{g}_a\equiv-\frac{\left\langle a\left|\sum_{i,j}{}'\left[\frac{1}{4}(\boldsymbol{\tau}_i\cdot\boldsymbol{\tau}_j-\tau_i^{(3)}\tau_j^{(3)})((G_V{}^{(\mu)})^2+(\Gamma_A{}^{(\mu)})^2\boldsymbol{\sigma}_i\cdot\boldsymbol{\sigma}_j)\right]\left[\frac{\sin(\langle\nu\rangle_a r_{ij})}{(\langle\nu\rangle_a r_{ij})}\varphi^*(r_i)\,\varphi(r_j)\right]\right|a\right\rangle}{Z((G_V{}^{(\mu)})^2+3(\Gamma_A{}^{(\mu)})^2)\left(\int|\varphi(r)|^2\mathfrak{D}_a(r)d\mathbf{r}\right)}. \tag{6c}$$

The quantity $\mathcal{g}_a(\mathcal{g}_a>0)$, which would vanish if the nucleus had $Z=A$ [in such a case: $(\boldsymbol{\tau}_i\cdot\boldsymbol{\tau}_j)|a\rangle=|a\rangle$; $\tau_i^{(3)}\tau_j^{(3)}|a\rangle=|a\rangle$] and also if $\langle\nu\rangle_a$ were $\gg\{(r_{ij})_{\text{Av}}\}^{-1}\approx$ mean nucleon momentum within nucleus, describes, within the context of the closure approximation, the inhibitory effect of the Pauli exclusion principle on the muon capture process. This inhibition may be visualized as arising from the fact that the neutron created in the $\mu^-+p\to n+\nu$ process cannot be produced in states already occupied by pre-existing neutrons of the parent nucleus, and the corresponding $\mathcal{g}_a$ may be expressed in terms of appropriate nucleon-nucleon correlation functions in the parent nucleus. We have

$$\begin{aligned}-\mathcal{g}_a=&\frac{\left\langle a\left|\sum_{i,j}{}'\left\{\frac{1}{4}(\boldsymbol{\tau}_i\cdot\boldsymbol{\tau}_j-\tau_i^{(3)}\tau_j^{(3)})\left[(G_V{}^{(\mu)})^2+(\Gamma_A{}^{(\mu)})^2\boldsymbol{\sigma}_i\cdot\boldsymbol{\sigma}_j\right]\right\}\left(\frac{1+P_{ij}}{2}\right)\right|a\right\rangle}{Z\left[(G_V{}^{(\mu)})^2+3(\Gamma_A{}^{(\mu)})^2\right]}\\&\times\int\int\frac{\sin(\langle\nu\rangle_a|\mathbf{r}-\mathbf{r}'|)}{(\langle\nu\rangle_a|\mathbf{r}-\mathbf{r}'|)}\varphi^*(r)\,\varphi(r')F_a{}^{(+)}(\mathbf{r},\mathbf{r}')d\mathbf{r}d\mathbf{r}'\Big/\int|\varphi(r)|^2\mathfrak{D}_a(r)d\mathbf{r}\\&+\frac{\left\langle a\left|\sum_{i,j}{}'\left\{\frac{1}{4}(\boldsymbol{\tau}_i\cdot\boldsymbol{\tau}_j-\tau_i^{(3)}\tau_j^{(3)})\left[(G_V{}^{(\mu)})^2+(\Gamma_A{}^{(\mu)})^2\boldsymbol{\sigma}_i\cdot\boldsymbol{\sigma}_j\right]\right\}\left(\frac{1-P_{ij}}{2}\right)\right|a\right\rangle}{Z\left[(G_V{}^{(\mu)})^2+3(\Gamma_A{}^{(\mu)})^2\right]}\\&\times\int\int\frac{\sin(\langle\nu\rangle_a|\mathbf{r}-\mathbf{r}'|)}{(\langle\nu\rangle_a|\mathbf{r}-\mathbf{r}'|)}\varphi^*(r)\,\varphi(r')F_a{}^{(-)}(\mathbf{r},\mathbf{r}')d\mathbf{r}d\mathbf{r}'\Big/\int|\varphi(r)|^2\mathfrak{D}_a(r)d\mathbf{r}\end{aligned} \tag{7a}$$

with

$$F_a^{(\pm)}(\mathbf{r},\mathbf{r}')\equiv\frac{\left\langle a\left|\sum_{i,j}'\{\frac{1}{4}(\boldsymbol{\tau}_i\cdot\boldsymbol{\tau}_j-\tau_i^{(3)}\tau_j^{(3)})[(G_V^{(\mu)})^2+(\Gamma_A^{(\mu)})^2\boldsymbol{\sigma}_i\cdot\boldsymbol{\sigma}_j]\}[\delta(\mathbf{r}-\mathbf{r}_i)\delta(\mathbf{r}'-\mathbf{r}_j)]\left(\frac{1\pm P_{ij}}{2}\right)\right|a\right\rangle}{\left\langle a\left|\sum_{i,j}'\{\frac{1}{4}(\boldsymbol{\tau}_i\cdot\boldsymbol{\tau}_j-\tau_i^{(3)}\tau_j^{(3)})[(G_V^{(\mu)})^2+(\Gamma_A^{(\mu)})^2\boldsymbol{\sigma}_i\cdot\boldsymbol{\sigma}_j]\}\left(\frac{1\pm P_{ij}}{2}\right)\right|a\right\rangle},\tag{7b}$$

$$P_{ij}\equiv-\left(\frac{1+\boldsymbol{\sigma}_i\cdot\boldsymbol{\sigma}_j}{2}\right)\left(\frac{1+\boldsymbol{\tau}_i\cdot\boldsymbol{\tau}_j}{2}\right).\tag{7c}$$

The $F_a^{(\pm)}(\mathbf{r},\mathbf{r}')$ are nucleon-nucleon correlation density functions associated with a space symmetric, space antisymmetric relative motion of the two nucleons since for $|a\rangle$ antisymmetric in $\mathbf{r}_i$, $\mathbf{r}_j$; $\sigma_i^{(3)}$, $\sigma_j^{(3)}$; $\tau_i^{(3)}$, $\tau_j^{(3)}$; $P_{ij}|a\rangle=$ (exchange operator for $\mathbf{r}_i$, $\mathbf{r}_j$) $|a\rangle$; it is to be noted that $F_a^{(-)}(\mathbf{r},\mathbf{r})=0$. One has further

$$\begin{aligned}&\langle a|\sum_{i,j}'\{\tfrac{1}{4}(\boldsymbol{\tau}_i\cdot\boldsymbol{\tau}_j-\tau_i^{(3)}\tau_j^{(3)})[(G_V^{(\mu)})^2+(\Gamma_A^{(\mu)})^2\boldsymbol{\sigma}_i\cdot\boldsymbol{\sigma}_j]\}|a\rangle\\&\quad=-[(G_V^{(\mu)})^2+3(\Gamma_A^{(\mu)})^2]\tfrac{1}{2}A+\langle a|(G_V^{(\mu)})^2[(\mathbf{T})^2-(T^{(3)})^2]+(\Gamma_A^{(\mu)})^2[(\mathbf{Y}^{(1)})^2+(\mathbf{Y}^{(2)})^2]|a\rangle,\end{aligned}\tag{7d}$$

$$\begin{aligned}&\langle a|\sum_{i,j}'[\tfrac{1}{4}(\boldsymbol{\tau}_i\cdot\boldsymbol{\tau}_j-\tau_i^{(3)}\tau_j^{(3)})[(G_V^{(\mu)})^2+(\Gamma_A^{(\mu)})^2\boldsymbol{\sigma}_i\cdot\boldsymbol{\sigma}_j]P_{ij}|a\rangle\\&\quad=-[(G_V^{(\mu)})^2+3(\Gamma_A^{(\mu)})^2]\frac{Z(A-Z)}{2}+[(G_V^{(\mu)})^2-(\Gamma_A^{(\mu)})^2]\langle a|(\mathbf{S}_{\rm pr})^2+(\mathbf{S}_{\rm neu})^2-(\mathbf{S}_{\rm pr}+\mathbf{S}_{\rm neu})^2|a\rangle\end{aligned}$$

with

$$\mathbf{T}\equiv\sum_i\tfrac{1}{2}\boldsymbol{\tau}_i;\quad\mathbf{Y}^{(1),(2),(3)}\equiv\sum_i\tfrac{1}{2}\tau_i^{(1),(2),(3)}\boldsymbol{\sigma}_i;\quad\mathbf{S}_{\rm pr}\equiv\sum_i\left(\frac{1+\tau_i^{(3)}}{2}\right)(\boldsymbol{\sigma}_i/2);\quad\mathbf{S}_{\rm neu}\equiv\sum_i\left(\frac{1-\tau_i^{(3)}}{2}\right)(\boldsymbol{\sigma}_i/2)\tag{7e}$$

as may be verified by using relations of the type:

$$\sum_{i,j}'\tfrac{1}{4}\boldsymbol{\tau}_i\cdot\boldsymbol{\tau}_j=\sum_{i,j}\tfrac{1}{4}\boldsymbol{\tau}_i\cdot\boldsymbol{\tau}_j-\sum_i\tfrac{1}{4}(\boldsymbol{\tau}_i)^2=(\mathbf{T})^2-\tfrac{3}{4}A.$$

Equations (7a) to (7e) and (6a) to (6c) yield

$$\begin{aligned}\Lambda^{(\mu)}(a)=(Z_{\rm eff})^4(\langle\eta\rangle_a)^2(272\ \sec^{-1})\mathcal{R}\Bigg\{&1-\left[\frac{A}{2Z}-\frac{\langle a|(G_V^{(\mu)})^2[(\mathbf{T})^2-(T^{(3)})^2]+(\Gamma_A^{(\mu)})^2[(\mathbf{Y}^{(1)})^2+(\mathbf{Y}^{(2)})^2]|a\rangle}{Z[(G_V^{(\mu)})^2+3(\Gamma_A^{(\mu)})^2]}\right]\\&\times\left[\frac{\iint\frac{\sin(\langle\nu\rangle_a|\mathbf{r}-\mathbf{r}'|)}{(\langle\nu\rangle_a|\mathbf{r}-\mathbf{r}'|)}\varphi^*(r)\varphi(r')\tfrac{1}{2}[F_a^{(+)}(\mathbf{r},\mathbf{r}')+F_a^{(-)}(\mathbf{r},\mathbf{r}')]d\mathbf{r}d\mathbf{r}'}{\int|\varphi(r)|^2\mathfrak{D}_a(r)d\mathbf{r}}\right]\\&-\left[\frac{A-Z}{2}-\frac{[(G_V^{(\mu)})^2-(\Gamma_A^{(\mu)})^2]\langle a|(\mathbf{S}_{\rm pr})^2+(\mathbf{S}_{\rm neu})^2-(\mathbf{S}_{\rm pr}+\mathbf{S}_{\rm neu})^2|a\rangle}{Z[(G_V^{(\mu)})^2+3(\Gamma_A^{(\mu)})^2]}\right]\\&\times\left[\frac{\iint\frac{\sin(\langle\nu\rangle_a|\mathbf{r}-\mathbf{r}'|)}{(\langle\nu\rangle_a|\mathbf{r}-\mathbf{r}'|)}\varphi^*(r)\varphi(r')\tfrac{1}{2}[F_a^{(+)}(\mathbf{r},\mathbf{r}')-F_a^{(-)}(\mathbf{r},\mathbf{r}')]d\mathbf{r}d\mathbf{r}'}{\int|\varphi(r)|^2\mathfrak{D}_a(r)d\mathbf{r}}\right]\Bigg\}.\end{aligned}\tag{8}$$

Equation (8) for $\Lambda_{(a)}{}^{(\mu)}$ is essentially exact within the limitations of the closure approximation.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

We proceed to evaluate $\Lambda^{(\mu)}(a)$ for the heavier nuclei, $Z>6$, $A>12$. Dropping terms $\sim 1/Z$ in Eq. (8) yields

$$\Lambda^{(\mu)}(a)\cong(Z_{\text{eff}})^4(\langle\eta\rangle_a)^2(272\ \text{sec}^{-1})\mathfrak{R}\left\{1-\left(\frac{A}{2Z}\right)\left[\frac{\int\int\frac{\sin(\langle\nu\rangle_a|\mathbf{r}-\mathbf{r}'|)}{(\langle\nu\rangle_a|\mathbf{r}-\mathbf{r}'|)}\varphi^*(r)\varphi(r')\tfrac{1}{2}[F_a^{(+)}(\mathbf{r},\mathbf{r}')+F_a^{(-)}(\mathbf{r},\mathbf{r}')]d\mathbf{r}d\mathbf{r}'}{\int|\varphi(r)|^2\mathfrak{D}_a(r)d\mathbf{r}}\right]\right.$$
$$\left.-\left(\frac{A-Z}{2}\right)\left[\frac{\int\int\frac{\sin(\langle\nu\rangle_a|\mathbf{r}-\mathbf{r}'|)}{(\langle\nu\rangle_a|\mathbf{r}-\mathbf{r}'|)}\varphi^*(r)\varphi(r')\tfrac{1}{2}[F_a^{(+)}(\mathbf{r},\mathbf{r}')-F_a^{(-)}(\mathbf{r},\mathbf{r}')]d\mathbf{r}d\mathbf{r}'}{\int|\varphi(r)|^2\mathfrak{D}_a(r)d\mathbf{r}}\right]\right\}. \quad (9)$$

Then, adopting physically reasonable functional forms for $F_a^{(\pm)}(\mathbf{r},\mathbf{r}')$, $\mathfrak{D}_a(r)$ such as,

$$F_a^{(\pm)}(\mathbf{r},\mathbf{r}')=C_a^{(\pm)}\mathfrak{D}_a(r)\mathfrak{D}_a(r')(1\pm f_a(|\mathbf{r}-\mathbf{r}'|)); \quad f_a(|\mathbf{r}-\mathbf{r}'|)=\begin{matrix}1:|\mathbf{r}-\mathbf{r}'|\leqq d\\0:|\mathbf{r}-\mathbf{r}'|>d\end{matrix};$$
$$(C_a^{\pm})^{-1}=\int\int\mathfrak{D}_a(r)\mathfrak{D}_a(r')(1\pm f_a(|\mathbf{r}-\mathbf{r}'|))d\mathbf{r}d\mathbf{r}'; \quad \mathfrak{D}_a(r)=\begin{cases}1/[(4\pi/3)r_0^3A]:r\leqq r_0A^{\frac{1}{3}}\\0\qquad\qquad\qquad:r>r_0A^{\frac{1}{3}}\end{cases}; \quad (10)$$

remembering that $[\sin(\langle\nu\rangle_a|\mathbf{r}-\mathbf{r}'|)]/(\langle\nu\rangle_a|\mathbf{r}-\mathbf{r}'|)$ and $f_a(|\mathbf{r}-\mathbf{r}'|)$ are both *short ranged* functions with comparable ranges $(\langle\nu\rangle_a)^{-1}\approx d\approx r_0\ll r_0A^{\frac{1}{3}}$, and again neglecting terms $\sim 1/Z$, we have

$$\Lambda^{(\mu)}(a)\cong(Z_{\text{eff}})^4(\langle\eta\rangle_a)^2(272\ \text{sec}^{-1})\mathfrak{R}$$
$$\times\left\{1-\left(\frac{A-Z}{2A}\right)\left[\frac{A\int\int\frac{\sin(\langle\nu\rangle_a|\mathbf{r}-\mathbf{r}'|)}{(\langle\nu\rangle_a|\mathbf{r}-\mathbf{r}'|)}\varphi^*(r)\varphi(r')\mathfrak{D}_a(r)\mathfrak{D}_a(r')f_a(|\mathbf{r}-\mathbf{r}'|)d\mathbf{r}d\mathbf{r}'}{\int|\varphi(r)|^2\mathfrak{D}_a(r)d\mathbf{r}}\right]\right\}$$
$$\equiv(Z_{\text{eff}})^4(\langle\eta\rangle_a)^2(272\ \text{sec}^{-1})\mathfrak{R}\left\{1-\left(\frac{A-Z}{2A}\right)\delta_a\right\}. \quad (11a)$$

Further, using once more the *short ranged* character of $f_a(|\mathbf{r}-\mathbf{r}'|)$, we obtain

$$\delta_a\cong A\left(\frac{1}{(4\pi/3)r_0^3A}\right)\int|\varphi(r)|^2\mathfrak{D}_a(r)d\mathbf{r}\int\frac{\sin(\langle\nu\rangle_a\rho)}{(\langle\nu\rangle_a\rho)}f_a(\rho)d\rho\Big/\int|\varphi(r)|^2\mathfrak{D}_a(r)d\mathbf{r}$$
$$=\left(\frac{d}{r_0}\right)^3\left[1-\frac{1}{10}(\langle\nu\rangle_ar_0)^2\left(\frac{d}{r_0}\right)^2+\cdots\right]\cong\left(\frac{d}{r_0}\right)^3\left[1-0.024\left(\frac{d}{r_0}\right)^2+\cdots\right] \quad (11b)$$

where we have taken $\langle\nu\rangle_a\cong 0.75m_\mu$ (see below), $r_0\cong 1.25\times10^{-13}$ cm$=0.67/m_\mu$. Thus, within the present approximation, the "nucleon-nucleon correlation" parameter δ_a and the exclusion principle inhibition factor $\mathcal{I}_a$, proportional to the fraction of nucleons which are neutrons and to δ_a: $\mathcal{I}_a\cong((A-Z)/2A)\delta_a$ [Eqs. (6a), (6c), (11a), and (11b)], are both essentially determined by the parameter d/r_0, i.e., by the ratio of the characteristic lengths entering into $f_a(|\mathbf{r}-\mathbf{r}'|)$ and $\mathfrak{D}_a(r)$. The characteristic length d is the radius of the Pauli-Fermi "correlation region of influence," e.g., the Pauli-Fermi "correlation hole" surrounding each nucleon, and is determined by the interplay of the nucleon-nucleon forces and the exclusion principle. It is to be noted that up to terms $\sim 1/Z$, $\mathcal{I}_a$ vanishes with vanishing d, i.e., with vanishing nucleon-nucleon correlation.

To obtain the numerical value of d/r_0 and so of δ_a we consider the expression for the Coulomb energy of the parent nucleus. We have

$$E_{\text{Coul}}=\left\langle a\left|\sum_{i,j}{}'\frac{1}{2}\left(\frac{1+\tau_i^{(3)}}{2}\right)\left(\frac{1+\tau_j^{(3)}}{2}\right)\left(\frac{e^2}{r_{ij}}\right)\right|a\right\rangle, \quad (12)$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

and using a procedure analogous to that employed in the evaluation of $\mathcal{I}_a$ [Eqs. (6c) to (7e)] we obtain a formula first given by Feenberg and Goertzel,[8]

$$E_{\text{Coul}}=\tfrac{1}{2}Z(Z-1)\int\int\frac{e^2}{|\mathbf{r}-\mathbf{r}'|}\tfrac{1}{4}(G_a^{(+)}(\mathbf{r},\mathbf{r}')+3G_a^{(-)}(\mathbf{r},\mathbf{r}'))d\mathbf{r}d\mathbf{r}'$$
$$+(\tfrac{3}{4}Z-\langle a|(\mathbf{S}_{\text{pr}})^2|a\rangle)\int\int\frac{e^2}{|\mathbf{r}-\mathbf{r}'|}\tfrac{1}{2}(G_a^{(+)}(\mathbf{r},\mathbf{r}')-G_a^{(-)}(\mathbf{r},\mathbf{r}'))d\mathbf{r}d\mathbf{r}', \quad (13a)$$

where

$$G_a^{(\pm)}(\mathbf{r},\mathbf{r}')\equiv\frac{\left\langle a\left|\sum_{i,j}{}'\left[\left(\frac{1+\tau_i^{(3)}}{2}\right)\left(\frac{1+\tau_j^{(3)}}{2}\right)\right][\delta(\mathbf{r}-\mathbf{r}_i)\delta(\mathbf{r}'-\mathbf{r}_j)]\left(\frac{1+P_{ij}}{2}\right)\right|a\right\rangle}{\left\langle a\left|\sum_{i,j}{}'\left[\left(\frac{1+\tau_i^{(3)}}{2}\right)\left(\frac{1+\tau_j^{(3)}}{2}\right)\right]\left(\frac{1\pm P_{ij}}{2}\right)\right|a\right\rangle} \quad (13b)$$

is the proton-proton correlation density function associated with a space symmetric, space antisymmetric relative motion of the two protons. Comparing Eq. (13b) for $G_a^{\pm}(\mathbf{r},\mathbf{r}')$ with Eq. (7b) for $F_a^{(\pm)}(\mathbf{r},\mathbf{r}')$ we see that, in each case, the same spin and isobaric-spin operators occur in the integrals in the numerator and in the denominator so that the influence of these spin and isobaric-spin operators may be expected roughly to cancel. (This is almost rigorously true for nuclei in the $1s$ shell, e.g., He_2^4, where $|a\rangle$ factorizes into $\Phi_a(\mathbf{r}_1,\cdots,\mathbf{r}_4)\times X_a(\sigma_1^{(3)},\cdots,\sigma_4^{(3)};\tau_1^{(3)},\cdots,\tau_4^{(3)})$ to a good approximation.) It thus appears reasonable to identity $G_a^{(\pm)}(\mathbf{r},\mathbf{r}')$ with $F_a^{(\pm)}(\mathbf{r},\mathbf{r}')$ so that from Eqs. (13a) and (10),

$$E_{\text{Coul}}=(\tfrac{1}{2}Z(Z-1))\left(\frac{6}{5}\frac{e^2}{r_0A^{\frac{1}{3}}}\left(1-\frac{(d/r_0)^2}{A^{\frac{2}{3}}}\right)\right)+(\tfrac{3}{4}Z-\langle a|(\mathbf{S}_{\text{pr}})^2|a\rangle)\left(\frac{6}{5}\frac{e^2}{r_0A^{\frac{1}{3}}}\frac{(d/r_0)^2}{A^{\frac{2}{3}}}\right). \quad (13c)$$

A "best fit" of Eq. (13c) to the experimentally determined Coulomb energy differences of various light and medium-heavy mirror nuclei yields

$$\frac{d}{r_0}=1.47;\quad \delta_a=3.0\ [\text{from Eq. (11b)}]. \quad (14)$$

In this "best fit" the value of r_0 used is consistent with the electron-nucleus elastic scattering data[9]—the d/r_0 values of the individual nuclei naturally fluctuate somewhat about the aforementioned "best fit" value so that an assignment of, say, 10% uncertainty to the resultant value of 3.0 for δ_a appears quite reasonable. Equations (11a) and (14) yield values of the total muon capture rate, $\Lambda^{(\mu)}(a)$, which can be compared with experiment—it is to be noted that the effect of the exclusion principle inhibition is very important numerically since

$$\{1-\mathcal{I}_a\}\cong\left\{1-\left(\frac{A-Z}{2A}\right)\delta_a\right\}\cong\left\{1-\left(\frac{A-Z}{2A}\right)3\right\}=\frac{1}{4}$$

for Ca_{20}^{40}; $=\frac{1}{8}$ for Ca_{20}^{48}; $=5/32$ for Mo_{42}^{96}; $=19/208$ for Pb_{82}^{208}, etc. The associated *isotope effect* in the total muon capture rate is thus expected to be quite large, e.g., $\Lambda^{(\mu)}(Ca_{20}^{48})/\Lambda^{(\mu)}(Ca_{20}^{40})\cong\frac{1}{2}$, and would be interesting to verify experimentally using separated isotope targets.

Alternatively, one need not appeal to any relation between $F_a^{(\pm)}(\mathbf{r},\mathbf{r}')$ and $G_a^{(\pm)}(\mathbf{r},\mathbf{r}')$ with $G_a^{(\pm)}(\mathbf{r},\mathbf{r}')$ found from E_{Coul} in order to determine δ_a, but adopt instead the less ambitious procedure of fitting Eq. (11a) for $\Lambda^{(\mu)}(a)$ to the available data for the total muon capture rates, with use of a single Z, A-independent adjustable parameter δ_a. A successful fit of this type would also determine $(\langle\eta\rangle_a)^2\mathcal{R}$, i.e., with a reliable estimate of $\langle\eta\rangle_a\cong\langle\nu\rangle_a/m_\mu$ [Eq. (3d)] would determine $\mathcal{R}\equiv((G_V^{(\mu)})^2+3(\Gamma_A^{(\mu)})^2)/((g_V^{(\beta)})^2+3(g_A^{(\beta)})^2)$ [Eq. (6b)]. A more rigorous treatment would involve use of Eq. (8) for $\Lambda^{(\mu)}(a)$, without neglect of terms $\sim 1/Z$, with $\int|\varphi(r)|^2\mathcal{D}_a(r)d\mathbf{r}\equiv(Z_{\text{eff}})^4/Z^4$ appropriately expressed via a proton density function $\mathcal{D}_a(r)$ obtained from electron-nucleus elastic scattering data,[9] and with the nucleon-nucleon correlation density functions $F_a^{(\pm)}(\mathbf{r},\mathbf{r}')$, again identified with $G_a^{\pm}(\mathbf{r},\mathbf{r}')$ as deduced from an analysis of *inelastic* electron-nucleus scattering.[9] Such a more rigorous treatment must await the performance and the interpretation of the appropriate inelastic electron-nucleus scattering experiments.[10]

[8] E. Feenberg and G. Goertzel, Phys. Rev. **70**, 597 (1946).

[9] R. Hofstadter, Ann. Rev. Nuclear Sci. **7**, 231 (1957).

[10] H. A. Tolhoek, in a preprint received after this manuscript was completed, has applied the closure approximation to the calculation of $\Lambda^{(\mu)}(a)$ in a manner which, in effect, involves the expansion of $\exp(i\langle\nu\rangle_a\mathbf{v}_1\cdot\mathbf{r}_{ij})$ or of $\sin(\langle\nu\rangle_a r_{ij})/(\langle\nu\rangle_a r_{ij})$ [as in Eq. (4a) or (6c) or (8)] in powers of $\langle\nu\rangle_a r_{ij}\approx\langle\nu\rangle_a r_0A^{\frac{1}{3}}$. Tolhoek keeps terms only up to $(\langle\nu\rangle_a r_{ij})^2$ in this expansion. It is however to be emphasized that such an expansion converges rather slowly for the heavier nuclei ($Z>6$, $A>12$) and the results obtained by means of it are quite unreliable. It is to be noted that, contrary to the impression given by Tolhoek, no such expansion is used in the present procedure in the crucial passage from Eq. (8) to Eq. (11a).

TABLE I.

	$\langle\nu\rangle_a/m_\mu$	$(\langle\eta\rangle_a)^2$	$\langle a\vert(\mathbf{T})^2-(\mathbf{T}^{(3)})^2\vert a\rangle$	$\langle a\vert(\mathbf{Y}^{(1)})^2+(\mathbf{Y}^{(2)})^2\vert a\rangle$	$\langle a\vert(\mathbf{S}_{pr})^2+(\mathbf{S}_{neu})^2-(\mathbf{S}_{pr}+\mathbf{S}_{neu})^2\vert a\rangle$
H_1^1	0.94	0.58	1/2	3/2	0
H_1^2	0.90	0.65	0	2	−1/2
He_2^3	0.95	0.78	1/2	3/2	0
He_2^4	0.75	0.50	0	0	0

In concluding this section we apply Eq. (8) for $\Lambda^{(\mu)}(a)$ to the light nuclei H_1^1, H_1^2, He_2^3, He_2^4. We have from Table I and Eq. (8),

$$\Lambda^{(\mu)}(H_1^1)=1^4\times0.58\times272\ \text{sec}^{-1}\times\mathfrak{R}\times1,$$

$$\Lambda^{(\mu)}(H_1^2)\cong1^4\times0.65\times272\ \text{sec}^{-1}\times\mathfrak{R}\times\left\{1-\left[\frac{(G_V^{(\mu)})^2+(\Gamma_A^{(\mu)})^2}{(G_V^{(\mu)})^2+3(\Gamma_A^{(\mu)})^2}\right]\left[\int\int\frac{\sin(\langle\nu\rangle_a\vert\mathbf{r}-\mathbf{r}'\vert)}{(\langle\nu\rangle_a\vert\mathbf{r}-\mathbf{r}'\vert)}F_a^{(+)}(\mathbf{r},\mathbf{r}')d\mathbf{r}d\mathbf{r}'\right]\right\},\tag{15}$$

$$\Lambda^{(\mu)}(He_2^3)\cong2^4\times0.78\times272\ \text{sec}^{-1}\times\mathfrak{R}\times\left\{1-\frac{1}{2}\left[\int\int\frac{\sin(\langle\nu\rangle_a\vert\mathbf{r}-\mathbf{r}'\vert)}{(\langle\nu\rangle_a\vert\mathbf{r}-\mathbf{r}'\vert)}F_a^{(+)}(\mathbf{r},\mathbf{r}')d\mathbf{r}d\mathbf{r}'\right]\right\},$$

$$\Lambda^{(\mu)}(He_2^4)\cong2^4\times0.50\times272\ \text{sec}^{-1}\times\mathfrak{R}\times\left\{1-\left[\int\int\frac{\sin(\langle\nu\rangle_a\vert\mathbf{r}-\mathbf{r}'\vert)}{(\langle\nu\rangle_a\vert\mathbf{r}-\mathbf{r}'\vert)}F_a^{(+)}(\mathbf{r},\mathbf{r}')d\mathbf{r}d\mathbf{r}'\right]\right\},$$

which exhibits forms for the corresponding exclusion principle inhibition factors, $\mathcal{I}_a$ [Eqs. (15) and (6a) to (6c)]. With regard to the first two columns of Table I for $\langle\nu\rangle_a$ [Eq. (2c)] and $\langle\eta\rangle_a$ [Eq. (3c)] reasonable estimates have been made for $\langle E_b-E_a\rangle=\langle$excitation energy of daughter nucleus $b\rangle+((E_b)_{\text{ground state}}-E_a)$; also $\varphi(r)\approx\exp(-Zm_\mu' r/137)$ has been approximated by 1 within the integrals. Further, from Eq. (7b), the $\mathbf{r}_i$ being here coordinates relative to the nucleus' center of mass,

$$F_a^{(+)}(\mathbf{r},\mathbf{r}')=\int\int|\Phi_a(\mathbf{r}_1,\mathbf{r}_2)|^2\delta(\mathbf{r}_1+\mathbf{r}_2)\delta(\mathbf{r}-\mathbf{r}_1)\delta(\mathbf{r}'-\mathbf{r}_2)d\mathbf{r}_1d\mathbf{r}_2=|\Phi_a(\mathbf{r},\mathbf{r}')|^2\delta(\mathbf{r}+\mathbf{r}'):H_1^2$$

$$F_a^{(+)}(\mathbf{r},\mathbf{r}')=\int\int\int|\Phi_a(\mathbf{r}_1,\mathbf{r}_2,\mathbf{r}_3)|^2\delta(\mathbf{r}_1+\mathbf{r}_2+\mathbf{r}_3)\delta(\mathbf{r}-\mathbf{r}_1)\delta(\mathbf{r}'-\mathbf{r}_2)d\mathbf{r}_1d\mathbf{r}_2d\mathbf{r}_3=|\Phi_a[\mathbf{r},\mathbf{r}',-(\mathbf{r}+\mathbf{r}')]|^2:He_2^3\tag{16}$$

$$F_a^{(+)}(\mathbf{r},\mathbf{r}')=\int\int\int\int|\Phi_a(\mathbf{r}_1,\mathbf{r}_2,\mathbf{r}_3,\mathbf{r}_4)|^2\delta(\mathbf{r}_1+\mathbf{r}_2+\mathbf{r}_3+\mathbf{r}_4)\delta(\mathbf{r}-\mathbf{r}_1)\delta(\mathbf{r}'-\mathbf{r}_2)d\mathbf{r}_1d\mathbf{r}_2d\mathbf{r}_3d\mathbf{r}_4$$

$$=\int|\Phi_a[\mathbf{r},\mathbf{r}',\mathbf{r}_3,-(\mathbf{r}+\mathbf{r}'+\mathbf{r}_3)]|^2d\mathbf{r}_3:He_2^4,$$

where the Φ_a are space wave functions in the corresponding H_1^2, He_2^3, He_2^4 space, spin, isobaric-spin wave functions $|a\rangle\cong\Phi_a(\mathbf{r}_1,\mathbf{r}_2,\cdots)X_a(\sigma_1^{(3)},\sigma_2^{(3)},\cdots;\tau_1^{(3)},\tau_2^{(3)},\cdots)$ with $\Phi_a(\mathbf{r}_1,\mathbf{r}_2,\cdots)=\Phi_a(r_{12},\cdots)=P_{ij}\Phi_a(\mathbf{r}_1,\mathbf{r}_2,\cdots)$. The appropriate spin, isobaric-spin wave functions, X_a, have been used together with Eq. (7e) in order to obtain the entries in the last three columns of Table I. Use of simple variational trial forms for Φ_a enables evaluation of the $F_a^{(+)}(\mathbf{r},\mathbf{r}')$ in Eq. (16) which, together with the $\langle\nu\rangle_a$ estimates of the first column, give the integrals in Eq. (15). Employing also numerical values of $\mathfrak{R}$ quoted below [Eq. (19)] and a value of $(\Gamma_A^{(\mu)}/G_V^{(\mu)})^2=1.53$ calculated from Eqs. (1b), (1c), and (4b) with $(g_A^{(\beta)}/g_V^{(\beta)})=-1.21$,[11] we obtain

$$\Lambda^{(\mu)}(H_1^1)=1^4\times0.58\times272\ \text{sec}^{-1}\times\mathfrak{R}\times1=158\ \text{sec}^{-1}\times\mathfrak{R}=169\ \text{sec}^{-1},$$

$$\Lambda^{(\mu)}(H_1^2)\cong1^4\times0.65\times272\ \text{sec}^{-1}\times\mathfrak{R}\times\left\{1-\left[\frac{(G_V^{(\mu)})^2+(\Gamma_A^{(\mu)})^2}{(G_V^{(\mu)})^2+3(\Gamma_A^{(\mu)})^2}\right]\times0.64\right\}$$

$$=177\ \text{sec}^{-1}\times\mathfrak{R}\times\left\{1-\left[\frac{1+(\Gamma_A^{(\mu)}/G_V^{(\mu)})^2}{1+3(\Gamma_A^{(\mu)}/G_V^{(\mu)})^2}\right]\times0.64\right\}=135\ \text{sec}^{-1}\tag{17}$$

$$\Lambda^{(\mu)}(He_2^{(3)})\cong2^4\times0.78\times272\ \text{sec}^{-1}\times\mathfrak{R}\times(1-\tfrac{1}{2}\times0.66)=23\times10^2\ \text{sec}^{-1}\times\mathfrak{R}=25\times10^2\ \text{sec}^{-1}$$

$$\Lambda^{(\mu)}(He_2^{(4)})\cong2^4\times0.50\times272\ \text{sec}^{-1}\times\mathfrak{R}\times(1-0.80)=4.4\times10^2\ \text{sec}^{-1}\times\mathfrak{R}=4.7\times10^2\ \text{sec}^{-1}.$$

The dependence of $\Lambda^{(\mu)}(H_1^2)$ on the ratio $(\Gamma_A{}^{(\mu)}/G_V{}^{(\mu)})^2$ is especially to be noted[12] as is the enormous isotope effect—factor $\cong 5$—between $\Lambda^{(\mu)}(He_2^3)$ and $\Lambda^{(\mu)}(He_2^4)$. Both of these are essentially manifestations of the inhibitions of the exclusion principle on the total muon capture rate. Thus in $\mu^-+H_1^2 \rightarrow \nu+n+n$ the dineutron must be produced in the ${}^3P_1$ state if $\Gamma_A{}^{(\mu)}=0$ while for $|\Gamma_A{}^{(\mu)}| \gtrsim G_V{}^{(\mu)}$ production in the dineutron ${}^1S_0$ state is possible. Since the dineutron ${}^1S_0$ state spatially overlaps far better with the deuteron ground ${}^3S_1$ state than does the dineutron ${}^3P_1$ state, dineutron production in the ${}^1S_0$ state when $|\Gamma_A{}^{(\mu)}| \gtrsim G_V{}^{(\mu)}$ is indeed predominant, and one expects $\Lambda^{(\mu)}(H_1^2)$ to be greater when $(\Gamma_A{}^{(\mu)}/G_V{}^{(\mu)})^2 \gg 1$ than when $(\Gamma_A{}^{(\mu)}/G_V{}^{(\mu)})^2 \ll 1$ just as predicted by Eq. (17). In a similar way the factor of 5 difference between the rates of $\mu^-+He_2^3 \rightarrow \nu+H_1^3$ and $\mu^-+He_2^4 \rightarrow \nu+H_1^4$ may be viewed as largely arising from the fact that the H_1^3 may be formed in ${}^2S_{\frac{1}{2}}$ states (bound or unbound) which spatially overlap well with the ${}^2S_{\frac{1}{2}}$ ground state of He_2^3 while the H_1^4 is formed in (unbound) ${}^3P_{2,1,0}$, ${}^1P_0$ states which all have a poor spatial overlap with the ${}^1S_0$ ground state of He_2^4.

3. COMPARISON OF CLOSURE APPROXIMATION EXPRESSION FOR THE TOTAL MUON CAPTURE RATE WITH EXPERIMENT

Equation (11a) for $\Lambda^{(\mu)}(a)$ has been compared by Telegdi, Sens, Swanson, and Yovanovitch[13] with their definitive measurements of the total muon capture rates in 29 elements from C_6^{12} to U_{92}^{238}. These investigators first calculated values of $(Z_{\text{eff}})^4$ [according to Eq. (4c)] for the various elements studied and then found that a plot of their $[\Lambda^{(\mu)}(a)]_{\text{exper}}/(Z_{\text{eff}})^4$ values *versus* the corresponding $(A-Z)/2A$ values gave a nice straight line in agreement with Eq. (11a); the values of δ_a and $[(\langle\eta_a\rangle_a)^2(272\ \text{sec}^{-1})\mathfrak{R}]$, determined by a weighted least squares fit of their individual experimental points to this straight line, were

$$\delta_a=3.15 \quad [vs\ \delta_a=3.0 \text{ in Eq. (14)}] \qquad (18a)$$

and

$$(\langle\eta\rangle_a)^2(272\ \text{sec}^{-1})\mathfrak{R}=188\ \text{sec}^{-1}\ \text{(experimental)}. \qquad (18b)$$

On the other hand, Eqs. (1b), (1c), (4b), (6b), and (3d), and $(g_A{}^{(\beta)}/g_V{}^{(\beta)})=-1.21$ [11] yield:

$$\mathfrak{R}=\begin{matrix}1.06:\langle\eta\rangle_a\cong\langle\nu\rangle_a/m_\mu\cong 0.75\\ 1.07:\langle\eta\rangle_a\cong\langle\nu\rangle_a/m_\mu\cong 0.85-0.95,\end{matrix} \qquad (19)$$

while the best *a priori* estimate for

$$\langle\eta\rangle_a\cong\langle\nu\rangle_a/m_\mu\cong\{1-(\epsilon_a/m_\mu -\langle\text{excitation energy of daughter nucleus } b\rangle/m_\mu -[(E_b)_{\text{ground state}}-E_a]/m_\mu\},$$

[Eq. (3d)] supposed valid in the mean for all the various pairs of nuclei (b,a) involved, is $\langle\eta\rangle_a\cong\langle\nu\rangle_a/m_\mu\cong 0.75=80$ Mev/m_μ with an uncertainty of, say, 10%. This value of $\langle\nu\rangle_a/m_\mu$ corresponds to an $\langle$excitation energy of daughter nucleus $b\rangle\cong 15$ Mev which is of the order of those empirically observed. The value of $(\langle\eta\rangle_a)^2(272\ \text{sec}^{-1})\mathfrak{R}$ for $\langle\eta\rangle_a\cong\langle\nu\rangle_a/m_\mu\cong 0.75=80$ Mev/m_μ is, using Eq. (19);

$$(\langle\eta\rangle_a)^2(272\ \text{sec}^{-1})\mathfrak{R}=161\ \text{sec}^{-1}\ \text{(theoretical)} \qquad (20)$$

which, in view of the uncertainty in the value of $(\langle\eta\rangle_a)^2$, must be considered in essential agreement with the experimental value of 188 sec^{-1} [Eq. (18b)]—thus, for example, the not unreasonable choice of $\langle\nu\rangle_a/m_\mu \cong 0.80=85$ Mev/m_μ yields $(\langle\eta\rangle_a)^2(272\ \text{sec}^{-1})\mathfrak{R}=185$ sec^{-1} (theoretical). In this way one finds support for the combination of basic assumptions on which our effective Hamiltonian $H_{\text{eff}}{}^{(\mu)}$ [Eqs. (1a) to (1c)] rests, *viz.*: (a) "universality" between muon-bare nucleon and electron-bare nucleon coupling constants which implies the numerical relations of Eq. (1c) between the effective muon-dressed nucleon and electron-dressed nucleon coupling constants; (b) the presence of an "induced" pseudoscalar interaction[3,4] with an effective muon-dressed nucleon coupling constant $g_P{}^{(\mu)}=8g_A{}^{(\beta)}$ [Eq. (1c)]; and (c) the presence of anomalous nucleon magnetic moment contributions in the effective muon-dressed nucleon interaction associated with the assumption of a "conserved vector current." [5] In particular, if this assumption of the conserved vector current is abandoned and the anomalous nucleon magnetic moment contributions $\sim(\mu_p-\mu_n)$ to the effective muon-dressed coupling constants $G_A{}^{(\mu)}$, $G_p{}^{(\mu)}$ omitted from Eqs. (1b), (4b), and (6b), the quantity $\mathfrak{R}$ of Eq. (6b) is 0.90 rather than 1.06 and

$$(\langle\eta\rangle_a)^2(272\ \text{sec}^{-1})\mathfrak{R}=137\ \text{sec}^{-1}\ \text{(theoretical)}. \qquad (20)$$

It thus appears that somewhat better agreement is reached between theoretical and experimental values of the total muon capture rates if the assumption of a conserved vector current is retained.

4. MUON CAPTURE TO PARTICULAR FINAL STATES OF DAUGHTER NUCLEUS

The first investigation in which a *partial* muon capture rate was determined is due to Godfrey.[14] Godfrey studied experimentally the rate of that muon capture reaction

$$\mu^-+C_6^{12} \rightarrow \nu+B_5^{12}$$

[12] H. Primakoff, Phys. Rev. **91**, 480 (A) (1953), and *Proceedings of the Fifth Annual Rochester Conference on High Energy Physics*, New York (1955), p. 174; A. Rudik, Doklady Akad. Nauk. **92**, 739 (1953); H. Überall and L. Wolfenstein, Nuovo cimento **10**, 136 (1958).

[13] V. Telegdi (private communication); Sens, Swanson, Telegdi, and Yovanovitch, Phys. Rev. **107**, 1464 (1957); J. Sens, Ph.D. thesis, University of Chicago (1958) and Phys. Rev. **113**, 679 (1959).

[14] T. N. K. Godfrey, Ph.D. thesis, Princeton University (1954), and Phys. Rev. **92**, 512 (1953).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

which was followed by the beta decay of B_5^{12} and accordingly obtained the partial rate of muon capture to all the bound states of B_5^{12}. He further gave a qualitative argument in favor of the view that most of the muon capture transitions to the bound states of B_5^{12} actually go to the ground state of B_5^{12}. As a result he identified his *observed* partial muon capture rate with the rate from C_6^{12} to the B_5^{12} ground state. Godfrey then established an approximate theoretical relation between the nuclear matrix elements for muon capture and for beta decay between the ground states of C_6^{12} and B_5^{12}. By using this relation and comparing his observed muon capture rate with the known B_5^{12} decay rate he concluded that the Gamow-Teller coupling constants in muon capture and in beta decay are approximately equal.

Fujii and Primakoff[1] recently re-examined and refined the relation between the nuclear matrix elements for muon capture and for beta decay between the ground states of C_6^{12} and B_5^{12}, and also extended the argument to the calculation of the ground state to ground-state partial muon capture rates in the reactions,

$$\mu^-+\mathrm{Li}_3^6 \rightarrow \nu+\mathrm{He}_2^6,$$
$$\mu^-+\mathrm{He}_2^3 \rightarrow \nu+\mathrm{H}_1^3.$$

Using the expressions for the muon capture transition matrix elements, $\mathrm{M.E.}^{(\mu)}$, given in Eqs. (2a) and (2b) and the analogous expressions for the corresponding beta-decay transition matrix elements, $\mathrm{M.E.}^{(\beta)}$,

$$|\mathrm{M.E.}^{(\beta)}|^2 = \frac{1}{(2\pi)^6} F_{ba}(Z,E_e)\,|\mathrm{M.E._{nucl}}^{(\beta)}(b\rightarrow a)|^2, \quad (21a)$$

$$|\mathrm{M.E._{nucl}}^{(\beta)}(b\rightarrow a)|^2 = (g_V{}^{(\beta)})^2|\langle a|\textstyle\sum_i \tau_i{}^{(+)}|b\rangle|^2 + (g_A{}^{(\beta)})^2|\langle a|\textstyle\sum_i \tau_i{}^{(+)}\boldsymbol{\sigma}_i|b\rangle|^2. \quad (21b)$$

Fujii and Primakoff obtained an expression for the ratio of transition rates of muon capture from $|a\rangle$ to $|b\rangle$ and beta decay from $|b\rangle$ to $|a\rangle$, $\Lambda^{(\mu)}(a\rightarrow b)/\Lambda^{\beta}(b\rightarrow a)$,

$$\frac{\Lambda^{(\mu)}(a\rightarrow b)}{\Lambda^{(\beta)}(b\rightarrow a)} = \left[\pi(\eta_{ba})^2\frac{Z^3 m_\mu{}^5}{(137)^3}\frac{1}{f_{ba}}\right]\times\left(\frac{2J_b+1}{2J_a+1}\right) \times\left[\frac{\int\frac{d\nu_1}{4\pi}\sum_{M_b,M_a}|\mathrm{M.E._{nucl}}^{(\mu)}(a\rightarrow b)|^2}{\sum_{M_b,M_a}|\mathrm{M.E._{nucl}}^{(\beta)}(b\rightarrow a)|^2}\right] \equiv k\times\left(\frac{2J_b+1}{2J_a+1}\right)\times X, \quad (22a)$$

where

$$f_{ba}=\int_1^{(E_e)_{\max}} = F_{ba}(Z,E_e)((E_e)_{\max}-E_e)^2 \times E_e((E_e)^2-1)^{\frac{1}{2}}dE_e \quad (22b)$$

$F_{ba}(Z,E)$ = Fermi function.

Fujii and Primakoff then calculated, employing appropriate approximations for $|a\rangle$, $|b\rangle$, the ratio of the nuclear matrix elements for muon capture and for beta decay—X in Eq. (22a)—as:

$$X(\mathrm{He}_2^3 \leftrightarrows \mathrm{H}_1^3)=0.791$$
$$X(\mathrm{Li}_3^6 \leftrightarrows \mathrm{He}_2^6)=0.619 \quad (23)$$
$$X(\mathrm{C}_6^{12} \leftrightarrows \mathrm{B}_5^{12})=0.612$$

and, using also known values for η_{ba} [Eq. (3c)] and $\Lambda^{(\beta)}(b\rightarrow a)/f_{ba}=\ln 2/[f_{ba}\tau_{\frac{1}{2}}(b\rightarrow a)]$, found, from Eqs. (23) and (22a),

$$\Lambda^{(\mu)}(\mathrm{He}_2^3\rightarrow \mathrm{H}_1^3)=1.46\times10^3\ \mathrm{sec}^{-1},$$
$$\Lambda^{(\mu)}(\mathrm{Li}_3^6\rightarrow \mathrm{He}_2^6)=1.79\times10^3\ \mathrm{sec}^{-1}, \quad (24)$$
$$\Lambda^{(\mu)}(\mathrm{C}_6^{12}\rightarrow \mathrm{B}_5^{12})=7.86\times10^3\ \mathrm{sec}^{-1},$$

with an over-all uncertainty of some 10 to 15%. A calculation by Wolfenstein,[15] based on general assumptions entirely similar to those of Fujii and Primakoff, yields $\Lambda^{(\mu)}(\mathrm{C}_6^{12}\rightarrow \mathrm{B}_5^{12})=7.4\times10^3\ \mathrm{sec}^{-1}$.

As regards experimental values of $\Lambda^{(\mu)}(a\rightarrow b)$, data are at present available only in the $\mathrm{C}_6^{12}\rightarrow \mathrm{B}_5^{12}$ case and are:

$$[\Lambda^{(\mu)}(\mathrm{C}_6^{12}\rightarrow \mathrm{B}_5^{12})]_{\mathrm{exper}} = \begin{cases} (9.05\pm0.95)\times10^3\ \mathrm{sec}^{-1},{}^{16} \\ (9.18\pm0.5)\times10^3\ \mathrm{sec}^{-1},{}^{17} \\ (6.6\pm1.1)\times10^3\ \mathrm{sec}^{-1},{}^{18} \\ (6.8\pm1.5)\times10^3\ \mathrm{sec}^{-1},{}^{19} \\ (5.9\pm1.5)\times10^3\ \mathrm{sec}^{-1}.{}^{14} \end{cases} \quad (25)$$

TABLE II.

$\Lambda^{(\mu)}(C_6^{12}\to B_5^{12})$ in $sec^{-1}\times10^{-3}$	Terms $\sim(\mu_p-\mu_n)$	$g_P^{(\mu)}/g_A^{(\beta)}$
7.86	included	+8
6.34	omitted	+8
11.80	included	−8
10.25	omitted	−8

It is thus clear, from Eqs. (24) and (25), that the theoretical value of $\Lambda^{(\mu)}(C_6^{12}\to B_5^{12})$ agrees, within the over-all theoretical and experimental uncertainties, with the corresponding experimental value. This agreement offers further support for the validity of our effective Hamiltonian $H_{\text{eff}}^{(\mu)}$ [Eqs. (1a) to (1c)].

It may be of interest in concluding this section to append a table—Table II—giving the theoretical values of $\Lambda^{(\mu)}(C_6^{12}\to B_5^{12})$ with the assumption of the conserved vector current abandoned, i.e., with anomalous magnetic moment contributions $[\sim(\mu_p-\mu_n)]$ to $G_A^{(\mu)}$, $G_P^{(\mu)}$ [Eq. (1b)] omitted and with $g_P^{(\mu)}$ {within $G_P^{(\mu)}$ [Eq. (1c)]} taken as $-8g_A^{(\beta)}$ as well as $+8g_A^{(\beta)}$. Such an ambiguity in the sign of $g_P^{(\mu)}/g_A^{(\beta)}$ may be contemplated since, without a sufficiently detailed theory of the $\pi^+\to\mu^++\nu$ process,[3] one can fix, on the basis of the known π^+ lifetime, only the square of the effective coupling constant for the $\mu^-+\pi^+\to\nu$ "step" [3,4] in the $\mu^-+p\to\mu^-+\pi^++n\to\nu+n$ "two-step" process. We find from Eqs. (2a), (2b), (21a) to (22b), (1b), and (1c), the numerical results given in Table II. These results, together with the values of $[\Lambda^{(\mu)}(C_6^{12}\to B_5^{12})]_{\text{exper}}$ in Eq. (25), indicate that (1) assumption of $g_P^{(\mu)}/g_A^{(\beta)}=-8$, which is inconsistent with the usually accepted detailed theory of the $\pi^+\to\mu^++\nu$ process which involves the dominance of the $p+\bar{n}$ "intermediate state",[3] yields values of $\Lambda^{(\mu)}(C_6^{12}\to B_5^{12})$ which fit experiment less well than values of $\Lambda^{(\mu)}(C_6^{12}\to B_5^{12})$ calculated with the assumption of $g_P^{(\mu)}/g_A^{(\beta)}=+8$; (2) if future observations uphold the first pair of experimental values in Eq. (25), use of $g_P^{(\mu)}/g_A^{(\beta)}=+8$ will, for agreement between experiment and theory of $\Lambda^{(\mu)}(C_6^{12}\to B_6^{12})$, require inclusion of the anomalous magnetic moment contributions to $G_A^{(\mu)}$, $G_P^{(\mu)}$ and so support the assumption of a conserved vector current. This last conclusion agrees with that reached at the end of Sec. 3 on the basis of a comparison of experiment and theory for the total muon capture rate, $\Lambda^{(\mu)}(a)$.

5. "HYPERFINE" EFFECT IN MUON CAPTURE RATE—MUON CAPTURE IN HYDROGEN

The total muon capture rate, $\Lambda^{(\mu)}(a)$, calculated in Sec. 2 or the partial muon capture rate, $\Lambda^{(\mu)}(a\to b)$, calculated in Sec. 4 are actually appropriate averages of the total or partial muon capture rates from the two individual hyperfine states of the parent mu-mesic atom, $\Lambda^{(\mu)}(J_a\pm\frac{1}{2};a)$ or $\Lambda^{(\mu)}(J_a\pm\frac{1}{2};a\to b)$, e.g.,

$$\Lambda^{(\mu)}(a)=\frac{2J_a+2}{4J_a+2}\Lambda^{(\mu)}(J_a+\tfrac{1}{2};a)+\frac{2J_a}{4J_a+2}\Lambda^{(\mu)}(J_a-\tfrac{1}{2};a). \tag{26}$$

Equation (26) represents such an appropriate average for $\Lambda^{(\mu)}(a)$ in terms of $\Lambda^{(\mu)}(J_a\pm\frac{1}{2};a)$; this average is "incoherent" and is weighted only according to the degeneracies of the two hyperfine states involved since (1) the energy difference, $\delta\epsilon_a$, between these two hyperfine states is much greater than their width, i.e.,

$$\delta\epsilon_a\gg\hbar[\Lambda_{\text{decay}}{}^{(\mu)}+\Lambda^{(\mu)}(J_a+\tfrac{1}{2};a)];$$

$$\delta\epsilon_a\gg\hbar[\Lambda_{\text{decay}}{}^{(\mu)}+\Lambda^{(\mu)}(J_a-\tfrac{1}{2};a)];$$

and (2) the rate of conversion from one of these states to the other is (with the exception of hydrogen and deuterium) sufficiently smaller than $\Lambda_{\text{decay}}{}^{(\mu)}+\Lambda^{(\mu)}(J_a\pm\frac{1}{2};a)$ for the various mu-mesic atoms of interest.[20] The physical reason for the difference between $\Lambda^{(\mu)}(J_a+\frac{1}{2};a)$ and $\Lambda^{(\mu)}(J_a-\frac{1}{2};a)$ arises, as discussed by Bernstein, Lee, Yang, and Primakoff [21] (B.L.Y. and P.), from the combined action of the following three effects (1) the correlation between the spin of the muon, $\frac{1}{2}\boldsymbol{\sigma}$, and the spin of the parent nucleus $\mathbf{J}_a$ is different in the two hyperfine states $F_a^{(\pm)}=J_a\pm\frac{1}{2}$; (2) there is, in general, a correlation between the spin $\frac{1}{2}\boldsymbol{\sigma}_i$ of the proton that captures the muon and $\mathbf{J}_a$; (3) the capture rate of the muon by the proton depends on their relative spin orientation via the terms $G_A^{(\mu)}\boldsymbol{\sigma}\cdot\boldsymbol{\sigma}_i$ and $G_P^{(\mu)}\boldsymbol{\sigma}\cdot\boldsymbol{\nu}_1\boldsymbol{\sigma}_i\cdot\boldsymbol{\nu}_1$ in the effective Hamiltonian $H_{\text{eff}}^{(\mu)}$ of Eqs. (1a) to (1c).

The total muon capture rates from the two individual hyperfine states $F_a^{(\pm)}=J_a\pm\frac{1}{2}$, $\Lambda^{(\mu)}(J_a\pm\frac{1}{2};a)$, can be calculated on the basis of the $H_{\text{eff}}^{(\mu)}$ of Eqs. (1a) to (1c) by the closure approximation method described in Sec. 2. By using a procedure similar to that involved in the derivation of Eqs. (3a) to (8) we find that

---

[20] Conversion from the energetically higher to the energetically lower of the two hyperfine mu-mesic atom states occurs (1) via collisions with atoms of the muon moderating medium—this is important only for the electrically neutral and hence mobile hydrogen and deuterium mu-mesic atoms—see below; (2) via spontaneous magnetic dipole radiation; (3) via Auger electron ejection. The rates of (2) and (3) may be readily estimated and are, respectively:

$$R_{(2)}\approx10\left(\frac{1}{137}\right)^{13}(Z_{\text{eff}})^9\left(\frac{m_\mu}{m_p}\right)^3\frac{m_\mu c^2}{\hbar}$$

and

$$R_{(3)}\approx10\left(\frac{1}{137}\right)^{6}Z\left(\frac{m_e}{m_\mu}\right)^3\frac{m_\mu c^2}{\hbar},$$

so that for example, $R_{(2)}\approx1\times10^3$ sec^{-1}, $R_{(3)}\approx4\times10^5$ sec^{-1} for $Al_{13}{}^{27}$; on the other hand, the value of

$$\{\Lambda_{\text{decay}}{}^{(\mu)}+\Lambda^{(\mu)}(J_a\pm\tfrac{1}{2};a)\}$$

for $Al_{13}{}^{27}$ is $\approx1.2\times10^6$ sec^{-1}.

$$\alpha_a{}'^{(\pm)}\equiv\left[\int\int\frac{\sin(\langle\nu\rangle_a|\mathbf{r}-\mathbf{r}'|)}{(\langle\nu\rangle_a|\mathbf{r}-\mathbf{r}'|)}\varphi^*(r)\varphi(r')\tfrac{1}{2}(F_a{}'^{(+)}(\mathbf{r},\mathbf{r}')\pm F_a{}'^{(-)}(\mathbf{r},\mathbf{r}'))d\mathbf{r}d\mathbf{r}'\right]\Big/\left[\int|\varphi(r)|^2\mathfrak{D}_a{}'(r)d\mathbf{r}\right],\tag{27b}$$

$$\mathfrak{D}_a{}'(r)\equiv\frac{1}{2J_a+1}\sum_{M_a}\frac{\langle E_a,J_a,M_a|\mathbf{J}\cdot\sum_i[(1+\tau_i{}^{(3)})/2]\boldsymbol{\sigma}_i\delta(\mathbf{r}-\mathbf{r}_i)|E_a,J_a,M_a\rangle}{\langle E_a,J_a,M_a|\mathbf{J}\cdot\sum_i[(1+\tau_i{}^{(3)})/2]\boldsymbol{\sigma}_i|E_a,J_a,M_a\rangle},$$

$$F_a{}'^{(\pm)}(\mathbf{r},\mathbf{r}')\equiv\frac{\langle a|\mathbf{J}\cdot\sum'_{i,j}[\frac{1}{4}(\boldsymbol{\tau}_i\cdot\boldsymbol{\tau}_j-\tau_i{}^{(3)}\tau_j{}^{(3)})(b^{(\mu)}+d^{(\mu)})(\boldsymbol{\sigma}_i+\boldsymbol{\sigma}_j)-\frac{1}{4}(\boldsymbol{\tau}_i\times\boldsymbol{\tau}_j)^{(3)}(b^{(\mu)}-d^{(\mu)})(\boldsymbol{\sigma}_i\times\boldsymbol{\sigma}_j)]\times[\delta(\mathbf{r}-\mathbf{r}_i)\delta(\mathbf{r}'-\mathbf{r}_j)](1+P_{ij})/2|a\rangle}{\langle a|\mathbf{J}\cdot\sum'_{i,j}[\frac{1}{4}(\boldsymbol{\tau}_i\cdot\boldsymbol{\tau}_j-\tau_i{}^{(3)}\tau_j{}^{(3)})(b^{(\mu)}+d^{(\mu)})(\boldsymbol{\sigma}_i+\boldsymbol{\sigma}_j)-\frac{1}{4}(\boldsymbol{\tau}_i\times\boldsymbol{\tau}_j)^{(3)}(b^{(\mu)}-d^{(\mu)}(\boldsymbol{\sigma}_i\times\boldsymbol{\sigma}_j)]\times(1+P_{ij})/2|a\rangle},$$

$$\alpha_a{}^{(\pm)}\equiv\left[\int\int\frac{\sin(\langle\nu\rangle_a|\mathbf{r}-\mathbf{r}'|)}{(\langle\nu\rangle_a|\mathbf{r}-\mathbf{r}'|)}\varphi^*(r)\varphi(r')\tfrac{1}{2}(F_a{}^{(+)}(\mathbf{r},\mathbf{r}')\pm F_a{}^{(-)}(\mathbf{r},\mathbf{r}'))d\mathbf{r}d\mathbf{r}'\right]\Big/\left[\int|\varphi(r)|^2\mathfrak{D}_a(r)d\mathbf{r}\right],$$

$$\gamma_a{}^{(+)}\equiv\langle a|(G_V{}^{(\mu)})^2((\mathbf{T})^2-(T^{(3)})^2)+(\Gamma_A{}^{(\mu)})^2((\mathbf{Y}^{(1)})^2+(\mathbf{Y}^{(2)})^2)|a\rangle,$$

$$\gamma_a{}^{(-)}\equiv((G_V{}^{(\mu)})^2-(\Gamma_A{}^{(\mu)})^2)\langle a|(\mathbf{S}_{\rm pr})^2+(\mathbf{S}_{\rm neu})^2-(\mathbf{S}_{\rm pr}+\mathbf{S}_{\rm neu})^2|a\rangle.$$

We now apply Eq. (27a) to the case of an odd Z, odd A nucleus so that $\langle a|2\mathbf{J}\cdot\mathbf{S}_{\rm neu}|a\rangle=0$. Considering also the heavier nuclei, $Z>6$, $A>12$, and hence dropping terms $\sim 1/Z$ within the curly bracket of Eq. (27a), we have:

$$\frac{\Lambda^{(\mu)}(J_a\pm\tfrac{1}{2};a)}{\Lambda^{(\mu)}(a)}-1\cong\pm(J_a+\tfrac{1}{2}\pm\tfrac{1}{2})^{-1}\frac{b^{(\mu)}}{a^{(\mu)}}\frac{\langle a|2\mathbf{J}\cdot\mathbf{S}_{\rm pr}|a\rangle}{Z}\left\{\frac{\xi_a-\left[\frac{1}{2}-\frac{1}{2}\frac{\langle a|2\mathbf{J}\cdot\mathbf{K}|a\rangle}{\langle a|2\mathbf{J}\cdot\mathbf{S}_{\rm pr}|a\rangle}\right]\alpha_a{}'^{(+)}-\left[\frac{A-Z}{2}\right]\alpha_a{}'^{(-)}}{1-[A/2Z]\alpha_a{}^{(+)}-[(A-Z)/2]\alpha_a{}^{(-)}}\right\}\tag{28a}$$

so that

$$\frac{\Lambda^{(\mu)}(J_a+\tfrac{1}{2};a)-\Lambda^{(\mu)}(J_a-\tfrac{1}{2};a)}{\Lambda^{(\mu)}(a)}\cong\frac{2J_a+1}{J_a(J_a+1)}\frac{b^{(\mu)}}{a^{(\mu)}}\frac{\langle a|2\mathbf{J}\cdot\mathbf{S}_{\rm pr}|a\rangle}{Z}\left\{\frac{\xi_a-\left[\frac{1}{2}-\frac{1}{2}\frac{\langle a|2\mathbf{J}\cdot\mathbf{K}|a\rangle}{\langle a|2\mathbf{J}\cdot\mathbf{S}_{\rm pr}|a\rangle}\right]\alpha_a{}'^{(+)}-\left[\frac{A-Z}{2}\right]\alpha_a{}'^{(-)}}{1-[A/2Z]\alpha_a{}^{(+)}-[(A-Z)/2]\alpha_a{}^{(-)}}\right\}.\tag{28b}$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

The quantity in the curly brackets in Eq. (28a) or (28b) is the ratio of the exclusion principle inhibition factors for $\Lambda^{(\mu)}(J_a+\frac{1}{2};a)-\Lambda^{(\mu)}(J_a-\frac{1}{2};a)$ and for $\Lambda^{(\mu)}(a)$ and should be close to unity. Assuming in addition that for the purpose of calculating $\langle a|2\mathbf{J}\cdot\mathbf{S}_{\rm pr}|a\rangle$ one can visualize the odd Z, odd A nucleus as consisting of an "outside" proton with orbital angular momentum $\mathbf{L}_a$ moving about a spinless "core," one has

$$\langle a|2\mathbf{J}\cdot\mathbf{S}_{\rm pr}|a\rangle=J_a(J_a+1)-L_a(L_a+1)+\tfrac{3}{4}=\begin{matrix}J_a+1:J_a=L_a+\frac{1}{2}\\-J_a\ :J_a=L_a-\frac{1}{2}\end{matrix} \tag{29}$$

so that, substituting into Eq. (28b),

$$\frac{\Lambda^{(\mu)}(J_a+\frac{1}{2};a)-\Lambda^{(\mu)}(J_a-\frac{1}{2};a)}{\Lambda^{(\mu)}(a)}\cong\frac{b^{(\mu)}}{a^{(\mu)}}\frac{1}{Z}\times\begin{bmatrix}(2J_a+1)/J_a\\-(2J_a+1)/(J_a+1)\end{bmatrix}\begin{matrix}:J_a=L_a+\frac{1}{2}\\:J_a=L_a-\frac{1}{2}\end{matrix} \tag{30}$$

in essential agreement with the result for

$$(\Lambda^{(\mu)}(J_a+\tfrac{1}{2};a)-\Lambda^{(\mu)}(J_a-\tfrac{1}{2};a))/\Lambda^{(\mu)}(a)$$

obtained in another way by B.L.Y. and P.[21] The combination of coupling constants in Eq. (30), $b^{(\mu)}/a^{(\mu)}$, has the numerical value, using Eqs. (27b), (1b), (1c), and (3d), and $(g_A{}^{(\beta)}/g_V{}^{(\beta)})=-1.21$,[11]

$$\frac{b^{(\mu)}}{a^{(\mu)}}=-0.945. \tag{31}$$

As an example of the magnitude of the hyperfine effect we calculate the quantity

$$(\Lambda^{(\mu)}(J_a+\tfrac{1}{2};a)-\Lambda^{(\mu)}(J_a-\tfrac{1}{2};a))/\Lambda^{(\mu)}(a)$$ from Eqs. (30) and (31) for $Al_{13}{}^{27}$. Here, $Z=13$, $J_a=\frac{5}{2}$, $L_a=2$, so that we have

$$\frac{\Lambda^{(\mu)}(J_a+\frac{1}{2};a)-\Lambda^{(\mu)}(J_a-\frac{1}{2};a)}{\Lambda^{(\mu)}(a)}\cong-0.17, \tag{32}$$

which appears sufficiently large to be observed with available experimental techniques.

We now apply Eqs. (27a) and (27b) to the case of muon capture in hydrogen. Here

$$\langle a|2\mathbf{J}\cdot\mathbf{S}_{\rm neu}|a\rangle=0;\quad\langle a|2\mathbf{J}\cdot\mathbf{S}_{\rm pr}|a\rangle=2\cdot\tfrac{3}{4};$$
$$\langle a|2\mathbf{J}\cdot\mathbf{K}|a\rangle=2\cdot\tfrac{3}{4};\quad\langle a|(\mathbf{T})^2-(T^{(3)})^2|a\rangle=\tfrac{1}{2};$$
$$\langle a|(\mathbf{Y}^{(1)})^2+(\mathbf{Y}^{(2)})^2|a\rangle=\tfrac{3}{2};$$
$$\langle a|(\mathbf{S}_{\rm pr})^2+(\mathbf{S}_{\rm neu})^2-(\mathbf{S}_{\rm pr}+\mathbf{S}_{\rm neu})^2|a\rangle=0;$$
$$b^{(\mu)}/a^{(\mu)}=-0.922$$

[from Eqs. (27b), (1b), (1c), (2c), and $(g_A{}^{(\beta)}/g_V{}^{(\beta)})=-1.21$ [11]], $\Lambda^{(\mu)}(H_1{}^1)=169$ sec^{-1} [Eq. (17)], so that

$$\Lambda^{(\mu)}(\tfrac{1}{2}+\tfrac{1}{2};H_1{}^1)=\Lambda^{(\mu)}(H_1{}^1)\left(1+\frac{b^{(\mu)}}{a^{(\mu)}}\right)=13\text{ sec}^{-1}, \tag{33a}$$

$$\Lambda^{(\mu)}(\tfrac{1}{2}-\tfrac{1}{2};H_1{}^1)=\Lambda^{(\mu)}(H_1{}^1)\left(1-\frac{3b^{(\mu)}}{a^{(\mu)}}\right)=636\text{ sec}^{-1}. \tag{33b}$$

Thus the hyperfine effect is enormous—

$$(\Lambda^{(\mu)}(\tfrac{1}{2}-\tfrac{1}{2};H_1{}^1)/\Lambda^{(\mu)}(\tfrac{1}{2}+\tfrac{1}{2};H_1{}^1))\cong50.$$

Muon capture in hydrogen is also unique in that within a time $\approx[p\mu^-]$ mu-mesic atom mean life $\tau^{\pm}$

$$(\tau^{\pm}=\{\Lambda_{\rm decay}{}^{(\mu)}+\Lambda^{(\mu)}(\tfrac{1}{2}\pm\tfrac{1}{2};H_1{}^1)\}^{-1}\approx1/\Lambda_{\rm decay}{}^{(\mu)}=2.21\times10^{-6}\text{ sec})$$

there is, under certain circumstances, a high probability of conversion from the energetically higher triplet state with $F_a{}^{(+)}=\frac{1}{2}+\frac{1}{2}$ to the energetically lower singlet state with $F_a{}^{(-)}=\frac{1}{2}-\frac{1}{2}$. This is a consequence of the fact that, as pointed out by Gershtein and Zeldovich,[22] the $[p\mu^-]$ mu-mesic is electrically neutral and so wanders through the hydrogen gas or liquid making collisions with the $(H_1{}^1)_2$ molecules—these collisions occasionally result in "exchange" between the proton in the incident $[p\mu^-]$ mu-mesic atom with one direction of spin and a proton in the target $(H_1{}^1)_2$ molecule with the opposite direction of spin, with the net result that the $[p\mu^-]$ is converted from the triplet state to the singlet state. The rate of such a collisional conversion process is estimated by Gershtein[22] to be $\approx5\times10^9$ sec^{-1} at an $(H_1{}^1)_2$ molecule number density, $\mathfrak{N}/V$, of 2×10^{22}/cm^3—thus at $\mathfrak{N}/V$ less than, say, 2×10^{17}/cm^3 there is no appreciable collisional triplet to singlet conversion and the muon capture rate is, from Eqs. (33a), (33b), and (26),

$$\tfrac{3}{4}\Lambda^{(\mu)}(\tfrac{1}{2}+\tfrac{1}{2};H_1{}^1)+\tfrac{1}{4}\Lambda^{(\mu)}(\tfrac{1}{2}-\tfrac{1}{2};H_1{}^1)=\Lambda^{(\mu)}(H_1{}^1)=169\text{ sec}^{-1}.$$

With increasing $\mathfrak{N}/V$ the collisional triplet to singlet conversion becomes progressively more important and at $\mathfrak{N}/V\approx10^{20}$/cm^3 practically all the $[p\mu^-]$ mu-mesic atoms are in the singlet state at the instant of muon decay or capture—the corresponding muon capture rate is, from Eq. (33b), $\Lambda^{(\mu)}(\frac{1}{2}-\frac{1}{2};H_1{}^1)=636$ sec^{-1}. At still higher $\mathfrak{N}/V$, e.g., at $\mathfrak{N}/V$ of the order of those in liquid hydrogen, formation of mu-mesic hydrogen molecule ions, $[p\mu^-p]$, becomes dominant[23] and it is expected that most of the muons will be found at the instant of their decay or capture in the lowest Bohr orbit of a

$[p\mu^- p]$. Any such $[p\mu^- p]$ must have a total spin angular momentum of $\frac{1}{2}$ (since one of its parents is a singlet $[p\mu^-]$) and so possesses a muon spin $\boldsymbol{\sigma}$—proton spin $\boldsymbol{\sigma}_1$, $\boldsymbol{\sigma}_2$ configuration intermediate between that in a triplet and that in a singlet $[p\mu_-]$—in fact

$$\langle(\mathbf{F})^2\rangle_a = \tfrac{3}{4} = \langle[\tfrac{1}{2}\boldsymbol{\sigma} + (\tfrac{1}{2}\boldsymbol{\sigma}_1 + \tfrac{1}{2}\boldsymbol{\sigma}_2)]^2\rangle_a$$
$$= \tfrac{3}{4} + \langle(\tfrac{1}{2}\boldsymbol{\sigma}_1 + \tfrac{1}{2}\boldsymbol{\sigma}_2)^2\rangle_a + 2\langle(\tfrac{1}{2}\boldsymbol{\sigma})\cdot(\tfrac{1}{2}\boldsymbol{\sigma}_1 + \tfrac{1}{2}\boldsymbol{\sigma}_2)\rangle_a$$

so that

$$\langle\boldsymbol{\sigma}\cdot\boldsymbol{\sigma}_1\rangle_a = \langle\boldsymbol{\sigma}\cdot\boldsymbol{\sigma}_2\rangle_a = -\langle(\tfrac{1}{2}\boldsymbol{\sigma}_1 + \tfrac{1}{2}\boldsymbol{\sigma}_2)^2\rangle_a = 0, -2$$

in *para*, *ortho* $[p\mu^- p]$ while $\langle\boldsymbol{\sigma}\cdot\boldsymbol{\sigma}_1\rangle_a = 1, -3$ in triplet, singlet $[p\mu^-]$. Further, since from Eqs. (33a) and (33b),

$$\Lambda^{(\mu)}(\tfrac{1}{2}\pm\tfrac{1}{2}; \mathrm{H}_1{}^1) \sim \left(1 + \langle\boldsymbol{\sigma}\cdot\boldsymbol{\sigma}_1\rangle_{a;\pm}\frac{b^{(\mu)}}{a^{(\mu)}}\right)$$
$$= \left(1 + \begin{pmatrix}1\\-3\end{pmatrix}\times\frac{b^{(\mu)}}{a^{(\mu)}}\right)$$

the muon capture rate in *para* $[p\mu^- p]$, *ortho* $[p\mu^- p]$ will, in an analogous fashion, be

$$\sim\left(1 + \langle\boldsymbol{\sigma}\cdot\boldsymbol{\sigma}_1\rangle_{a;\,para,\,ortho}\frac{b^{(\mu)}}{a^{(\mu)}}\right) = \left(1 + \begin{pmatrix}0\\-2\end{pmatrix}\times\frac{b^{(\mu)}}{a^{(\mu)}}\right).$$

It follows that at high $\mathfrak{N}/V$ the muon capture rate has the form

$$x_1\left(\frac{\mathfrak{N}}{V}\right)\left[\Lambda^{(\mu)}(\mathrm{H}_1{}^1)\left(1 - \frac{3b^{(\mu)}}{a^{(\mu)}}\right)\right]$$
$$+ x_2\left(\frac{\mathfrak{N}}{V}\right)[(2\gamma)\Lambda^{(\mu)}(\mathrm{H}_1{}^1)]$$
$$+ x_3\left(\frac{\mathfrak{N}}{V}\right)\left[(2\gamma)\Lambda^{(\mu)}(\mathrm{H}_1{}^1)\left(1 - \frac{2b^{(\mu)}}{a^{(\mu)}}\right)\right]$$
$$= \left\{x_1\left(\frac{\mathfrak{N}}{V}\right)[636] + x_2\left(\frac{\mathfrak{N}}{V}\right)[(2\gamma)(169)]\right.$$
$$\left. + x_3\left(\frac{\mathfrak{N}}{V}\right)[(2\gamma)(480)]\right\}\ \mathrm{sec}^{-1}, \quad (34)$$

where $x_1(\mathfrak{N}/V)$, $x_2(\mathfrak{N}/V)$, $x_3(\mathfrak{N}/V)$, are the fractions of muons found in singlet $[p\mu^-]$, *para* $[p\mu^- p]$ and *ortho* $[p\mu^- p]$ at the $\mathfrak{N}/V$ in question—$x_1(\mathfrak{N}/V) + x_2(N/V) + x_3(\mathfrak{N}/V) = 1$—and γ is the ratio of the absolute square of the muon orbital wave function at the proton position in $[p\mu^- p]$ and in $[p\mu^-]$. Equations (33a), (33b), and (34) show that the muon capture rate in hydrogen, considered as a function of $\mathfrak{N}/V$, exhibits a maximum, $\cong 636$ sec^{-1}, at an intermediate value of $\mathfrak{N}/V$; if in addition $2\gamma \cong 1$ and $(x_2(\mathfrak{N}/V)/x_3(\mathfrak{N}/V)) \gg 1$ this rate falls to values $\cong 169$ sec^{-1} at high $\mathfrak{N}/V$ as well as at very low $\mathfrak{N}/V$.

It is necessary for the physical relevance of the whole above discussion that the isotopically natural hydrogen in which the muons stop be purified of deuterium to an extent—factor ≈ 25–50 in relative abundance—sufficient to prevent any frequent occurrence of the "exchange" reaction $[p\mu^-] + d \rightarrow [d\mu^-] + p$. Any appreciable rate for such an exchange reaction with the subsequent formation of $[d\mu^- p]$ and the resultant "muon catalysis" of $d + p \rightarrow \mathrm{He}_2{}^3 + \gamma$ complicates the situation very considerably. On the other hand, a similar analysis may be given for muons stopping in pure deuterium with the major difference that at high $\mathfrak{N}/V$ the sequence of reactions:

$$[d\mu^-] + d \rightarrow [d\mu^- d]; \quad [d\mu^- d] \nearrow \mathrm{He}_2{}^3 + n + \mu^-$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \searrow \mathrm{H}_1{}^3 + p + \mu^-$$

is anticipated with most of the muons eventually being trapped in Bohr orbits about the $\mathrm{He}_2{}^3$ nuclei.[24] Thus most muons stopping in pure liquid deuterium which are eventually captured by nuclei, are captured by nuclei of $\mathrm{He}_2{}^3$, a circumstance which permits study of muon capture in $\mathrm{He}_2{}^3$ without any anterior possession of a $\mathrm{He}_2{}^3$ target.

In concluding this section we remark again that the study of muon capture in hydrogen will not only ultimately yield the most reliable values of the effective muon—dressed nucleon coupling constants, $G_V{}^{(\mu)}$, $G_A{}^{(\mu)}$, $G_P{}^{(\mu)}$, i.e., values free of "nuclear physics" uncertainties, but will also shed light on several other interesting effects such as the collisional conversion in $[p\mu^-]$ and the formation of *para* $[p\mu^- p]$ and *ortho* $[p\mu^- p]$.

6. RADIATIVE MUON CAPTURE—TOTAL RATE AND PHOTON-NEUTRINO ANGULAR CORRELATION

We now discuss the process of radiative muon capture. Here calculations of the total rate and of the shape of the corresponding internal bremsstrahlung (I.B.) momentum spectrum have been made by Cantwell[25] for capture by light and medium-heavy nuclei ($Z/137 \ll 1$). Cantwell uses the effective Hamiltonian of Eqs. (1a) and (1b) but with all nucleon recoil corrections, i.e. all terms $\sim \nu/m_p$ omitted so that $G_V{}^{(\mu)} = g_V{}^{(\mu)}$; $G_A{}^{(\mu)} = g_A{}^{(\mu)}$; $G_P{}^{(\mu)} = 0$. The radiative capture is visualized as predominantly due to the "two-step process"

$$\mu^- + p \rightarrow \gamma + (\mu^-)' + p \rightarrow \gamma + \nu + n \quad (35)$$

and a second-order perturbation calculation, using an appropriate (free particle) Green's function to describe the virtual intermediate μ^- states, is carried out. In this way Cantwell obtains a relation for the relative

probability of radiative to nonradiative muon capture

$$\frac{\sum_b \Lambda_{\rm rad}{}^{(\mu)}(a\to b;\gamma_{ba})d(\gamma_{ba}/\gamma_{ba}{}^{\rm max})d\gamma_1}{\sum_b \Lambda^{(\mu)}(a\to b)}$$

$$=\sum_b\left[\left(\frac{1}{4\pi^2}\frac{1}{137}\right)\left(\frac{\gamma_{ba}{}^{\rm max}}{m_\mu}\right)^2\left(1-\frac{\gamma_{ba}}{\gamma_{ba}{}^{\rm max}}\right)^2\left(\frac{\gamma_{ba}}{\gamma_{ba}{}^{\rm max}}\right)d\left(\frac{\gamma_{ba}}{\gamma_{ba}{}^{\rm max}}\right)d\gamma_1\right]$$

$$\times\left[\int\frac{d\nu_1}{4\pi}\{(g_V{}^{(\mu)})^2(1+\nu_1\cdot\gamma_1)|\langle b|\exp'|a\rangle|^2+(g_A{}^{(\mu)})^2(1-\nu_1\cdot\gamma_1)|\langle b|(\exp')\sigma|a\rangle|^2\right.$$

$$\left.+(g_A{}^{(\mu)})^2 2\,\mathrm{Re}(\nu_1\cdot\langle b|(\exp')\sigma|a\rangle^*\gamma_1\cdot\langle b|(\exp')\sigma|a\rangle)\right]$$

$$=\frac{}{\sum_b\left[\int\frac{d\nu_1}{4\pi}\{(g_V{}^{(\mu)})^2|\langle b|\exp|a\rangle|^2+(g_A{}^{(\mu)})^2|\langle b|(\exp)\sigma|a\rangle|^2\}\right]}, \tag{36a}$$

where

$$\exp'\equiv\sum_i\tau_i{}^{(-)}\exp[-i(\nu_{ba}{}'+\gamma_{ba})\cdot\mathbf{r}_i]\varphi(r_i);\quad(\exp')\sigma\equiv\sum_i\tau_i{}^{(-)}\exp[-i(\nu_{ba}{}'+\gamma_{ba})\cdot\mathbf{r}_i]\varphi(r_i)\sigma_i,$$
$$\exp\equiv\sum_i\tau_i{}^{(-)}\exp(-i\nu_{ba}\cdot\mathbf{r}_i)\varphi(r_i);\quad(\exp)\sigma\equiv\sum_i\tau_i{}^{(-)}\exp(-i\nu_{ba}\cdot\mathbf{r}_i)\varphi(r_i)\sigma_i. \tag{36b}$$

In Eq. (36a) the sum over b runs over all the energetically accessible states of the daughter nucleus; $\nu_{ba}{}'=\nu_{ba}{}'\nu_1$, $\gamma_{ba}=\gamma_{ba}\gamma_1$ are the momenta of the neutrino and I.B. photon emitted in the radiative capture; the energy, momentum conservation laws yield, analogously to Eqs. (2c) and (3d),

$$\nu_{ba}{}'+\gamma_{ba}\cong m_\mu\left[1-\frac{\epsilon_a}{m_\mu}-\frac{(E_b-E_a)}{m_\mu}\right]\cong\nu_{ba}. \tag{36c}$$

The first square bracket in the numerator represents an I.B. momentum spectrum of the same shape as that found by Morrison and Schiff in allowed K-electron orbital capture[26]; the second square bracket describes the dependence of the I.B. momentum spectrum on the wave functions $|a\rangle$, $|b\rangle$ of the parent and daughter nuclei—this second square bracket is however such for $\gamma_{ba}/\gamma_{ba}{}^{\rm max}=\gamma_{ba}/\nu_{ba}\cong 0$ and $\cong 1$ that the I.B. momentum spectrum has the allowed K-capture shape both near its low-energy end and its high-energy end. Thus a careful study of the shape of I.B. momentum spectrum near its high-energy end will yield $\langle\gamma\rangle_a{}^{\rm max}$, the average value of $\gamma_{ba}{}^{\rm max}$ over the states b; since $\langle\gamma\rangle_a{}^{\rm max}=\langle\nu\rangle_a$ one will in this way find empirically the average value of the neutrino energy involved in nonradiative muon capture by a particular parent nucleus and so remove the major uncertainty associated with the evaluation of the coupling constant ratio $\mathfrak{R}$ [Eq. (6b)] from the experimental data [see Sec. 3, Eqs. (19), (20), *et seq.*].

We now apply the closure approximation for the evaluation of the sums over b in Eq. (36a). By using the techniques of Eqs. (3b) to (6c), we obtain

$$\frac{\Lambda_{\rm rad}{}^{(\mu)}(a;\langle\gamma\rangle_a)dx_a d\gamma_1}{\Lambda^{(\mu)}(a)}=\left[\left(\frac{1}{4\pi^2}\frac{1}{137}\right)\left(\frac{\langle\gamma\rangle_a{}^{\rm max}}{m_\mu}\right)^2(1-x_a)^2x_a dx_a d\gamma_1\right]$$

$$\times\left\{\frac{((g_V{}^{(\mu)})^2+3(g_A{}^{(\mu)})^2)\int\frac{d\nu_1}{4\pi}(1-g_a{}'(\nu_1,\gamma_1))+((g_V{}^{(\mu)})^2-(g_A{}^{(\mu)})^2)\int\frac{d\nu_1}{4\pi}\nu_1\cdot\gamma_1(1-g_a{}''(\nu_1,\gamma_1))}{((g_V{}^{(\mu)})^2+3(g_A{}^{(\mu)})^2)(1-g_a)}\right\}, \tag{37a}$$

where g_a is the nonradiative capture exclusion principle inhibition factor given in Eq. (6c) and $g_a{}'(\nu_1,\gamma_1)$, $g_a{}''(\nu_1,\gamma_1)$ are the corresponding radiative capture inhibition factors

$$g_a{}'(\nu_1,\gamma_1)=-\frac{\langle a|\sum_{i,j}{}'[\tfrac{1}{4}(\tau_i\cdot\tau_j-\tau_i{}^{(3)}\tau_j{}^{(3)})((g_V{}^{(\mu)})^2+(g_A{}^{(\mu)})^2\sigma_i\cdot\sigma_j)][\exp\{i(\langle\nu'\rangle_a\nu_1+\langle\gamma\rangle_a\gamma_1)\cdot\mathbf{r}_{ij}\}\varphi^*(r_i)\varphi(r_j)]|a\rangle}{Z[(g_V{}^{(\mu)})^2+3(g_A{}^{(\mu)})^2]\left[\int|\varphi(\mathbf{r})|^2\mathfrak{D}_a(r)d\mathbf{r}\right]}, \tag{37b}$$

$$g_a{}''(\nu_1,\gamma_1)=-\frac{\langle a|\sum_{i,j}{}'[\tfrac{1}{4}(\tau_i\cdot\tau_j-\tau_i{}^{(3)}\tau_j{}^{(3)})((g_V{}^{(\mu)})^2-\tfrac{1}{3}(g_A{}^{(\mu)})^2\sigma_i\cdot\sigma_j)][\exp\{i(\langle\nu'\rangle_a\nu_1+\langle\gamma\rangle_a\gamma_1)\cdot\mathbf{r}_{ij}\}\varphi^*(r_i)\varphi(r_j)]|a\rangle}{Z[(g_V{}^{(\mu)})^2-(g_A{}^{(\mu)})^2]\left[\int|\varphi(\mathbf{r})|^2\mathfrak{D}_a(r)d\mathbf{r}\right]} \tag{37c}$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

[26] P. Morrison and L. I. Schiff, Phys. Rev. 58, 24 (1940).

with

$$\langle\nu'\rangle_a+\langle\gamma\rangle_a\cong m_\mu\left\{1-\frac{\epsilon_a}{m_\mu}-\frac{\langle\text{excitation energy of daughter nucleus } b\rangle}{m_\mu}-\frac{[(E_b)_{\text{ground state}}-E_a]}{m_\mu}\right\} \tag{37d}$$

$$x_a\equiv\frac{\langle\gamma\rangle_a}{\langle\gamma_a\rangle^{\max}}=\frac{\langle\gamma\rangle_a}{\langle\nu\rangle_a}\,.$$

As a rough first approximation to evaluate Eq. (37a), we take $g_a'(\nu_1,\gamma_1)\cong g_a''(\nu_1,\gamma_1)\cong g_a$; in this case the I.B. momentum spectrum has the allowed K-capture shape $\sim(1-x_a)^2x_a$ and the I.B. photon-neutrino angular correlation function is

$$1+\left(\frac{(g_V{}^{(\mu)})^2-(g_A{}^{(\mu)})^2}{(g_V{}^{(\mu)})^2+3(g_A{}^{(\mu)})^2}\right)\nu_1\cdot\gamma_1. \tag{38}$$

Equation (38) is rigorous for radiative muon capture by protons and has been derived directly for this case by Huang, Yang, and Lee[27] (H.Y. and L.). As a second approximation, we can use the techniques of Eqs. (7a) to (11b) and obtain for the heavier nuclei, $Z>6$, $A>12$

$$g_a'(\nu_1,\gamma_1)\cong g_a''(\nu_1,\gamma_1)\cong\left(\frac{A-Z}{2A}\right)\left(\frac{d}{r_0}\right)^3\times\left[1-\frac{1}{10}(\langle\nu'\rangle_a r_0\nu_1+\langle\gamma\rangle_a r_0\gamma_1)^2\left(\frac{d}{r_0}\right)^2+\cdots\right] \tag{39a}$$

entirely analogous to the result [Eqs. (6a), (11a), and (11b)]

$$g_a\cong\left(\frac{A-Z}{2A}\right)\delta_a\cong\left(\frac{A-Z}{2A}\right)\left(\frac{d}{r_0}\right)^3\times\left[1-\frac{1}{10}(\nu_a r_0)^2\left(\frac{d}{r_0}\right)^2+\cdots\right]. \tag{39b}$$

Equations (37a), (39a), and (39b) yield

$$\frac{\Lambda_{\text{rad}}{}^{(\mu)}(a;\langle\gamma\rangle_a)dx_a d\gamma_1}{\Lambda^{(\mu)}(a)}\cong\left[\left(\frac{1}{4\pi^2}\frac{1}{137}\right)\left(\frac{\langle\gamma\rangle_a{}^{\max}}{m_\mu}\right)^2(1-x_a)^2x_a dx_a d\gamma_1\right]\times\left\{1-(1-x_a)x_a\left\{\frac{1}{5}+\frac{1}{15}\left[\frac{(g_A{}^{(\mu)})^2-(g_V{}^{(\mu)})^2}{(g_V{}^{(\mu)})^2+3(g_A{}^{(\mu)})^2}\right]\right\}\right\}\times\left[\frac{\left(\frac{A-Z}{2A}\right)\delta_a}{1-\left(\frac{A-Z}{2A}\right)\delta_a}\right]\left[\left(\frac{d}{r_0}\right)^2(\langle\gamma\rangle_a{}^{\max}r_0)^2\right] \tag{40}$$

which shows that the correction factor to the allowed K-capture shape for the I.B. momentum spectrum involves [as does the I.B. photon-neutrino angular correlation, Eq. (38)] the quantity $(g_A{}^{(\mu)}/g_V{}^{(\mu)})^2$. Taking

$$(g_A{}^{(\mu)}/g_V{}^{(\mu)})^2\cong(g_A{}^{(\beta)}/g_V{}^{(\beta)})^2=(1.21)^2\,{}^{11};$$

$$(d/r_0)^2=(1.47)^2\cong(\delta_a)^{\frac{2}{3}},$$

$$\delta_a=3.0\ \text{[Eqs. (11b) and (14)]};$$

$$\langle\gamma\rangle_a{}^{\max}=\langle\nu\rangle_a\cong\tfrac{3}{4}m_\mu,$$

$$r_0\cong\frac{0.67}{m_\mu}\ \text{[Eq. (11b) } et\ seq.\text{]}$$

and $(A-Z)/2A\cong\frac{1}{4}$, Eq. (40) gives

$$\frac{\Lambda_{\text{rad}}{}^{(\mu)}(a;\langle\gamma\rangle_a)dx_a}{\Lambda^{(\mu)}(a)}\cong\left[\left(\frac{1}{\pi}\frac{1}{137}\right)\left(\frac{3}{4}\right)^2(1-x_a)^2x_a dx_a\right]\times[1-0.35(1-x_a)x_a] \tag{41}$$

so that the ratio of the total radiative capture rate,

$$\Lambda_{\text{rad}}{}^{(\mu)}(a)=\int_0^1\Lambda_{\text{rad}}{}^{(\mu)}(a,\langle\gamma\rangle_a)dx_a,$$

to the total nonradiative capture rate is

$$\frac{\Lambda_{\text{rad}}{}^{(\mu)}(a)}{\Lambda^{(\mu)}(a)}\cong\left[\left(\frac{1}{12\pi}\frac{1}{137}\right)\left(\frac{3}{4}\right)^2\right]\left[1-\frac{0.35}{5}\right]=1\times10^{-4}. \tag{42}$$

Equations (40), (41), and (42) hold also for radiative muon capture by a proton upon omission of the term $(\langle\gamma\rangle_a{}^{\max}/m_\mu)^2=(\frac{3}{4})^2$ and of the term $\sim(1-x_a)x_a$, $-0.35/5$—this has been shown directly in the case of Eq. (42) by H.Y. and L.[27] and may be seen from Eq. (37a) since for a proton $\langle\gamma\rangle_a{}^{\max}/m_\mu=0.94\cong1$ and $g_a'(\nu_1,\gamma_1)=0$, $g_a''(\nu_1,\gamma_1)=0$ (as $Z=A$).

Cantwell[25] has given, on the basis of the evaluation of Eqs. (37a) to (37d) with a simple variational trial form for

$$a|\rangle\cong\Phi_a(\mathbf{r}_1,\mathbf{r}_2,\cdots)X_a(\sigma_1{}^{(3)},\sigma_2{}^{(3)},\cdots;\tau_1{}^{(3)},\tau_2{}^{(3)},\cdots)$$

[Eqs. (16) *et seq.*], an expression for

$$\frac{\Lambda_{\text{rad}}{}^{(\mu)}(a,\langle\gamma\rangle_a)dx_a}{\Lambda^{(\mu)}(a)}$$

[27] Huang, Yang, and Lee, Phys. Rev. 108, 1348 (1957).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

in the case $\mu^-+He_2^4 \rightarrow \gamma+\nu+H_1^4$. This expression corresponds to a correction factor to the allowed K-capture shape $\cong[1-1.8(1-x_a)x_a]$ (for $(g_A^{(\mu)}/g_V^{(\mu)})^2 \cong(g_A^{(\beta)}/g_V^{(\beta)})^2=(1.21)^2$ [11]) rather than

$$\cong[1-0.35(1-x_a)x_a]$$

as predicted by Eq. (41) for the heavier nuclei. We should also mention that all of the results in Eqs. (36a) to (42) refer, in the case $J_a\neq 0$, to the appropriate averages [as in Eq. (26)] of the various radiative and nonradiative muon capture rates over the two $(J_a+\frac{1}{2}, J_a-\frac{1}{2})$ hyperfine states of the parent mu-mesic atom.

The I.B. momentum spectrum of Eqs. (40) or (41), is susceptible to observational test—a plot of experimental values of $\Lambda_{rad}^{(\mu)}(a;\langle\gamma\rangle_a)/[(1-x_a)^2x_a]$ *vs* the corresponding $(1-x_a)x_a$ should, if our approximations are sufficiently accurate, lie on a straight line with a slope whose value yields $(g_A^{(\mu)}/g_V^{(\mu)})^2$ (subject to the uncertainty in the numerical value of δ_a). This I.B. spectrum peaks at $x_a\cong\frac{1}{3}$ or $\langle\gamma\rangle_a\cong 27$ Mev and still has very appreciable values at $\langle\gamma\rangle_a\geqq 55$ Mev, i.e., at I.B. photon energies high compared to the energies of any numerous background photons. This fact should permit detection of the muon radiative capture in spite of the relative rarity of the phenomenon.

In concluding the present section it is important to emphasize the interest of a calculation of radiative muon capture using an effective Hamiltonian which includes all nucleon recoil corrections (terms $\sim\nu/m_p$) and in particular contains the "induced" pseudoscalar and the "conserved vector current" anomalous magnetic moment contributions. Such a calculation is now being carried out by Bernstein[28] and is expected to exhibit additional terms in the correction factor to the allowed K-capture shape for the I.B. momentum spectrum.

7. PARITY NONCONSERVATION EFFECTS

The anticipated presence of parity nonconservation effects in maximum amounts in the muon capture process is incorporated into the effective Hamiltonian of Eq. (1a) through the assumption that the emitted neutrino carries unit negative helicity—this is expressed mathematically by the (two-component neutrino coupling type) spin projection operator $(1-\boldsymbol{\sigma}\cdot\boldsymbol{\nu}_1)/\sqrt{2}$ in the $H_{eff}^{(\mu)}$ of Eq. (1a). No direct experimental test of this assumption is as yet available for muon capture but it has now been established that neutrinos emitted in the analogous processes of electron orbital capture and positron beta decay do possess a helicity $=-1$.[11] It would clearly be of great interest to observe parity nonconservation effects in muon capture and the present section is devoted to a discussion of four phenomena in which pseudoscalar quantities are to be measured—cf. Eqs. (44), (53), (57), and (59).

(a) Angular Distribution of Recoil Nuclei in Capture of Polarized Muons

Experimental evidence is now available that negative muons still retain an appreciable fraction of their spin polarization at the instant of decay or capture from the lowest Bohr orbit of the parent mu-mesic atom. This evidence is based on the observation of an anisotropic angular distribution of the decay electrons relative to a unit vector, $\mathbf{s}_{\mu;1}$, in the direction of the muon spin,

$$1-P_\mu\tfrac{1}{3}(\mathbf{s}_{\mu;1}\cdot\mathbf{p}_{el;1}), \tag{43a}$$

$$(\mathbf{s}_{\mu;1}\cdot\mathbf{p}_{neg.\ muon;1})=+1,^{29} \tag{43b}$$

and corresponds to a residual muon polarization at the instant of decay or capture, P_μ, of about 15 to 20% for the case of various spin zero parent nuclei.[30] The angular distribution of recoil daughter nuclei in a particular state, the recoils being formed in muon capture by spin zero parent nuclei, is then also expected to exhibit an anisotropy relative to $\mathbf{s}_{\mu;1}$, *viz.*,

$$1+P_\mu\alpha(a\rightarrow b)(\mathbf{s}_{\mu;1}\cdot\mathbf{p}_{rec;1}), \tag{44}$$

where $\mathbf{p}_{rec;1}$ is a unit vector in the direction of the recoiling nucleus and the anisotropy coefficient, $\alpha(a\rightarrow b)$, is a quantity involving the muon capture nuclear matrix elements of Eq. (2b). To avoid complications associated with the "hyperfine" effect (Sec. 5) we confine our discussion until further notice to the case of zero spin parent nuclei—this case is in addition distinguished by a lack of hyperfine-structure induced muon depolarization which, for example if $J_a=\frac{1}{2}$, cuts down the otherwise effective value of P_μ by a factor of at least 2 [see Eqs. (52b) to (52d)].

Calculation of $\alpha(a\rightarrow b)$ on the basis of the $H_{eff}^{(\mu)}$ of Eq. (1a) yields

$$\alpha(a\rightarrow b)\cong\frac{\sum_{M_b,M_a}\{(G_V^{(\mu)})^2|\langle b|\exp|a\rangle|^2+\frac{1}{3}(-(G_A^{(\mu)})^2+(G_P^{(\mu)})^2-2G_A^{(\mu)}G_P^{(\mu)})|\langle b|(\exp)\boldsymbol{\sigma}|a\rangle|^2\}}{\sum_{M_b,M_a}\{(G_V^{(\mu)})^2|\langle b|\exp|a\rangle|^2+\frac{1}{3}(3(G_A^{(\mu)})^2+(G_P^{(\mu)})^2-2G_A^{(\mu)}G_P^{(\mu)})|\langle b|(\exp)\boldsymbol{\sigma}|a\rangle|^2\}} \tag{45}$$

[28] J. Bernstein (to be published).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

subject to the assumption that the wave functions $|a; J_a=0^+\rangle$, $|b; J_i\rangle$ are such that

$$\sum_{M_b,M_a} |\langle b|(\exp)\boldsymbol{\sigma}\cdot\boldsymbol{\nu}_1|a\rangle|^2 \cong \tfrac{1}{3}\sum_{M_b,M_a}|\langle b|(\exp)\boldsymbol{\sigma}|a\rangle|^2.\ ^{1}$$

Formulas equivalent to that in Eq. (45), but without inclusion of the anomalous magnetic moment terms in the corresponding $H_{\rm eff}{}^{(\mu)}$ and sometimes without the term in $G_P{}^{(\mu)}$, have been given by Ioffe,[31] H. Y. and L.,[27] Shapiro, Dolinsky, and Blokhintsev,[32] Wolfenstein,[33] Überall,[34] Treiman,[35] and Fulton.[36]

In a case such as the ground state ($J_a=0^+$) to ground state ($J_b=1^+$) transition in $\mu^-+C_6{}^{12}\rightarrow\nu+B_5{}^{12}$ (Sec. 4) the spin independent nuclear matrix element $\langle b|\exp|a\rangle$ [Eq. (36b)] vanishes[1] and Eq. (45) becomes [using also Eqs. (1b) and (1c) with $\nu_{ba}=0.86\,m_\mu$ [Eq. (2c)], and $(g_A{}^{(\beta)}/g_V{}^{(\beta)})=-1.21$ [11])

$$\alpha(a\rightarrow b)=\frac{-(G_A{}^{(\mu)})^2+(G_P{}^{(\mu)})^2-2G_A{}^{(\mu)}G_P{}^{(\mu)}}{3(G_A{}^{(\mu)})^2+(G_P{}^{(\mu)})^2-2G_A{}^{(\mu)}G_P{}^{(\mu)}}=-0.73. \tag{46}$$

Thus an accurate measurement of the angular distribution of the ground state $B_5{}^{12}$ recoils, P_μ being determined by a parallel measurement of the muon decay electron angular distribution [Eq. (43a)], would yield information about the ratio $G_P{}^{(\mu)}/G_A{}^{(\mu)}$ and hence about the ratio $g_P{}^{(\mu)}/g_A{}^{(\beta)}$ [Eq. (1c) *et seq.*]. The corresponding $\alpha(a\rightarrow b)$ [Eq. (46)] is, fortunately, quite sensitive to the exact value of $g_P{}^{(\mu)}/g_A{}^{\beta}$ and to the omission or inclusion of the terms $\sim(\mu_p-\mu_n)$ being, for example, -0.33 if $g_P{}^{(\mu)}/g_A{}^{(\beta)}=0$ and if the terms $\sim(\mu_p-\mu_n)$ are absent.

We now apply the closure approximation to find the anisotropy coefficient, $\alpha(a)$,

$$\alpha(a)\equiv\frac{\sum_b\{(G_V{}^{(\mu)})^2|\langle b|\exp|a\rangle|^2+\frac{1}{3}(-(G_A{}^{(\mu)})^2+(G_P{}^{(\mu)})^2-2G_A{}^{(\mu)}G_P{}^{(\mu)})|\langle b|(\exp)\boldsymbol{\sigma}|a\rangle|^2\}}{\sum_b\{(G_V{}^{(\mu)})^2|\langle b|\exp|a\rangle|^2+\frac{1}{3}(3(G_A{}^{(\mu)})^2+(G_P{}^{(\mu)})^2-2G_A{}^{(\mu)}G_P{}^{(\mu)})|\langle b|(\exp)\boldsymbol{\sigma}|a\rangle|^2\}}$$

$$=\frac{(G_V{}^{(\mu)})^2\langle a|[\exp]_a{}^+[\exp]_a|a\rangle+\frac{1}{3}(-(G_A{}^{(\mu)})^2+(G_P{}^{(\mu)})^2-2G_A{}^{(\mu)}G_P{}^{(\mu)})\langle a|[(\exp)\boldsymbol{\sigma}]_a{}^+\cdot[(\exp)\boldsymbol{\sigma}]_a|a\rangle,}{(G_V{}^{(\mu)})^2\langle a|[\exp]_a{}^+[\exp]_a|a\rangle+\frac{1}{3}(3(G_A{}^{(\mu)})^2+(G_P{}^{(\mu)})^2-2G_A{}^{(\mu)}G_P{}^{(\mu)})\langle a|[\exp)\boldsymbol{\sigma}]_a{}^+\cdot[(\exp)\boldsymbol{\sigma}]_a|a\rangle}, \tag{47a}$$

where

$$[\exp]_a\equiv\textstyle\sum_i\tau_i{}^{(-)}\exp(-i\langle\nu\rangle_a\boldsymbol{\nu}_1\cdot\mathbf{r}_i)\varphi(r_i);\quad [(\exp)\boldsymbol{\sigma}]_a\equiv\sum_i\tau_i{}^{(-)}\exp(-i\langle\nu\rangle_a\boldsymbol{\nu}_1\cdot\mathbf{r}_i)\varphi(r_i)\boldsymbol{\sigma}_i \tag{47b}$$

which enters into the recoil nucleus angular distribution, $1+P_\mu\alpha(a)(\mathbf{s}_{\mu;1}\cdot\mathbf{p}_{\rm rec;1})$, appropriate to the total muon capture rate by the parent nucleus. Employing the techniques of Eqs. (4a) to (11b) then gives, for the heavier nuclei, $Z>6$, $A>12$ {using also Eqs. (1b) and (1c) with $\langle\nu\rangle_a=0.75\,m_\mu$ [Eq. (3d)] and $g_A{}^{(\beta)}/g_V{}^{(\beta)}=-1.21$ [11]},

$$\alpha(a)\cong\frac{(G_V{}^{(\mu)})^2-(G_A{}^{(\mu)})^2+(G_P{}^{(\mu)})^2-2G_A{}^{(\mu)}G_P{}^{(\mu)}}{(G_V{}^{(\mu)})^2+3(G_A{}^{(\mu)})^2+(G_P{}^{(\mu)})^2-2G_A{}^{(\mu)}G_P{}^{(\mu)}}$$

$$=-0.39. \tag{48}$$

Further, if the daughter nucleus is unbound even in its ground state, e.g.,

$$\mu^-+Mg_{12}{}^{26}\rightarrow\nu+\{Na_{11}{}^{26}\rightarrow Na_{11}{}^{25}+n_0{}^1\}, \tag{49}$$

it is not unreasonable to suppose that in the great majority of energetically accessible final states a single neutron carries off most of the available recoil momentum. Under such circumstances the angular distribution of the recoiling neutrons is, approximately,

$$1+P_\mu\alpha(a)(\mathbf{s}_{\mu;1}\cdot\mathbf{p}_{\rm neu;1}), \tag{50}$$

where $\alpha(a)$ is as in Eq. (48) and $\mathbf{p}_{\rm neu;1}$ is a unit vector in the recoil neutron direction. Überall[34] has considered, on the basis of a Fermi gas model, the effective interaction of the recoiling neutron with the remaining nucleons and has concluded that this effective interaction is probably not sufficiently strong to distort appreciably the angular distribution in Eq. (50).

We now consider recoil anisotropy for the case of muon capture by parent nuclei with nonzero spin. Here the anisotropy coefficients are different in the two different hyperfine states of the parent mu-mesic atom, i.e., one must distinguish between $\alpha(J_a+\frac{1}{2};a)$ and $\alpha(J_a-\frac{1}{2};a)$. As a general rule it is obvious that $\alpha(J_a-\frac{1}{2};a)=0$ for $J_a=\frac{1}{2}$ since the corresponding parent atom hyperfine state is then a singlet and so is spatially spherical. As a particular illustration we may give the formulas for the case of the hydrogen mu-mesic atom $[p\mu^-]$. Here, by the remark just made,

$$\alpha(\tfrac{1}{2}-\tfrac{1}{2};H_1{}^1)=0, \tag{51a}$$

and, as shown in a calculation by Bernstein and Primakoff,[37]

$$\alpha(\tfrac{1}{2}+\tfrac{1}{2};\,H_1{}^1)=\frac{\tfrac{1}{2}[(G_V{}^{(\mu)}+G_A{}^{(\mu)})^2+(G_P{}^{(\mu)})^2-2(G_V{}^{(\mu)}+G_A{}^{(\mu)})G_P{}^{(\mu)}]}{\tfrac{3}{4}[(G_V{}^{(\mu)}+G_A{}^{(\mu)})^2+(G_P{}^{(\mu)})^2-\tfrac{2}{3}(G_V{}^{(\mu)}+G_A{}^{(\mu)})G_P{}^{(\mu)}]}. \tag{51b}$$

Thus at low $(H_1{}^1)_2$ molecule number densities, where there is no appreciable collisional hyperfine triplet to singlet conversion (Sec. 5), the angular distribution of the recoil neutrons is:

$$\frac{\tfrac{3}{4}\Lambda^{(\mu)}(\tfrac{1}{2}+\tfrac{1}{2};\,H_1{}^1)[1+P_\mu\alpha(\tfrac{1}{2}+\tfrac{1}{2};\,H_1{}^1)(\mathbf{s}_{\mu;1}\cdot\mathbf{p}_{\text{neu};1})]+\tfrac{1}{4}\Lambda^{(\mu)}(\tfrac{1}{2}-\tfrac{1}{2};\,H_1{}^1)}{\Lambda^{(\mu)}(H_1{}^1)} \tag{52a}$$

or {using also Eqs. (33a), (33b), (27b), (1b), and (1c) (with $\langle\nu\rangle_a=0.94\,m_\mu$ [Eq. (2c)], and $(g_A{}^{(\beta)}/g_V{}^{(\beta)})=-1.21$ [11])},

$$1+\frac{P_\mu}{2}\frac{[(G_V{}^{(\mu)}+G_A{}^{(\mu)})^2+(G_P{}^{(\mu)})^2-2(G_V{}^{(\mu)}+G_A{}^{(\mu)})G_P{}^{(\mu)}]}{[(G_V{}^{(\mu)})^2+3(G_A{}^{(\mu)})^2+(G_P{}^{(\mu)})^2-2G_A{}^{(\mu)}G_P{}^{(\mu)}]}(\mathbf{s}_{\mu;1}\cdot\mathbf{p}_{\text{neu};1}) \tag{52b}$$

$$=1+\frac{P_\mu}{2}[0.01](\mathbf{s}_{\mu;1}\mathbf{p}_{\text{neu};1}), \tag{52c}$$

while the corresponding muon decay electron angular distribution becomes

$$1-\frac{P_\mu}{2}\tfrac{1}{3}(\mathbf{s}_{\mu;1}\cdot\mathbf{p}_{\text{el};1}). \tag{52d}$$

P_μ must be interpreted in Eqs. (52a) to (52d) as what the residual muon polarization would be, at the instant of decay or capture, if the parent proton did not create any hyperfine-structure induced depolarization in the muon $1s_{\frac{1}{2}}$ orbit—it is seen that the numerical values of $G_V{}^{(\mu)}$, $G_A{}^{(\mu)}$, $G_P{}^{(\mu)}$ are such that the recoil neutron distribution is practically isotropic; this is expected since $[\Lambda^{(\mu)}(\frac{1}{2}+\frac{1}{2};\,H_1{}^1)/\Lambda^{(\mu)}(\frac{1}{2}-\frac{1}{2};\,H_1{}^1)]\ll 1$ [Eqs. (33a) and (33b)]. At higher $(H_1{}^1)_2$ molecule densities all the $[p\mu^-]$ are collisionally converted into the hyperfine singlet state (Sec. 5), so that as already noted above and as first pointed out by Gershtein and Zeldovich,[22] the recoil neutron distribution is here certainly expected to be isotropic.

(b) Angular Distribution of Photons in Radiative Capture of Polarized Muons

The internal bremsstrahlung (I.B.) photons emitted in the radiative capture of polarized muons are also expected to be characterized by an anisotropic angular distribution relative to $\mathbf{s}_{\mu;1}$; this distribution is, for the case of zero spin parent nuclei with the daughter nuclei formed in a particular state:

$$1+P_\mu\beta(a\to b;\,\gamma_{ba})(\mathbf{s}_{\mu;1}\cdot\boldsymbol{\gamma}_1), \tag{53}$$

where $\boldsymbol{\gamma}_{ba}=\gamma_{ba}\boldsymbol{\gamma}_1$ is the I.B. photon momentum vector, $\beta(a\to b;\,\gamma_{ba})$ the corresponding anisotropy coefficient, and, for the reasons mentioned in Sec. 7(a), the discussion is again confined to the case of zero spin parent nuclei.

The anisotropy coefficient $\beta(a\to b;\,\gamma_{ba})$ of Eq. (53) may be directly calculated or may be obtained on the basis of a theorem of Cutkosky[38] which shows that this $\beta(a\to b;\,\gamma_{ba})$ is numerically equal to the helicity of a *massless* positron emitted in the beta-decay process: $|a;Z,A\rangle\to|b;Z-1,A\rangle+e^+\!+\nu$ ($Z/137\ll 1$; beta-decay process allowed or forbidden). Now in a beta-decay theory described by an effective Hamiltonian of the type of Eq. (1a) with $G_V{}^{(\mu)}\to g_V{}^{(\beta)}$, $G_A{}^{(\mu)}\to g_A{}^{(\beta)}$, $G_P{}^{(\mu)}\to 0$ the helicity of such a massless positron is $+1$ —thus in a muon radiative capture theory with an $H_{\text{eff}}{}^{(\mu)}$ characterized by $G_V{}^{(\mu)}=g_V{}^{(\mu)}$, $G_A{}^{(\mu)}=g_A{}^{(\mu)}$, $G_P{}^{(\mu)}=0$, i.e., with an $H_{\text{eff}}{}^{(\mu)}$ in which all nucleon recoil effects (terms $\sim\nu/m_p$) are omitted, one has

$$\beta(a\to b;\,\gamma_{ba})=1. \tag{54}$$

Thus, summing over all the energetically accessible states of the daughter nucleus, we obtain

$$\beta(a;\,\langle\boldsymbol{\gamma}\rangle_a)=\frac{\sum_b\beta(a\to b;\,\gamma_{ba})\Lambda_{\text{rad}}{}^{(\mu)}(a\to b;\,\gamma_{ba}}{\sum_b\Lambda_{\text{rad}}{}^{(\mu)}(a\to b;\,\gamma_{ba})}=1, \tag{55}$$

which last pair of equations have also been explicitly derived by H.Y. and L.[27] and by Bernstein.[28]

There is now very considerable interest in a calculation of $\beta(a\to b;\,\gamma_{ba})$, $\beta(a;\,\langle\boldsymbol{\gamma}\rangle_a)$, where one includes nucleon recoil terms $\sim\nu/m_p$ into the appropriate effective Hamiltonian, i.e., includes in particular the induced pseudoscalar and the conserved vector current anomalous magnetic moment contributions—such a calculation is being carried out by Bernstein.[28] The effect of the pseudoscalar term can be foreseen quali-

[37] J. Bernstein and H. Primakoff (to be published).

[38] R. E. Cutkosky, Phys. Rev. **107**, 330 (1957).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

tatively on the basis of Cutkosky's theorem[38] since it is known that with an effective V, A, P beta-decay interaction the helicity of a massless positron is less than unity; hence in a theory with $g_P{}^{(\mu)}\neq 0$ the calculated values of $\beta(a\rightarrow b;\gamma_{ba})$, $\beta(a;\langle\gamma\rangle_a)$ will also be less than unity. Thus any measurement of the I.B. photon angular distribution sufficiently accurate to fix a reliable value for $(1-\beta(a;\langle\gamma\rangle_a))$ will, upon comparison with Bernstein's theoretical expression[28] for $\beta(a;\langle\gamma\rangle_a)$, yield an "experimental" value of $g_P{}^{(\mu)}$ which can be compared with the Goldberger-Treiman[3]-Wolfenstein[4] theoretical value of $8g_A{}^{(\beta)}$ [Eq. (1c)].

(c) Polarization of Recoil Nuclei in Muon Capture

The recoil daughter nuclei formed in muon capture are in general polarized even when the polarization of the muon itself at the instant of capture is negligible. This effect has been discussed in a fairly general way by Treiman[35] and by Fulton,[36] and for the particular case of the hydrogen mu-mesic atom by Gershtein and Zeldovich[22] and by Bernstein and Primakoff.[37] For $[p\mu^-]$ in the hyperfine singlet state Gershtein and Zeldovich[22] point out that conservation of angular momentum and the assumption that the neutrino has unit negative helicity ensures, independent of the magnitudes of the various coupling constants in $H_{\rm eff}{}^{(\mu)}$, that the helicity of the recil neutron is $=-1$. For $[p\mu^-]$ in the hyperfine triplet state an explicit calculation by Bernstein and Primakoff[37] shows that the recoil neutron helicity is

$$-\frac{1}{3}\frac{(G_V{}^{(\mu)}+G_A{}^{(\mu)})^2+(G_P{}^{(\mu)})^2-6(G_V{}^{(\mu)}+G_A{}^{(\mu)})G_P{}^{(\mu)}}{(G_V{}^{(\mu)}+G_A{}^{(\mu)})^2+(G_P{}^{(\mu)})^2-\frac{2}{3}(G_V{}^{(\mu)}+G_A{}^{(\mu)})G_P{}^{(\mu)}} \quad (56a)$$

so that at low $(H_1{}^1)_2$ molecule number densities the over-all recoil neutron helicity is {using also Eqs. (33a), (33b), (27b), (1b), and (1c) (with $\langle\nu\rangle_a=0.94\,m_\mu$ [Eq. (2c)] and $(g_A{}^{(\beta)}/g_V{}^{(\beta)})=-1.21$ [11])}

$$\frac{3}{4}\frac{\Lambda^{(\mu)}(\frac{1}{2}+\frac{1}{2};H_1{}^1)}{\Lambda^{(\mu)}(H_1{}^1)}\left[-\frac{1}{3}\frac{(G_V{}^{(\mu)}+G_A{}^{(\mu)})^2+(G_P{}^{(\mu)})^2-6(G_V{}^{(\mu)}+G_A{}^{(\mu)})G_P{}^{(\mu)}}{(G_V{}^{(\mu)}+G_A{}^{(\mu)})^2+(G_P{}^{(\mu)})^2-\frac{2}{3}(G_V{}^{(\mu)}+G_A{}^{(\mu)})G_P{}^{(\mu)}}\right]+\frac{1}{4}\frac{\Lambda^{(\mu)}(\frac{1}{2}-\frac{1}{2};H_1{}^1)}{\Lambda^{(\mu)}(H_1{}^1)}[-1]$$

$$=2\frac{G_V{}^{(\mu)}G_A{}^{(\mu)}-(G_A{}^{(\mu)})^2-G_V{}^{(\mu)}G_P{}^{(\mu)}}{(G_V{}^{(\mu)})^2+3(G_A{}^{(\mu)})^2+(G_P{}^{(\mu)})^2-2G_A{}^{(\mu)}G_P{}^{(\mu)}}=-0.99. \quad (56b)$$

This is very close to -1 as is indeed expected from the fact that $[\Lambda^{(\mu)}(\frac{1}{2}+\frac{1}{2};H_1{}^1)/\Lambda^{(\mu)}(\frac{1}{2}-\frac{1}{2};H_1{}^1)]\ll 1$ [Eqs. (33a) and (33b)].

In the calculation given by Treiman[35] and by Fulton[36] the $H_{\rm eff}{}^{(\mu)}$ of Eq. (1a) with $G_V{}^{(\mu)}=g_V{}^{(\mu)}$, $G_A{}^{(\mu)}=g_A{}^{(\mu)}$, $G_P{}^{(\mu)}=0$, has been used; also, for the reasons mentioned in Sec. 7a, the discussion should be confined to the case of zero spin parent nuclei. Making the additional assumption that the wave functions $|a;J_a=0^+\rangle$, $|b;J_b\rangle$ of the parent and daughter nuclei are such that the s-wave part of $\exp(-i\nu_{ba}\cdot\mathbf{r}_i)$ predominates over the d wave, g wave, $\cdots$ parts in the nuclear matrix elements,[1] so that $J_b=1^+$, one may calculate the polarization of the recoil daughter nuclei formed in a particular state with $J_b=1^+$. Since in a $J_a=0^+\rightarrow J_b=1^+$ transition, as for example $\mu^-+C_6{}^{12}=\nu+(B_5{}^{12})_{\text{ground state}}$, the spin independent nuclear matrix element $\langle b|\exp|a\rangle$ [Eq. (36b)] vanishes,[1] the spin dependent nuclear matrix element $\langle b|(\exp)\boldsymbol{\sigma}|a\rangle$ [Eq. (36b)] necessarily cancels out of the expression for the recoil polarization and this becomes

$$\langle\mathbf{J}_{b;1}(\mathbf{p}_{\text{rec};1})\rangle=-\frac{2}{3}\frac{-\mathbf{p}_{\text{rec};1}+P_\mu\mathbf{s}_{\mu;1}}{1-\frac{1}{3}P_\mu\mathbf{s}_{\mu;1}\mathbf{p}_{\text{rec};1}}. \quad (57)$$

Thus the recoil polarization is (anti) parallel to $\mathbf{p}_{\text{rec};1}$ only if the muon polarization at the instant of capture, P_μ, vanishes. One can also obtain the recoil polarization averaged over all possible directions of recoil: $\{\langle\mathbf{J}_{b;1}\rangle\}_{\text{Av}}$ —this turns out to be (Jackson, Treiman, and Wyld[39])

$$\{\langle\mathbf{J}_{b;1}\rangle\}_{\text{Av}}=\tfrac{2}{3}P_\mu\mathbf{s}_{\mu;1} \quad (58)$$

and is just what $\langle\mathbf{J}_{b;1}(\mathbf{p}_{\text{rec};1})\rangle$ would be in a theory with a parity conserving $H_{\rm eff}{}^{(\mu)}$. The quantity $\{\langle\mathbf{J}_{b;1}\rangle\}_{\text{Av}}$ has recently been measured by Love, Marder, Nadelhaft, Siegel, and Taylor[40] on the basis of the observation of the angular anisotropy, relative to $\mathbf{s}_{\mu;1}$, of the decay electrons of the daughter nucleus: $(B_5{}^{12})_{\text{ground state}}$. $\{\langle\mathbf{J}_{b;1}\rangle\}_{\text{Av}}$ was found to be positive if one identified the directions $\mathbf{s}_{\mu;1}$ and $\mathbf{p}_{\text{neg. muon};1}$ [Eq. (43b)] while its magnitude was appropriate to a reasonable amount of depolarization of the $B_5{}^{12}$ by hyperfine interaction with its atomic electrons.

(d) Polarization of Photons in Radiative Muon Capture

The internal bremsstrahlung (I.B.) photons emitted in radiative muon capture are circularly polarized independent of any residual polarization of the muon itself. Cutkosky,[38] H.Y. and L.[27] and Bernstein[28] have shown that the degree of circular polarization, $\beta'(a\rightarrow b;\gamma_{ba})$ of any I.B. photon with momentum γ_{ba}—$\beta'(a\rightarrow b;\gamma_{ba})=\pm 1$ for complete right-hand, left-hand

[39] Jackson, Treiman, and Wyld, Phys. Rev. **107**, 327 (1957).
[40] Love, Marder, Nadelhaft, Siegel, and Taylor, Phys. Rev. Letters **2**, 107 (1959).

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

circular polarization—is numerically equal to the parameter $\beta(a \to b; \gamma_{ba})$ which is the corresponding anisotropy coefficient of the I.B. photon momentum directional distribution [Eq. (53)]. The conclusions drawn in Sec. (7b) about $\beta(a \to b; \gamma_{ba})$, $\beta(a; \langle\gamma\rangle_a)$ therefore can be applied to the corresponding quantities $\beta'(a \to b; \gamma_{ba})$,

$$\beta'(a; \langle\gamma\rangle_a) = \frac{\sum_b \beta'(a \to b; \gamma_{ba}) \Lambda_{\text{rad}}{}^{(\mu)}(a \to b; \gamma_{ba})}{\sum_b \Lambda_{\text{rad}}{}^{(\mu)}(a \to b; \gamma_{ba})} \quad (59)$$

so that in particular one expects deviations from complete right circular polarization of the I.B. photons only to the extent that the induced pseudoscalar interaction is present.

ACKNOWLEDGMENT

I should like to thank Professor V. L. Telegdi for many interesting and informative discussions on the subject of muon capture and for the communication of experimental data before publication.

Strange Particle Decay Processes and the Fermi Interaction*

R. H. DALITZ

Enrico Fermi Institute for Nuclear Studies, University of Chicago, Chicago, Illinois

1. INTRODUCTION

IT recently has become apparent that the processes of beta decay, muon decay, and nuclear capture of μ^- mesons may each be well described in terms of a four-fermion coupling of the form $V-A$, each of these couplings having a strength $gm_\pi^2 \sim 10^{-7}$. Feynman and Gell-Mann[1] have suggested that these interactions may be parts of a more general weak interaction expressed in terms of a weak interaction current J_μ, this general interaction having the form

$$H_{wk}=J_\mu^* J_\mu, \tag{1.1}$$

where the current J_μ consists of the sum

$$J_\mu=g^{\frac{1}{2}}\bar{\nu}\gamma_\mu(1+\gamma_5)\mu^+ + g^{\frac{1}{2}}\bar{\nu}\gamma_\mu(1+\gamma_5)e^+ + g^{\frac{1}{2}}\bar{n}\gamma_\mu(1+\gamma_5)p+\cdots. \tag{1.2}$$

These authors, and earlier Gershtein and Zeldovich,[2] have suggested further that the terms of J_μ which involve strongly interacting particles, but allow no change of strangeness, may obey a conservation principle.

As a result of these successes of the four-fermion interaction, attention is confined here to a survey of the possibility of accounting for strange particle decays by the addition of further terms to the current J_μ, terms which have the same form as those of Eq. (1.2) but which do not conserve strangeness. There are many possibilities for additional terms of this kind, for example $\bar{\Lambda}\gamma_\mu(1+\gamma_5)p$, $\bar{\Sigma}^-\gamma_\mu(1+\gamma_5)n$, $\bar{\Xi}^-\gamma_\mu(1+\gamma_5)\Lambda$, etc. The coupling of these terms to those of (1.2) which involve strongly interacting particles and no change in strangeness then lead directly to the pionic decay modes which are observed for the hyperons; their coupling to the leptonic terms of (1.2) leads to leptonic decay modes for the hyperons. The decay of K mesons is then interpreted as due to their coupling to virtual hyperon-nucleon pairs which allow weak decays for the K mesons through the four-fermion couplings of the expression (1.2), for example

$$K^+ \xrightarrow[\text{strong}]{} p+\bar{\Lambda}\begin{cases}\xrightarrow[\text{weak}]{} \mu^+ + \bar{\nu}, & (1.3a)\\ \xrightarrow[\text{weak}]{} p+\bar{n} \xrightarrow[\text{strong}]{} \pi^+ + \pi^- + \pi^+. & (1.3b)\end{cases}$$

The possibility of a qualitative account of the decay modes of hyperons and K particles on the basis of such four-fermion couplings has been known for some time. It was first put forward by Dallaporta[3] and by Gell-Mann,[4] and has been discussed in some detail by Gell-Mann and Rosenfeld[5] in their recent review article.

At this stage it is necessary to inquire to what extent this scheme offers the possibility of accounting quantitatively[6] for the branching ratios and detailed characteristics of these decay modes. However, such a complete program is not carried through here. Our present purpose is simply to discuss the degree of agreement between the data and those expectations from this model which do not depend on detailed theoretical calculations of its consequences.

2. PIONIC DECAY MODES FOR STRANGE PARTICLES

First *the* Λ *decay modes*,

$$\Lambda \to \begin{cases} p+\pi^-, & (2.1a)\\ n+\pi^0, & (2.1b)\end{cases}$$

are considered. These modes are regarded as the result of weak interactions connecting $(\bar{\Lambda}p)$ and $(\bar{n}p)$. With a parity nonconserving weak interaction, each of these modes requires two parameters (s_-,p_-) and (s_0,p_0), which denote the amplitudes for emission of s- and p-wave pions in the π^-- and π^0-decay processes (2.1), respectively. Assuming time-reversal invariance to be valid for both strong and weak interactions, the phases of these amplitudes arise only from the scattering in the final pion-nucleon state, as first pointed out by Takeda.[7] Since the relevant pion-nucleon phase shifts are known to be small at the energy of Λ decay, the parameters s

[6] The absence of evidence for the beta decay of the Λ particle appeared a stumbling block for this scheme for a long time. However this process has now been observed by Crawford, Cresti, Good, Kalbfleisch, Stevenson, and Ticho [Phys. Rev. Letters 1, 377 (1958)] and by Nordin, Orear, Reed, Rosenfeld, Solmitz, Taft, and Tripp [Phys. Rev. Letters 1, 380 (1958)]. The observed rate suggests (cf. Sec. 4) that the term of J_μ associated with this process may have an amplitude of order 0.3 relative to that for beta decay of the neutron.

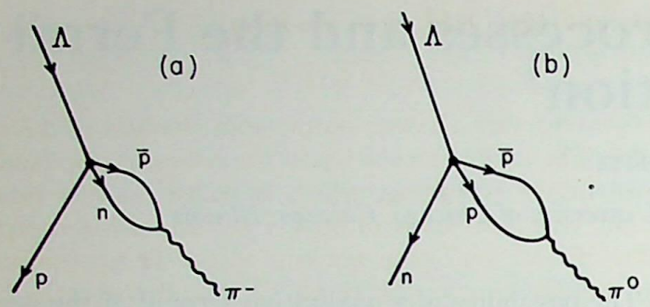

FIG. 1. The simplest graphs leading to pionic Λ decay through the Fermi interaction.

and p will be assumed real. The experimental information bearing on these parameters is at present limited to the following[8]:

$$(s_0^2+p_0^2)/(s_-^2+p_-^2)=0.59\pm0.07, \quad (2.2a)$$

$$\alpha_-=2s_-p_-/(s_-^2+p_-^2)\gtrsim 0.73\pm0.14, \quad (2.2b)$$

the first representing the branching ratio between the modes (2.1), the second representing the information available on the up-down asymmetry in the decay of polarized Λ particles. The condition (2.2b) limits p_-/s_- to lie between the limits

$$0.45\lesssim|p_-/s_-|\lesssim 2.25. \quad (2.3)$$

Calculation of the amplitudes for the processes (2.1) from the four-fermion weak couplings of the type $(\bar{\Lambda}p)(\bar{p}n)$ would involve consideration of many complicated radiative corrections arising from the strong pion couplings of these fermions, a task beyond our present ability. For the purpose of orientation, we confine attention to the simplest possible graphs leading to these decay processes, those shown in Fig. 1. For this graph the amplitude for process (2.1a) takes the form

$$\sqrt{2}C(\bar{\Lambda}\gamma_\mu(1+\gamma_5)p)\partial\phi_\pi/\partial x_\mu$$
$$=\sqrt{2}C\{(m_\Lambda-m)+(m_\Lambda+m)\boldsymbol{\sigma}\cdot\mathbf{q}/2m\}, \quad (2.4)$$

in the nonrelativistic limit appropriate to the low-energy release in Λ decay, when $\mathbf{q}$ denotes the pion momentum. This crude estimate leads to a ratio $p_-/s_-=(m_\Lambda-m)q/2m(m_\Lambda+m)=0.64$, corresponding to a value $\alpha_-=+0.9$ for the polarization coefficient in Λ decay. This value of p_-/s_- lies within the limits (2.3) from the up-down asymmetry observed[8] in polarized Λ-particle decay and corresponds to the sign recently[9] deduced for α from the polarization observed for protons resulting from the decay of unpolarized Λ particles. Such a large value of p_-/s_- is characteristic of a coupling which involves V coupling with the chirality factor $(1+\gamma_5)$; in the same approximation, S coupling (with this chirality factor) would lead to a ratio $p_-/s_-\sim q/2m=0.05$ and the large lower limit observed for α_- would then be difficult to understand in terms of a chirality factor.

Further evidence concerning this ratio p_-/s_- may be obtained from the data on the frequency of the two-body decay mode

$$_\Lambda H^4\rightarrow\pi^-+He^4, \quad (2.5)$$

relative to that for all the three-body π^--decay modes of $_\Lambda H^4$, for example π^-+p+H^3 or π^-+n+He^3. Systematic investigation by the EFINS–NU emulsion groups[10] at Chicago has established 35 examples of the two-body mode (2.5), compared with a maximum of 27 examples for other π^--mesonic modes of $_\Lambda H^4$ decay. This last figure includes six events which probably represent three-body modes of $_\Lambda H^4$ decay but which could not be uniquely established as representing $_\Lambda H^4$ decay events. From this evidence the proportion R of π^--mesonic $_\Lambda H^4$ decays which proceed through the two-body mode (2.5) is rather high, in fact,

$$R\gtrsim 0.6\pm0.1. \quad (2.6)$$

If the ground state of $_\Lambda H^4$ has spin $J=1$, the process (2.5) must involve the emission of a p-wave pion. This can take place only through the p channel of Λ decay since the initial and final nuclear systems consist predominantly of s states. According to a recent estimate,[11] the value R_1 for this case cannot exceed 0.25, reaching this value only with the upper limit (2.3) for p_-/s_-. On the other hand, with $J=0$, the pion emission can proceed through the s channel of the Λ-decay interaction and the corresponding estimate R_0 can reach a value of 0.45 with the use of the lower limit (2.3) for p_-/s_-. There is now some reason[12] to believe that these calculations may involve some overestimate of the probability of the three-body modes, and correction for this will allow correspondingly larger estimates (by as much as 20%) for R. However, the qualitative conclusion appears definite, that it is difficult to account for the value (2.6) observed for R unless $J=0$ for $_\Lambda H^4$ and $p_-/s_-<1$. With this last conclusion,

[8] D. Glaser, *Proceedings of the 1958 Annual International Conference on High Energy Physics at CERN*, p. 265; Glaser, Good, and Morrison, *Proceedings of the 1958 Annual International Conference on High Energy Physics at CERN*, p. 270.

[11] R. H. Dalitz, Phys. Rev. **112**, 605 (1958).

[12] R. H. Dalitz and L. Liu (to be published). [*Note added in proof.*—Re-examination of the calculation reported in reference 11 has shown that the conclusions drawn above are too strong. With $J=0$, the values calculated for R are consistent with the experimental result (2.6), within the stated error, for values of p_-/s_- less than 1.5. With $J=1$, the calculated value of R is within two standard deviations of (2.6) for $p_-/s_->1$. Consequently, no conclusion concerning the value of p_-/s_- can be reached from these data alone until the spin of $_\Lambda H^4$ is known independently. Conversely, if a value of p_-/s_- could be obtained directly (for example, from observations on the proton polarization resulting from polarized Λ decay), this argument may allow the $_\Lambda H^4$ spin to be deduced. The evidence on the nonmesonic decay rates for Λ hypernuclei mentioned below does suggest that it is rather unlikely that p_-/s_- should exceed unity.]

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

it appears that the p_-/s_- ratio of 0.64 obtained from this crude model of Λ decay does not differ widely from the actual situation.

A similar crude calculation may be made for the mode (2.1b) on the basis of the $V-A$ interaction $(\bar{\Lambda}p)(\bar{p}n)$, with the result[13] $C(\bar{\Lambda}\gamma_\mu(1+\gamma_5)n)\partial\phi_0/\partial x_\mu$. This estimate predicts that

$$s_0/s_-=p_0/p_-=1/\sqrt{2}. \tag{2.7}$$

This is consistent with the observed ratio (2.2b) between the (π^0+n) and (π^-+p) modes of Λ decay, and it further requires that the polarization properties of these two modes should be identical, a prediction of current interest, since the ratio α_0/α_- may soon be determined from Λ particles by experiments in bubble chambers with working fluid of high density.

However, these experimental predictions would also follow directly from the $\Delta T=\frac{1}{2}$ selection rule proposed by Gell-Mann and Pais[14] for strange particle decays. With $T=0$ for the Λ particle, this would require $T=\frac{1}{2}$ for the $(\pi+N)$ system and therefore that

$$s_0/s_-=p_0/p_-=-1/\sqrt{2}. \tag{2.8}$$

It is obviously difficult to distinguish between the cases (2.7) and (2.8), since they differ only in the relative sign of the matrix elements for two different physical processes. However, this relative sign is, in principle, a physical observable and can have physical consequences, as shown in the following. At present there is no theoretical basis to favor the existence of such a $\Delta T=\frac{1}{2}$ selection rule. The proposal of this selection rule is based entirely on the empirical evidence that is discussed in the next section. It is possible to construct a four-fermion interaction which leads to this $\Delta T=\frac{1}{2}$ selection rule; in fact, for an interaction involving only the Λ hyperon, this would have the unique $(V-A)$ form

$$\{(\bar{\Lambda}p)(\bar{p}n)+(\bar{\Lambda}n)(\bar{n}n)\}. \tag{2.9}$$

However, this interaction does not fit with the viewpoint of Feynman and Gell-Mann as expressed in Eq. (1.1), since the only terms which they permit for the current J_μ involve a charge change ΔQ of one unit. This restriction appears necessary in order to forbid certain types of decay process (e.g., $\mu^+\rightarrow e^++e^-+e^+$, $K^+\rightarrow\pi^++\nu+\bar{\nu}$) whose occurrence has not been observed, and excludes terms of the type $(\bar{\nu}\nu)$, $(\bar{\Lambda}n)$ or $(\bar{n}n)$ from J_μ. The four-fermion interaction allowed by these considerations is composed of the current terms $(\bar{\Lambda}p)$ and $(\bar{p}n)$, leading to the form

$$(\bar{\Lambda}p)(\bar{p}n). \tag{2.10}$$

This interaction allows isotopic spin changes of $\Delta T=\frac{1}{2}$ and $\frac{3}{2}$. The crude calculation of the Λ-decay amplitudes given in the foregoing, which is based on this interaction, therefore leads to both $T=\frac{1}{2}$ and $T=\frac{3}{2}$ components in the final pion-nucleon state. These combine fortuitously to give the result (2.7) and the ratio 2:1 for the $(\pi^-+p)/(\pi^0+n)$ modes, in agreement with experiment. Inclusion of radiative corrections may be expected to modify the (π^0+n) and (π^-+p) amplitudes in quite different ways. On this view, the agreement between (2.2a) and the prediction of the $\Delta T=\frac{1}{2}$ rule would be regarded as fortuitous and would give no basis for expecting α_0/α_- to be unity, as would follow if the $\Delta T=\frac{1}{2}$ rule held. Observation of the polarization properties of $\Lambda\rightarrow n+\pi^0$ decay will therefore have considerable relevance for understanding of the $(\pi^-+p)/(\pi^0+n)$ ratio in Λ decay and of the basic mechanism underlying Λ decay.

The process of *nonmesonic decay of* Λ *hypernuclei* is of special interest concerning the mechanism underlying Λ decay, since the elementary four-fermion interactions (2.9) and (2.10) mentioned above actually correspond to processes of nonmesonic de-excitation of the Λ particle,[15] thus

$$\Lambda+p\rightarrow n+p \tag{2.11}$$

from interaction (2.10). The strength $\sqrt{f}$ appropriate to a current term $(\bar{\Lambda}p)$ in J_μ is not well-known empirically. The hypothesis of universality for the four-fermion weak interactions would require that f should equal g, the coupling strength appropriate to the terms $(\bar{\nu}e^+)$ or $(\bar{\nu}\mu^+)$; in fact, as shown later (cf. §4), there is reason to believe that f may be an order of magnitude smaller than g. To a sufficient approximation (of order 10%), it is sufficient to consider only the non-relativistic approximation to the $(V-A)$ interaction for (2.10), namely,

$$\begin{aligned}(fg)^{\frac{1}{2}}(\bar{\psi}_\Lambda\gamma_\mu(1+\gamma_5)\psi_p)(\bar{\psi}_p\gamma_\mu(1+\gamma_5)\psi_n)\\ \simeq(fg)^{\frac{1}{2}}\{\bar{\psi}_\Lambda\psi_p\bar{\psi}_p\psi_n-(\bar{\psi}_\Lambda\sigma_\Lambda\psi_p)\cdot(\bar{\psi}_p\sigma_N\psi_n)\}.\end{aligned} \tag{2.12}$$

This dominant term is parity conserving (conventionally, the Λ parity has been defined to be even); parity nonconserving terms are of order $v/c\sim0.25$ relative to this term. There are many radiative corrections due to the strong pion and K-meson couplings of these particles, which modify the form of the amplitude for the nonmesonic capture process (2.11) from this form (2.12). Several of the many possibilities are sketched in Fig. 2. Terms corresponding to Figs. 2(b) and 2(c) are of special importance and have been discussed in detail by Karplus and Ruderman.[16] They may be

[13] With the $V-A$ form of interaction, the interactions $(\bar{a}b)(\bar{c}d)$ and $(\bar{a}d)(\bar{b}c)$ are identical. Consequently, with $(\bar{\Lambda}n)(\bar{p}p)$ replacing $(\bar{\Lambda}p)(\bar{p}n)$, the same factor C appears here, but without the factor $\sqrt{2}$ since the emission is now of a π^0 meson instead of a π^- meson.

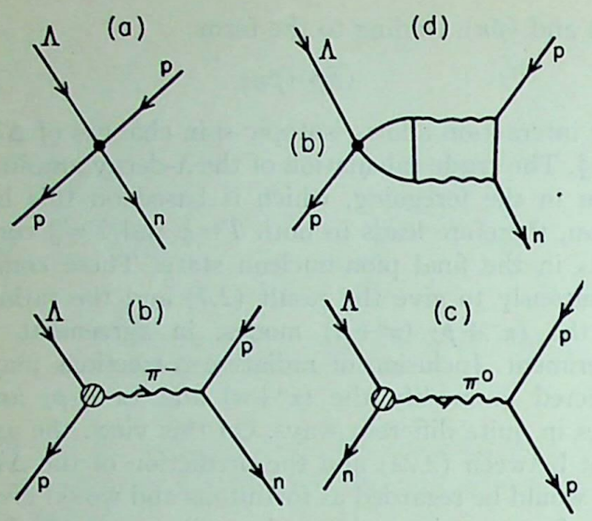

FIG. 2. The elementary four-fermion interaction (a) and some examples (b), (c), and (d) of pionic radiative corrections to this.

expressed phenomenologically in terms of the amplitudes for Λ decay and for pion-nucleon coupling. In physical terms, they represent the process of internal conversion of the pion field generated by the $\Lambda \rightarrow N+\pi$ decay interaction, due to the presence of a neighboring nucleon. The sum of these terms and the basic interaction (2.12) is

$$(fg)^{\frac{1}{2}}(1-\boldsymbol{\sigma}_\Lambda\cdot\boldsymbol{\sigma}_N)+\left\{\frac{\sqrt{2}G}{2m}\frac{4\pi(s_- - p_-\boldsymbol{\sigma}_\Lambda\cdot\mathbf{q})(-\boldsymbol{\sigma}_N\cdot\mathbf{q})}{\frac{1}{4}(m_\Lambda-m)^2-q^2-m_\pi{}^2}\right.$$

$$\left.+\frac{-G}{2m}P_{\Lambda N}{}^{\sigma}\frac{4\pi(s_0+p_0\boldsymbol{\sigma}_\Lambda\cdot\mathbf{q})(\boldsymbol{\sigma}_N\cdot\mathbf{q})}{\frac{1}{4}(m_\Lambda-m)^2-\mathbf{q}^2-m_\pi{}^2}\right\}. \quad (2.13)$$

where $\mathbf{q}$ is the momentum of the outgoing proton, G denotes the pion-nucleon coupling parameter ($G^2/hc \simeq 13.5$), $\boldsymbol{\sigma}_\Lambda$ is the spin vector of the initial Λ particle or final proton, $\boldsymbol{\sigma}_N$ is that of the initial proton or final neutron, and $P_{\Lambda N}{}^{\sigma}$ denotes the spin exchange operator $(1+\boldsymbol{\sigma}_\Lambda\cdot\boldsymbol{\sigma}_N)/2$. Since these last terms are coherent, as was realized by Cerulus,[17] the relative signs of (s_-,p_-) and (s_0,p_0) affect the rate computed for the nonmesonic capture process. The direct amplitude (2.12) interferes only with the p_- and p_0 terms of (2.13) in the total nonmesonic capture rate. The expression (2.13) now serves to illustrate two points:

(i) that the relative sign between s_- and s_0, and between p_- and p_0 does have physical consequences, although these cannot be computed completely in the present case, and

(ii) that the rate of nonmesonic capture generally depends on the relative spin orientation of the Λ particle and the nucleons present. The direct term (2.12) actually vanishes for a triplet spin configuration although its value is quite appreciable $[4(fg)^{\frac{1}{2}}]$ for a singlet configuration. This may be of importance in the light hypernuclei. For example, in ${}_\Lambda H^4$, the (Λp) spin orientation appears to be singlet, from the arguments given above on the decay modes of ${}_\Lambda H^4$, whereas in the mirror nucleus ${}_\Lambda He^4$, there are two protons and the (Λp) spin orientations are randomly distributed. The ratio of the nonmesonic capture process (2.11) in these systems therefore reflects the spin dependence of the amplitude for this process. To illustrate this effect, we give in Table I correction coefficients F_s and F_p for the Ruderman-Karplus calculation of the internal conversion coefficient R, as function of the (Λp) spin state. In terms of F_s, F_p, the internal conversion coefficient $R=$ (nonmesonic capture rate)/(π^--mesonic capture rate) is given by

$$R=(F_s s_-{}^2R_s+F_p p_-{}^2R_p)/(s_-{}^2+p_-{}^2), \quad (2.14)$$

where R_s, R_p are the coefficients computed for $l=0$ and 1 by Ruderman and Karplus. This estimate includes only the "internal conversion" graphs of Figs. 2(b) and 2(c) and neglects the direct term (2.12) as well as all other radiative corrections. It is intended only to illustrate the order of magnitude of these effects.

No example of nonmesonic decay for ${}_\Lambda H^4$ has yet been reported although many examples are known of nonmesonic decay for ${}_\Lambda He^4$ and ${}_\Lambda He^5$. This contrast may possibly be the result of experimental bias, since ${}_\Lambda H^4$ nonmesonic decay can lead only to a one-pronged star.

To sum up, we emphasize again the difficulty of making a quantitative estimate of the rate of nonmesonic Λ-hypernuclear decay in terms of the elementary four-fermion interaction, owing to the complications of the radiative corrections possible. However, there is one conclusion from the hypernuclear decay evidence which appears unlikely to be modified by the effect of further radiative corrections; with the estimates $R_s \simeq 1$, $R_p \simeq 17$ of Ruderman and Karplus for ${}_\Lambda He$ hypernuclei, the observed value of ~ 1.5 for $R({}_\Lambda He)$ obtained by Schlein[18] and by Silverstein[19] still requires that the amplitude p_- should be smaller than s_-. If p-channel emission were dominant relative to s-channel emission in free Λ decay, it would require very detailed cancellations to account for such a low value of R as that observed.

TABLE I. Correction factors to the internal conversion coefficient in hypernuclear decay.[a]

Spin state	(a) $\Delta T=\frac{1}{2}$ F_s	F_p	(b) Amplitudes (2.7) F_s	F_p
$S=0$	9/4	9/4	1/4	1/4
$S=1$	19/12	1/4	11/12	9/4
Spin average (appropriate for ${}_\Lambda He^4$ and ${}_\Lambda He^5$)	7/4	3/4	3/4	7/4

The decay processes of the Σ particles,

$$\Sigma^+ \rightarrow \begin{cases} n+\pi^+, & (2.15a) \\ p+\pi^0, & (2.15b) \end{cases}$$

$$\Sigma^- \rightarrow n+\pi^-, \quad (2.15c)$$

could already take place through the interaction (2.10), since the Σ and Λ particles are strongly coupled, but probably occur also through additional four-fermion couplings involving the Σ particles. The most general such coupling would allow isotopic spin changes ΔT up to $\frac{5}{2}$ in strange particle decays. However, the isotopic spin changes may be limited to $\Delta T \leqslant \frac{3}{2}$ by considering the interaction

$$\left\{(\bar{\Sigma}^- n)+\frac{1}{\sqrt{2}}(\bar{\Sigma}^0 p)\right\}(\bar{p}n). \quad (2.16)$$

It is attractive to combine this with $(fg/2)^{\frac{1}{2}}$ times the term (2.10) to give the form

$$(fg)^{\frac{1}{2}}(\bar{Z}N)(\bar{p}n) = (fg)^{\frac{1}{2}}\left\{(\bar{\Sigma}^- n)+\left(\frac{\bar{\Lambda}+\bar{\Sigma}^0}{\sqrt{2}}p\right)\right\}(\bar{p}n), \quad (2.17)$$

where Y, Z denote the combinations

$$Z=\begin{pmatrix}(\Lambda+\Sigma^0)/\sqrt{2}\\ \Sigma^-\end{pmatrix}, \quad Y=\begin{pmatrix}\Sigma^+\\ (\Lambda-\Sigma^0)/\sqrt{2}\end{pmatrix} \quad (2.18)$$

of Σ and Λ states appropriate to the hypothesis of a universal pion-hyperon coupling, advanced by Gell-Mann[20] and by Schwinger.[21] The interaction (2.17) appears naturally on the hypothesis that the strangeness nonconserving current J_μ' consists of the terms

$$J_\mu' = f^{\frac{1}{2}}(\bar{Z}\gamma_\mu(1+\gamma_5)N+\bar{\Xi}\gamma_\mu(1+\gamma_5)Y), \quad (2.19)$$

each of which is a spinor under isotopic spin rotations. The hypothesis of a $T=\frac{1}{2}$ form for the strangeness nonconserving current has been put forward especially by Okubo *et al.*[22]

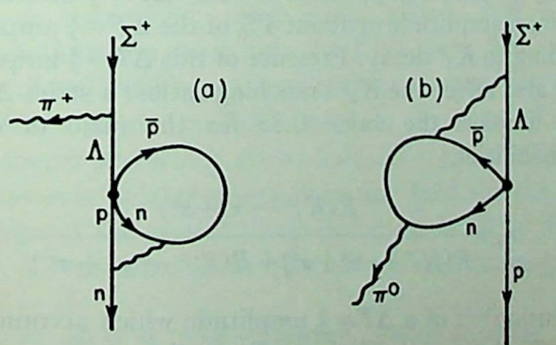

FIG. 3. Some of the lowest order graphs which lead to the Σ^+ decay processes through the four-fermion interaction $(\bar{Z}N)(\bar{N}N)$.

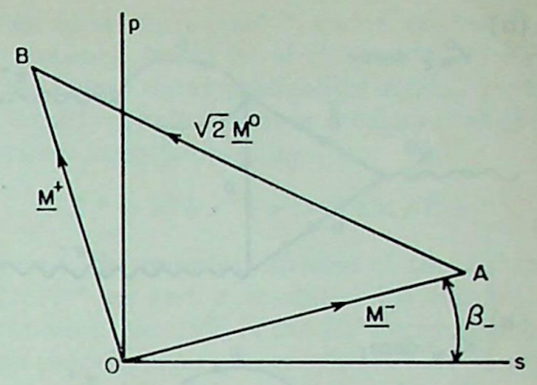

FIG. 4. The Gell-Mann—Rosenfeld diagram for representation of the matrix-elements for Σ^+ and Σ^- pionic decay modes.

The interaction current (2.19) is a $T=\frac{1}{2}$ form which corresponds to the rule $\Delta Q/\Delta s=+1$, whose empirical basis has been discussed recently by Gell-Mann and Feynman.[1] The main argument in support of this rule is the absence of evidence for $\Delta s=\pm 2$ decay interactions of strength comparable to those observed for $\Delta s=\pm 1$, since the combination of two interaction currents with $\Delta Q/\Delta s=+1$ and $\Delta Q/\Delta s=-1$ would generate a four-fermion interaction of amplitude $\sim g$ which gives rise to processes $\Delta s=\pm 2$. In accord with this rule, expression (2.19) does not include any term corresponding to decay of the Σ^+ particle. This means that the beta-decay process $\Sigma^+ \rightarrow n+e^++\bar{\nu}$ is forbidden with these interactions (however the beta decay $\Sigma^+ \rightarrow \Lambda+e^++\bar{\nu}$ is still an allowed process). The pionic processes (2.15) of Σ^+ decay are forbidden in the lowest approximation corresponding to the graphs of Fig. 1 for Λ decay, but take place through processes involving pionic radiative corrections, examples of which are shown in Fig. 3. The $\Sigma^- \rightarrow n+\pi^-$ decay, on the other hand, can take place already through the lowest order process analogous to that shown for Λ decay in Fig. 1.

For the phenomenological discussion of the decay processes (2.15), Gell-Mann and Rosenfeld[5] point out that it is convenient to represent each of the decay amplitudes for these processes as a vector $\mathbf{M}$ in an (s,p) space. With the assumption of time-reversal invariance, the smallness of $s_{\frac{1}{2}}$ and $p_{\frac{1}{2}}$ pion-nucleon phase shifts implies that the vectors $\mathbf{M}^+$, $\mathbf{M}^0$, $\mathbf{M}^-$ representing the processes (2.15) may be taken to be real. The existence of a $\Delta T=\frac{1}{2}$ rule would imply the following relationship between these real vectors,

$$\mathbf{M}^- = \mathbf{M}^+ + \sqrt{2}\mathbf{M}^0. \quad (2.20)$$

The decay rates observed for the three processes (2.15) are very nearly equal, which requires about equal magnitudes for M^-, M^+, and M^0. This requires that the vectors $\mathbf{M}^-$, $\mathbf{M}^+$, and $\sqrt{2}\mathbf{M}^0$ should form a right-angled triangle, as in Fig. 4. Carrying through the same lowest order calculation for Σ^- decay on the basis of the interaction (2.16) as was done for Λ decay leads to a value $p/s \sim 0.9$ for M^-, which would correspond to an

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

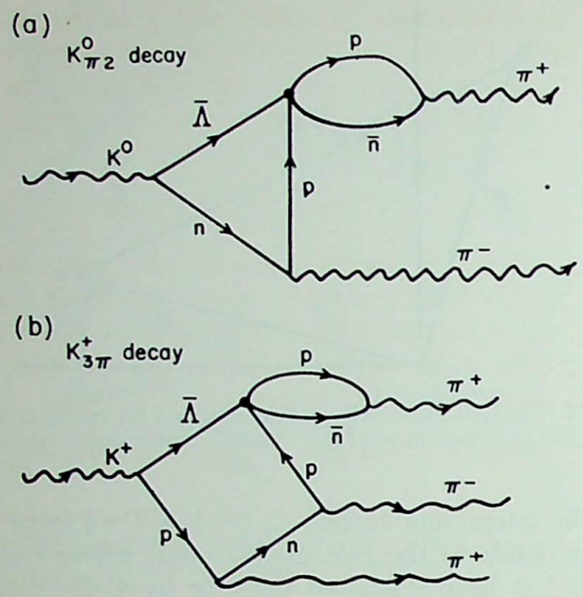

FIG. 5. Graphs illustrating the complexity of $K_{\pi 2}$ and $K_{3\pi}$ decay processes occurring through an elementary Fermi interaction.

angle $\beta_- \sim 40°$. As remarked, there is no corresponding lowest order calculation for Σ^+ decay. However the $\Delta T = \frac{1}{2}$ rule would then require that β_+ should have the value $-50°$ or $130°$, and that $\mathbf{M}^0$ should be parallel to either s or p axis.

The observations of Cool *et al.*[23] on up-down asymmetry in Σ^+ and Σ^- decay are completely opposite to these predictions, for they found that evidence for a polarization effect appears only in the (π^0+p) mode (2.15b), no polarization effect being observed for the (π^++n) mode nor for Σ^- decay. Their observations are not inconsistent with the $\Delta T = \frac{1}{2}$ rule but imply that the triangle of Fig. 4 should have its sides OA, OB quite close to the two axes, with $\mathbf{M}^0$ at an angle of order $\pm 45°$ to the axes. This failure of the lowest order calculation for Σ^- decay to agree with the data certainly casts doubt on its relevance in the case of Λ decay; there is certainly no reason to believe that the pionic radiative corrections should not have a large effect and the degree of agreement noted above for Λ decay may well be fortuitous. Alternatively, it may be that the $\Delta T = \frac{1}{2}$ rule does not hold here and that no up-down asymmetry has been observed for Σ^- decay because the relevant Σ^- production processes happen to give little polarization; if $\Delta T = \frac{3}{2}$ transitions are also effective, the present data certainly allow many other interpretations.

In terms of the interaction (2.19), $K_{\pi 2}$ and $K_{\pi 3}$ decay modes occur through even more complicated sequences of virtual processes, such as those of Fig. 5. With this situation, it is reasonable to expect the ratio of the matrix elements for $K_{\pi 2}{}^0$ and $K_{3\pi}{}^+$ decays to be of the order of magnitude $1/M$, M being the nucleon mass. Taking into account the ratio of phase space for 2π and 3π systems, the observed ratio $P(\theta_1{}^0)/P(\tau^+) = 3\times 10^3$ is in reasonable accord with this expectation. The situation for $K_{\pi 2}{}^+$ decay appears exceptional and provided the first evidence suggesting the possibility of an isotopic spin selection rule in strange particle decays, the topic discussed in the next section.

3. ISOTOPIC SPIN RELATIONSHIPS IN STRANGE PARTICLE DECAY

The possibility of a $\Delta T = \frac{1}{2}$ selection rule for strange particle decays was first suggested by the empirical data, especially by the large ratio between the partial lifetimes for the $K_{\pi 2}{}^+$ and $K_1{}^0$ decays. More recently, the possibility of isotopic spin relationships in weak decay processes has been considered in connection with the isotopic spin character of the weak interaction currents. Gell-Mann and Feynman[1] have suggested that the strangeness-conserving current involving strongly interacting particles may bear a close relationship to the $m_T = 1$ component of the isotopic spin vector for these particles; in fact, the current $(\bar{p}n)$ of expression (1.2) is already the $m_T = 1$ component of a $T = 1$ operator. On the other hand the strangeness nonconserving current (2.19) has a spinor character in isotopic spin. This would mean that the interaction (1.1) formed from $(\bar{Z}N)$ and $(\bar{p}n)$ would be a combination of $T = \frac{1}{2}$ and $\frac{3}{2}$ terms, so that $\Delta T = \frac{1}{2}$ and $\Delta T = \frac{3}{2}$ interactions would contribute to pionic decay processes for strange particles. On the other hand, the leptonic modes, which would result from combinations such as $(\bar{Z}N)(\bar{\nu}e)$, would allow only an isotopic spin change $\Delta T = \frac{1}{2}$, as far as concerns the strongly interacting particles among the decay products. The empirical evidence bearing on these possibilities is in the following.

$K_{\pi 2}$ Decay

A strict $\Delta T = \frac{1}{2}$ rule would forbid the $K_{\pi 2}{}^+$ decay since the final pions have even angular momentum and therefore isotopic spin $T = 2$ ($T = 0$ being excluded since the system has nonzero charge). Existence of $K_{\pi 2}{}^+$ decay implies the presence of some $\Delta T = \frac{3}{2}$ interaction, with an amplitude of about 4% of the $\Delta T = \frac{1}{2}$ amplitude leading to $K_1{}^0$ decay. Presence of this $\Delta T = \frac{3}{2}$ amplitude will also affect the $K_1{}^0$ branching ratios; a strict $\Delta T = \frac{1}{2}$ rule implies the value 0.33 for the ratio of decay probabilities,

$$r_0 = \frac{R(K_1{}^0 \to \pi^0+\pi^0)}{R(K_1{}^0 \to \pi^0+\pi^0)+R(K_1{}^0 \to \pi^++\pi^-)}. \tag{3.1}$$

Inclusion[24,25] of a $\Delta T = \frac{3}{2}$ amplitude which accounts for the $K_{\pi 2}{}^+$ partial lifetime allows this ratio r_0 to be between the limits

$$0.33\{1 \pm 4(2T_+/3T_0)^{\frac{1}{2}}\}, \tag{3.2}$$

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

where T_+ and T_0 are the $K_{\pi 2}^+$ and K_1^0 partial lifetimes, that is between 0.29 and 0.37. The empirical value of this ratio is still rather uncertain. The observation of γ rays from the neutral K_1^0 mode leads to the value 0.14 ± 0.06, whereas the observation of Λ particles produced in the π^-+p reaction, but unaccompanied by K_1^0 decay in the charged mode, leads to the value† 0.30 ± 0.06.

Λ and Σ Decay

The branching ratio $R(\Lambda\to p+\pi^-)/(R(\Lambda\to p+\pi^-)+R(\Lambda\to n+\pi^0))$ is observed to have the value 0.63 ± 0.03 in close agreement with expectation $(\frac{2}{3})$ from $\Delta T=\frac{1}{2}$. As emphasized by Okubo *et al.*,[22] this agreement could also be fortuitous, since there is a certain combination of final $T=\frac{1}{2}$ and $\frac{3}{2}$ states which also corresponds to the observed ratio.

The Σ-decay situation was discussed in the foregoing. The present evidence is compatible with the $\Delta T=\frac{1}{2}$ rule but provides no strong argument for it.

$K_{3\pi}$-Decay Modes

From the spectrum observed for τ^+ decay,[26] it is reasonable to conclude that the final 3π state is predominantly symmetrical between the three pions; this is also the theoretical expectation for the decay of a K particle of spin zero.[26] There are only two totally symmetric configurations for three pions, one with $T=1$ and the other with $T=3$. If the amplitudes of these states in $K_{3\pi}$ decay are denoted by I_1 and I_3, the ratio of the τ' and τ modes in K^+ decay is then given by[25]

$$R(\tau')/R(\tau)=1.295(I_1-2I_3)^2/(2I_1+I_3)^2. \quad (3.3)$$

The observed ratio 0.32 ± 0.05 obtained from the present data[27] agrees well with the value 0.325 expected for a pure $T=1$ state; however there is also a nonzero solution for I_3/I_1 which gives the observed value. Accepting the solution $I_3/I_1\approx0$, this agreement with experiment still does not provide any support for the $\Delta T=\frac{1}{2}$ hypothesis, since both $\Delta T=\frac{1}{2}$ and $\Delta T=\frac{3}{2}$ interactions can reach only the $T=1$ state. The experimental ratio will be attained with any interaction which produces pions predominantly in a state of total symmetry and which allows only $\Delta T=\frac{1}{2}$ and $\Delta T=\frac{3}{2}$.

However this situation does not hold for the comparison of the partial lifetimes for 3π decay of the K^+ and K_2^0 mesons. With the $\Delta T=\frac{1}{2}$ rule these partial lifetimes should be equal[25,28] and $\frac{2}{5}$ of the $K_2^0\to3\pi$ decay processes should be of the mode $(\pi^++\pi^-+\pi^0)$. With the known decay probability $R(K_{3\pi}^+)=6.0\times10^6$ sec^{-1}, the $\Delta T=\frac{1}{2}$ rule therefore predicts that this mode should have decay probability

$$R(K_2^0\to\pi^++\pi^-+\pi^0)=2.4\times10^6\ \text{sec}^{-1}. \quad (3.4)$$

In contrast, the empirical lifetime of the K_2^0 meson is $8.1^{+3.2}_{-2.4}\times10^{-8}$ sec and it is stated by Bardon *et al.*[29] that not more than 15% of the K_2^0 decay events giving charged particles can represent the $(\pi^++\pi^-+\pi^0)$ mode. This corresponds to the empirical statement

$$R(K_2^0\to\pi^++\pi^-+\pi^0)<1.8(\pm0.6)\times10^6\ \text{sec}^{-1}, \quad (3.5)$$

which certainly provides a considerable overestimate for the empirical value of this decay probability since it includes events for which this interpretation is doubtful and omits the possibility of unobserved neutral modes of decay. As a result, there is some degree of disagreement at this point which may provide evidence of the influence of $\Delta T=\frac{3}{2}$ interactions on this decay mode. If I_1 and I_1' denote the contributions of $\Delta T=\frac{1}{2}$ and $\Delta T=\frac{3}{2}$ interactions, respectively, to the final $T=1$ state, the amplitude of the $T=1$ configuration is $(I_1-\frac{1}{2}I_1')$ for $K_{3\pi}^+$ decay, but (I_1+I_1') for $K_2^0\to3\pi$ decay. Generally, assuming a totally symmetric state for the final three pions, the ratio of all 3π modes for K_2^0 and K^+ particles is

$$\frac{R(K_2^0\to3\pi)}{R(K^+\to3\pi)}=\frac{(I_1+I_1')^2+\frac{3}{2}I_3^2}{(I_1-\frac{1}{2}I_1')^2+I_3^2}. \quad (3.6)$$

With $I_3=0$ (absence of $\Delta T=\frac{5}{2}$ interactions), this ratio can fall to a value of 0.5 for a $\Delta T=\frac{3}{2}$ admixture as small as $I_1'/I_1=-0.2$. The ratio $(3\pi^0)/(\pi^++\pi^-+\pi^0)$ for K_2^0 decay should still be 1.5, and it would be of interest to have this prediction of the $K_2^0\to3\pi^0$ decay rate checked, for example by exposure of a dense bubble chamber in a K_2^0 beam.

Leptonic Modes

Here the hypothesis is that $\Delta T=\frac{1}{2}$ holds for the strongly interacting products of this decay. In this sense, interactions for which $\Delta T=\frac{1}{2}$ certainly do exist, as shown by the existence of the $K_{\mu2}^+$ mode, for which the only strongly-interacting particle taking part is the K^+ meson itself; the question is whether these are the only interactions. At present the main physical consequence of this rule is a relation between the amplitudes for $(\pi\mu\nu)$ or $(\pi e\nu)$ decay for K^+ and K^0

† *Note added in proof.*—Crawford, Cresti, Douglass, Good, Kalbfleisch, Stevenson, and Ticho [Phys. Rev. Letters 2, 266 (1959)] have now obtained the value 0.32 ± 0.04. Their observation of γ rays from three K_1^0 decay events raises the former value to 0.18 ± 0.05, still rather low.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

states, namely

$$M(K^0 \to \pi^- + \mu^+ + \bar{\nu}) = \sqrt{2} M(K^+ \to \pi^0 + \mu^+ + \bar{\nu}), \quad (3.7)$$

and a similar relation for the electron modes. Okubo *et al.*[22] point out that, irrespective of whether or not time-reversal invariance holds for these interactions, this result implies a definite relation between the K_2^0 and K^+ decay rates

$$R(K_2^0 \to \pi^\pm + \mu^\mp + \nu) = 2R(K^+ \to \pi^0 + \mu^+ + \bar{\nu}), \quad (3.8)$$

and a similar relation for the electron modes. With the decay rates 3.4×10^6 sec^{-1} and 3.3×10^6 sec^{-1} for the $K_{\mu3}^+$ and K_{e3}^+ modes, as given by Gell-Mann and Rosenfeld,[5] a total decay probability of 13.5×10^6 sec^{-1} is therefore predicted for the leptonic modes of K_2^0 decay. Since there are observed some $K_2^0 \to 3\pi$-decay events (the $\Delta T = \frac{1}{2}$ rule would require a total of 6.0×10^6 sec^{-1} for charged and neutral modes) in addition to these leptonic modes, the observed K_2^0 decay probability, given as $12.3^{+5.2}_{-3.5}\times10^6$ sec^{-1} by Bardon *et al.*,[29] is somewhat lower than these remarks would suggest. However this does not necessarily vitiate the $\Delta T = \frac{1}{2}$ rule for the leptonic modes for it may simply indicate some degree of cancellation between I_1 and I_1' for the 3π modes of K_2^0 decay. The empirical lower limit for $K_2^0 \to (\pi^+ + \pi^- + \pi^0)$ events is 5% of all charged modes, and the addition of 7.5% for $K_2^0 \to 3\pi^0$ modes (required if $T = 1$ holds for the final 3π state) would then bring the predicted probability only up to 15.3×10^6 sec^{-1}, well within the experimental errors of the observed value.

To sum up, the only evidence pointing strongly to the $\Delta T = \frac{1}{2}$ selection rule consists of the long partial lifetime for the $K_{\pi2}^+$ decay and the $(\pi^- + p)/(\pi^0 + n)$ branching ratio in Λ decay. In these cases, further tests of the $\Delta T = \frac{1}{2}$ rule will be possible in the comparison of the polarization properties of the two Λ-decay modes, and in a definitive measurement of the branching ratio in K_1^0 decay. On the other hand, none of the data at present available offers any strong conflict with the requirements of the $\Delta T = \frac{1}{2}$ rule, and all of the data is in accord with the hypothesis of a $T = \frac{1}{2}$ weak interaction current associated with the strangeness nonconserving decays.

4. LEPTONIC MODES OF STRANGE PARTICLE DECAY

K-Meson Decays

The existence of a four-fermion coupling involving a hyperon-nucleon term and a leptonic term, of the same strength whether the lepton be electron or muon, and consisting only of V and A terms, is at present in qualitative accord with the evidence on leptonic modes of K decay.

First, such an interaction accounts very naturally for the absence of evidence for K_{e2}^+ decay. The foregoing assumptions lead to an interaction of the form

$$C_K[\bar{\psi}_\nu \gamma_\mu (1+\gamma_5)\psi_L]\partial\phi_K/\partial x_\mu = C_K m_L(\bar{\psi}_\nu(1+\gamma_5)\psi_L)\phi_K \quad (4.1)$$

for K_{L2} decay, which implies a $K_{e2}^+/K_{\mu2}^+$ ratio of 2.5×10^{-5}. This corresponds to the prediction $\pi_{e2}^+/\pi_{\mu2}^+ = 1.25\times10^{-4}$ for the pion, now borne out by experiment, and is to be compared with the experimental upper limit, $K_{e2}^+/K_{\mu2}^+ < 0.01$, at present.

The decay probability for the $K_{\mu2}^+$ mode (48×10^6 sec^{-1}) is only about 20% greater than that for $\pi_{\mu2}^+$ decay, despite the much greater energy release. These lifetimes correspond to a ratio $(C_K/C_\pi)^2 \sim 1/15$. However, the relation between C_K and C_π is not necessarily simple but may depend on the following factors:

(a) The parity of the K meson (relative to even parity for the Λ particle). The expressions for the intermediate baryon loops between the initial meson and the point at which the four-fermion weak interaction is effective are quite different for a scalar K meson from those for π-meson decay. Even for a pseudoscalar K meson, the graphs for π-meson and K-meson leptonic decays do not generally correspond in detail unless the Λ and Σ particles have the same parity, their virtual K-meson interactions are neglected and their pion interactions have the global symmetry, and their weak interactions are closely correlated in a similar manner.

(b) The amplitude f^1 of the strangeness nonconserving current need not be the same as that for the strangeness conserving current. The radiative corrections to the former current have quite different structure from those for the latter, so that, even if the weak interaction current strengths are the same in the approximation where the strong pion and K-meson interactions are turned off, these coupling strengths may be modified by different effective renormalizations. In fact, the experimental data on the beta decay of the hyperons (see the following) require that f should be of an order of magnitude smaller than g.

(c) The K-hyperon coupling strength G_K^2/hc appears to be about an order of magnitude weaker than the pion-nucleon coupling strength $G^2/\hbar c \simeq 13.5$.

Consider now the three-body leptonic modes $K_{\mu3}$ and K_{e3}. Assuming only V and A interactions to be effective, the matrix elements for these processes may generally be written in the form‡

$$\{Rp_{K\alpha} + S(p_{K\alpha} - p_{\pi\alpha})\}(\bar{\psi}_\nu \gamma_\alpha (1+\gamma_5)\psi_L) = \bar{\psi}_\nu\{Rm_K\gamma_0(1+\gamma_5) + Sm_L(1+\gamma_5)\}\psi_L. \quad (4.2)$$

R and S are scalar functions of $p_K \cdot p_\pi / M^2 = m_K\omega_\pi/M^2$, which are independent of m_L. If time-reversal invariance

‡ *Note added in proof.*—See, for example, A. Pais and S. B. Treiman, Phys. Rev. **105**, 1616 (1957), R. Gatto, Phys. Rev. **111**, 1426 (1958), and references cited there. A recent preprint, "Decay of Hyperons and Mesons from the Universal Fermi Interaction," by A. Fujii and M. Kawaguchi is also relevant.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

holds for both strong and weak interactions, the ratio R/S will be real.[30] In K_{e3} decay, the term proportional to m_L may be neglected and the only contribution is from the R term of (4.2). Since the variation of $p_K \cdot p_\pi / M^2$ over the allowed range in K_{L3} decay is only about 0.05 it appears a reasonable first approximation to neglect the energy dependence of R, in which case the shape predicted for the electron spectrum is unique. This spectrum[31] is shown in Fig. 6, where comparison is made with the available data[27,32] on K_{e3}^+ decay. The agreement is rather poor, but the data are subject to experimental bias whose effect is difficult to estimate. If the hypothesis of a $T=\frac{1}{2}$ weak interaction current is valid, the expression (4.2) holds for both $K_{e3}^\pm$ decay and for the K_2^0 modes $(e^\pm+\nu+\pi^\mp)$.

In $K_{\mu 3}$ decay, both R and S terms contribute and there are therefore a range of theoretical possibilities for the $K_{\mu 3}$ spectrum, of which two examples[31] are shown in Fig. 7. This figure also shows the data obtained on $K_{\mu 3}^+$ decay in the emulsion investigation of Alexander *et al.*[27] who attempted to assess the effects of various empirical biases on this distribution and who conclude that these are so many and so little understood that no detailed comparison with the theoretical distributions is justified at present. With neglect of the energy variation of R and S, the ratio of the decay probabilities

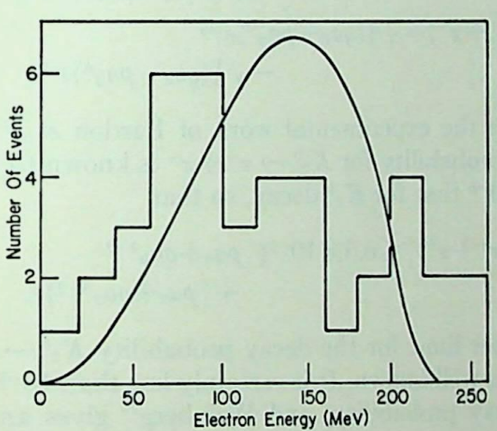

FIG. 6. The electron energy spectrum in K_{e3}^+ decay, compared with the theoretical prediction.

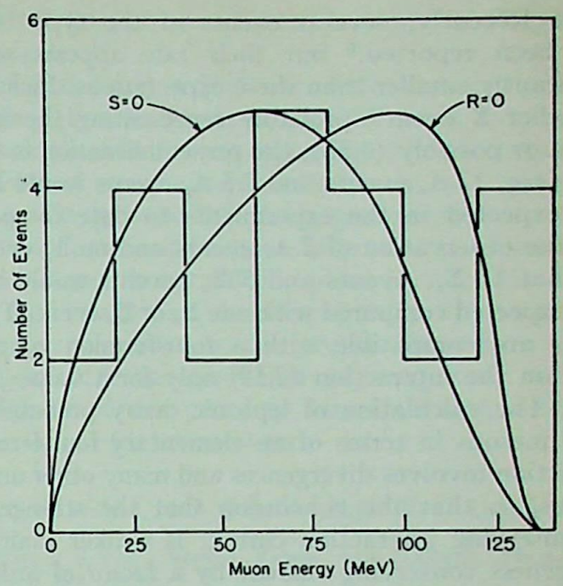

FIG. 7. The muon energy spectrum for $K_{\mu 3}^+$ decay according to Alexander *et al.*,[27] and two examples of the $K_{\mu 3}^+$ spectrum predicted by the interaction (4.2).

for K_{e3} and $K_{\mu 3}$ decay is

$$R(K_{e3})/R(K_{\mu 3}) = R^2/(0.80R^2+0.33RS+0.075S^2). \quad (4.3)$$

This ratio is limited to values less than 2.3, which does not disagree with the present empirical ratio of about unity. The ratio of the decay probabilities for K_{e3}^+ and $K_{\mu 2}^+$ modes is about 0.07, which corresponds to a value $R/C_K \sim 2/(3M)$, where M is the nucleon mass and C_K the coefficient in expression (4.1). This ratio is therefore in reasonable accord with qualitative expectation on the basis of the Fermi coupling model, since the additional pion is then emitted from the intermediate baryon pairs and the effective radius of the system is $\hbar/Mc$.

Hyperon Decays

One of the most direct consequences of Gell-Mann's tetrahedral scheme of four-fermion interactions is the prediction of a beta-decay process for the Λ and Σ^- hyperons, arising from the couplings $(\bar{\Lambda}p)(\bar{e}^+\bar{\nu})$ and $(\bar{\Sigma}^- n)(\bar{e}^+\bar{\nu})$ generated by expressions (1.1) and (1.2). With the strength $f^{\frac{1}{2}}$ of the interaction currents (2.19) equal to $g^{\frac{1}{2}}$, the expectation is that the beta decay and muon decay of the Λ particle,

$$\Lambda \rightarrow \begin{cases} p+e^-+\nu, & (4.4a) \\ p+\mu^-+\nu, & (4.4b) \end{cases}$$

should have rates 0.8% and 0.15%, respectively, of the total Λ-decay rate, and that Σ^- beta decay and muon decay

$$\Sigma^- \rightarrow \begin{cases} n+e^-+\nu, & (4.5a) \\ n+\mu^-+\nu, & (4.5b) \end{cases}$$

should have rates 5.7% and 2.5% that for normal Σ^-

[30] In the literature, it has frequently been stated that this ratio will be real as long as time-reversal invariance is valid for the strong interactions alone. When the strong interactions have this property, this conclusion is generally correct only if the K_{L3} mode arises from just one four-fermion interaction [for example, $(\bar{p}\Lambda)(\bar{\nu}L)$]. When there are several such four-fermion interactions, for example $(\bar{p}\Lambda)(\bar{\nu}L)$ and $(\bar{\Lambda}\Xi)(\bar{\nu}L)$, the K_{L3}-decay amplitude will consist of several coherent terms, thus

$$K^+ \rightarrow \left\{ \begin{matrix} \bar{\Lambda}+p \\ \bar{\Xi}^-+\Lambda \end{matrix} \right\} \rightarrow L^+ + \bar{\nu} + \pi^0,$$

and reality will hold for R/S only if the ratio of the coupling coefficients of these four-fermion interactions is also real; that is, if the weak interaction also satisfies time-reversal invariance.

[31] These K_{e3} and $K_{\mu 3}$ spectra are taken from the paper by Furuichi, Kodama, Ogawa, Sugahara, Wakasa, and Yonezawa, Progr. Theoret. Phys. 17, 89 (1957).

[32] Bruin, Holthuizen, and Jongejans, Nuovo cimento 9, 422 (1958), have collected together the data obtained with the same selection criteria.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

decay. Recently, several events of the type (4.4a) have been reported,[6] but their rate appears to be significantly smaller than these expectations. Including an earlier Σ event[33] probably representing the mode (4.5a), or possibly (4.5b), the present situation is that, with $f=g$, 12 Λ_e events and 2.5 Λ_μ events would have been expected in the experiments to date compared with the observation of 2 Λ_e events and no Λ_μ events, and that 11 Σ_e^- events and 5 Σ_μ^- events would have been expected compared with one Σ_μ or Σ_e event. These results are compatible with a four-fermion coupling based on the interaction (2.19) only for a value $f^{\frac{1}{2}}/g^{\frac{1}{2}} \sim 0.3$. The calculation of leptonic decay probabilities for K mesons in terms of an elementary four-fermion interaction involves divergences and many other uncertainties, so that the conclusion that the strangeness nonconserving interaction current is weaker than the strangeness conserving current by a factor of order 3 does not conflict with any evidence on K-meson decay.

5. TIME-REVERSAL INVARIANCE FOR WEAK INTERACTIONS

It has frequently been assumed that the weak interactions are invariant under time-reversal. In the present framework, this may be expressed as the assumption that the interaction constants for each term in the interaction current (1.2) may all be chosen to have the same phase.

There is very little direct information available at present on the validity of this assumption. In Λ decay, if the amplitudes s_- and p_- had relative phase ϕ, the expression for the polarization parameter α would have an additional factor $\cos\phi$. The experimental limitation (2.2b) shows that the angle ϕ cannot deviate by more than $\sim 45°$ from 0 or π, the values allowed with time-reversal invariance (neglecting the small pion-nucleon scattering phase shifts). No test is possible from the study of $K_{\mu 2}$-, K_{e3}-, or τ-decay modes. For $K_{\mu 3}^+$ decay, Sakurai[34] has pointed out that the violation of time-reversal for the weak interactions would generally imply that the muon polarization would generally have a component perpendicular to the (π^0,ν) plane. This possibility has yet to be examined experimentally. However, Sakurai's formulas show that, when the $K_{\mu 3}$ interaction is limited to the form (4.2), the existence of a relative phase between the coefficients R and S, which can arise if the strangeness nonconserving current (2.19) is not invariant under time-reversal, does not imply a normal component for the muon polarization.

Weinberg[35] has suggested recently that the most severe test of time-reversal at present may be the absence of 2π modes for K_2^0 decay. As pointed out by Lee *et al.*,[36] the K_1^0, K_2^0 states are generally expressible in terms of the K^0, $\bar{K}^0$ states by the relations

$$|K_1^0\rangle = p|K^0\rangle + q|\bar{K}^0\rangle, \tag{5.1a}$$

$$|K_2^0\rangle = q|K^0\rangle - p|\bar{K}^0\rangle, \tag{5.1b}$$

where p and q are generally complex numbers and $|p|^2+|q|^2=1$. If time-reversal invariance holds, which means that CP invariance is valid, then $p=q$ and both may be chosen real. Weinberg remarked that, for $j=0$, there are two final 2π states, one with $T=0$, the other $T=2$. If δ_0 and δ_2 denote the s-wave scattering phases for the pion-pion systems of $T=0$ and $T=2$, then the amplitudes for 2π decay of the K^0 system may be written

$$\langle K^0|2\pi, T=0\rangle = a_0 e^{i\delta_0}, \quad \langle K^0|2\pi, T=2\rangle = a_2 e^{i\delta_2}. \tag{5.2}$$

The corresponding amplitudes for $\bar{K}^0$ decay are directly related to these,

$$\langle \bar{K}^0|2\pi, T=0\rangle = a_0^* e^{i\delta_0}, \quad \langle \bar{K}^0|2\pi, T=2\rangle = a_2^* e^{i\delta_2}. \tag{5.3}$$

From these and Eqs. (5.1), the amplitudes for K_1^0 and K_2^0 decay to $2\pi^0$ and $\pi^+ + \pi^-$ states may then be deduced, for example,

$$\langle K_2^0|2\pi^0\rangle = \sqrt{\tfrac{1}{3}}(qa_0 - pa_0^*)e^{i\delta_0} + \sqrt{\tfrac{2}{3}}(qa_2 - pa_2^*)e^{i\delta_2}, \tag{5.4a}$$

$$\langle K_2^0|\pi^+ + \pi^-\rangle = \sqrt{\tfrac{2}{3}}(qa_0 - pa_0^*)e^{i\delta_0} - \sqrt{\tfrac{1}{3}}(qa_2 - pa_2^*)e^{i\delta_2}. \tag{5.4b}$$

From the experimental work of Bardon *et al.*,[29] the decay probability for $K_2^0 \to \pi^+ + \pi^-$ is known to be less than 10^{-5} that for K_1^0 decay, so that

$$|\langle K_2^0|\pi^+ + \pi^-\rangle| \lesssim 0.3\times 10^{-2}\{|pa_0 + qa_0^*|^2 + |pa_2 + qa_2^*|^2\}^{\frac{1}{2}}. \tag{5.5a}$$

An upper limit for the decay probability $K_2^0 \to \pi^0 + \pi^0$ is not as well known. It is certainly less than 10^{-3} of the K_1^0-decay probability, and Weinberg[35] gives an argument that this ratio is actually less than 2×10^{-4}. From this

$$|\langle K_2^0|\pi^0 + \pi^0\rangle| \lesssim 1.5\times 10^{-2}\{|pa_0 + qa_0^*|^2 + |pa_2 + qa_2^*|^2\}^{\frac{1}{2}}. \tag{5.5b}$$

If the right-hand sides of these inequalities were zero, these conditions would require, according to (5.4), that

$$a_0^*/a_0 = q/p = a_2^*/a_2, \tag{5.6}$$

and that a_0 and a_2 have the same phase, just the relationship which time-reversal invariance for the interaction $K^0 \to 2\pi$ would require.

However, owing to the uncertainty in the K_1^0 branching ratio, it is not clear exactly what restriction on the relative phases of a_2 and a_0 is implied by the empirical inequalities (5.5). If the $\Delta T = \frac{1}{2}$ rule held exactly, then the amplitude a_2 would be zero; the

Digitized by Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

inequalities (5.5) would then imply only that $a_0^*/a_0 = q/p$, a statement about the phase of a_0 which carries no implications concerning the time-reversal invariance of the decay interaction. If the ratio of $|(pa_2+qa_2^*)|$ and $|(pa_0+qa_0^*)|$ is taken from the ratio of the $K_{\pi 2}^+$ and K_1^0 decay probabilities, then it is still true that the phases of a_0^{*2} and q/p are very close; however the limitation on the phase of a_2 is given by

$$\left|\frac{qa_2-pa_2^*}{pa_2+qa_2^*}\right| \lesssim 0.014 \left|\frac{pa_0+qa_0^*}{pa_2+qa_2^*}\right| \sim \frac{1}{3}, \qquad (5.7)$$

which involves almost no restriction on the relative phase of a_2^{*2} and q/p. This argument would lead to a significant restriction on the relative phase of a_2 and a_0 if the present upper limit for the $K_2^0 \to \pi^0+\pi^0$ decay probability were improved by an order of magnitude or if the K_1^0 branching ratio were confirmed to lie in the range 0.1–0.2, as indicated by some of the present experiments.

So far, the only serious test of the assumed property of time-reversal invariance for the weak interactions has been provided by the experiments on the beta decay of polarized neutrons reported recently by Clark *et al.*[37] and by Burgy *et al.*[38] These experiments have shown that the Fermi and Gamow-Teller matrix-elements for neutron decay do not differ in phase by more than $\pm 8°$. For the strange particle decays, the only tests which have been available to the present have been rather inconclusive or have provided only very weak evidence in support of this property for the strangeness non-conserving weak interactions.

Status of Weak Interactions

MURRAY GELL-MANN

Norman Bridge Laboratory of Physics, California Institute of Technology, Pasadena, California

THE invited speakers have done an excellent job of describing the various topics within the field of weak interactions. The contributed papers have presented many fascinating results. Furthermore, what is rare these days at a physics conference, there has been plenty of discussion, which has brought out, I think, every point that was overlooked in the speeches. Evidently, there is no need for a summary.

A few words about what appear to me to be the principal questions that we would like to have answered in the future are given in the following.

Let us begin with those two beautiful and mysterious particles, the electron and the muon. The recent revolution in weak interactions has brought about measurements of the muon magnetic moment, confirming to a high degree of accuracy that the muon, like the electron, is a pure Dirac particle with electrodynamic coupling of the conventional form. It now seems clear also that the weak couplings of electron and muon are identical in form and strength, both involving the neutrino (presumably the same neutrino, although we have no way of proving that at the moment). Both electron and muon lack, so far as is known, any other interaction whatever, except the gravitational. And here appears the only known difference between them, their masses. Why do these two otherwise identical particles have different masses? No one has the slightest idea. This is perhaps the most interesting question in particle physics today. If it were not for this example, we might say that differences in mass among the elementary particles are always owing to differences in interaction. Or at least we might say that all the different particles are distinguished from one another by the values of symmetry quantum numbers. But the electron and muon seem to provide the first inkling of a radial quantum number in particle physics.

It is evidently important to refine existing measurements of the muon and electron still further, and to compare electron and muon scattering from the same target, in order to see whether the equivalence of the two particles really persists down to small distances.

The decay of the muon, involving just μ, e, and ν, offers an example of a pure weak interaction. The only known corrections are the electrodynamic ones, which are finite, have been calculated, and are easily taken into account. To within present accuracies, all our knowledge of the muon decay agrees with the very simple theory of the interaction given by the following formula for the Lagrangian density:

$$\mathfrak{L}_\mu=\sqrt{2}G\left(\bar{e}\gamma_\alpha\frac{1+\gamma_5}{\sqrt{2}}\nu\right)\left(\bar{\mu}\gamma_\alpha\frac{1+\gamma_5}{\sqrt{2}}\nu\right)^+$$

$$+\text{Hermitian conjugate (h.c.)}$$

or, for short,

$$\mathfrak{L}_\mu=\sqrt{2}G(\bar{e}\nu)(\bar{\mu}\nu)^+ + \text{h.c.} \quad (1)$$

We may describe this interaction by saying that it is the direct coupling in which e^-, μ^-, and ν appear with negative helicity only.

It seems, in fact, that in all weak interactions these particles appear with negative helicity and their antiparticles with positive helicity. It is a remarkable fact that this same grouping is followed by the law of conservation of leptons, which states that the number of leptons minus the number of antileptons is always conserved. The leptons all have negative helicity in the weak interactions, the antileptons all positive helicity.

Now there is a law of baryon conservation, too, and therefore we suspect that all baryons enter the weak interactions with the same helicity. Future experiments, suitably interpreted, will enable us to test this idea.

To return to the μ decay, it is of the highest importance to refine all experiments on the spectrum and asymmetries of μ decay in order to see whether any departures from the simple contact-interaction theory of Eq. (1) can be found. Accurate knowledge of the rate of decay is also valuable, because only in the μ decay can we be reasonably sure of measuring the true Fermi constant G, unaltered by the effects of strong couplings.

It is just these strong couplings that make β decay complicated. It is now well established that the β-decay interaction resembles that in μ decay; it is vector and axial vector and the strength is about the same. We do not, however measure the interaction Lagrangian directly, because of the strong couplings. At low momentum transfers, such as we have in nuclear β decay, we measure an *effective* Lagrangian density

$$\{\bar{n}[G_V\gamma_\alpha+(-G_A)\gamma_\alpha\gamma_5]p\}^+\left(e\gamma_\alpha\frac{1+\gamma_5}{\sqrt{2}}\nu\right)+\text{h.c.} \quad (2)$$

to be compared with

$$\{\bar{\mu}(G\gamma_\alpha+G\gamma_\alpha\gamma_5)\nu\}^+\left(\bar{e}\gamma_\alpha\frac{1+\gamma_5}{\sqrt{2}}\nu\right)+\text{h.c.}$$

as in Eq. (1) for μ decay. Here G_V and $-G_A$ are the effective or renormalized Fermi constants, containing effects of the strong interactions of nucleons.

G_V is determined experimentally from the rate of a $0\rightarrow 0$ transition such as the decay of O^{14}. Remark-

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

ably, it appears to be within one or two percent of the "pure" Fermi constant G determined from μ decay. There are two methods of measuring $-G_A/G_V$ without estimating nuclear matrix elements. One is the Argonne experiment on the asymmetry of electrons in the decay of polarized neutrons and gives $-G_A/G_V=1.25\pm0.04$. The other is a comparison of neutron and O^{14} lifetimes; it gives only the absolute value and yields

$$|-G_A/G_V|=1.19\pm0.04.$$

It is very tempting, then, to guess that the original Lagrangian for β decay is just like that for μ decay,

$$\mathfrak{L}_\beta=\sqrt{2}G(\bar{n}p)(\bar{e}\nu)^+ + \text{h.c.}, \quad (3)$$

with negative helicity for the nucleon. It is surprising, though, that the vector and axial vector renormalization factors are about 0.99 and 1.2, respectively; nearly 1 in spite of the strength of nuclear interactions. No one has any explanation for the closeness of the latter to unity. For the former, the closeness to unity is really striking, and a possible explanation has been suggested —the speculation that there is a "conserved vector current."

This speculation is suggested by an analogy between the vector weak interaction of baryons and mesons (without change of strangeness) and electromagnetism. For electromagnetism, a law of universality holds—all charged elementary particles have the same charge $\pm e$. The universality is not disturbed by strong interactions, which are present for the proton, for example, and not for the positron. The reason is that the electromagnetic current j_α is a conserved quantity: $\partial j_\alpha/\partial x_\alpha=0$.

Now the vector operator describing the nucleons in β decay is $\bar{n}\gamma_\alpha p$, which is not, in the Yukawa theory of strong interactions, a conserved quantity. It is, however, one term of a conserved quantity, the $x+iy$ component of the isotopic spin current,

$$\mathcal{J}_\alpha=\bar{n}\gamma_\alpha p+\sqrt{2}\frac{\partial\pi^+}{\partial x_\alpha}\pi^0-\sqrt{2}\pi^+\frac{\partial\pi^0}{\partial x_\alpha}$$
$$+\sqrt{2}\bar{\Sigma}^-\gamma_\alpha\Sigma^0-\sqrt{2}\bar{\Sigma}^0\gamma_\alpha\Sigma^+ +\cdots, \quad (4)$$

which obeys the conservation law $\partial\mathcal{J}_\alpha/\partial x_\alpha=0$ apart from electromagnetic effects.

If, then, in the original β-decay Lagrangian we replace $\bar{n}\gamma_\alpha(1+\gamma_5)p$ by the expression

$$\bar{n}\gamma_\alpha(1+\gamma_5)p+\sqrt{2}\frac{\partial\pi^+}{\partial x_\alpha}\pi^0-\sqrt{2}\pi^+\frac{\partial\pi^0}{\partial x_\alpha}$$
$$+\sqrt{2}\bar{\Sigma}^-\gamma_\alpha(1+\gamma_5)\Sigma^0-\sqrt{2}\bar{\Sigma}^0\gamma_\alpha(1+\gamma_5)\Sigma^+ +\cdots, \quad (5)$$

we have a theory in which G_V must equal G to within an electromagnetic correction of a percent or so. It is evidently worthwhile to refine the measurements and calculations involved in the determination of G_V/G.

It would also be good to have independent tests of the conserved current hypothesis. The simplest one is unfortunately very difficult; it involves measuring the rate of the rare decay $\pi^+\rightarrow\pi^0+e^++\nu$, never so far observed. If the conserved current hypothesis is correct, the rate* must be 0.37 ± 0.07/sec giving a branching ratio of $1.0\pm0.2\times10^{-8}$. Other β-decay theories will also lead to decay rates of this order of magnitude, but not (except accidentally) to the same number.

An easier test of the conserved current idea has been proposed, involving the ratio of the β-decay spectra of B^{12} and N^{12}. At this meeting, certain theoretical corrections have been presented that must be applied to the analysis of the results, but they do not vitiate the conclusion that the experiment can distinguish whether or not pions participate directly in the β-decay interaction as in Eq. (5). The $B^{12}-N^{12}$ experiment is being performed at the California Institute of Technology by Hilton and Sörgel, who will announce their results shortly. I would like to encourage other groups to do the same experiment, however, since it is a hard one and recent experience should have taught us that hard experiments should be repeated.

We have seen how the vector and axial vector coupling constants in β decay can be renormalized by effects of the pion cloud around the nucleon, giving, at low momentum transfer, the effective Lagrangian of Eq. (2). When we take into account finite momentum transfer to the nucleon, other pionic effects must show up, so that $G\gamma_\alpha(1+\gamma_5)$ is replaced, not simply by $G_V\gamma_\alpha+(-G_A)\gamma_\alpha\gamma_5$, but by the more complicated expression

$$G_VF_1(q^2)\gamma_\alpha+(-G_A)F_2(q^2)\gamma_\alpha\gamma_5$$
$$+AF_3(q^2)\sigma_{\alpha\beta}q_\beta+BF_4(q^2)\gamma_5q_\alpha. \quad (6)$$

Here q_α is the four-momentum transfer and the form factors $F_i(q^2)$ all have $F_i(0)=1$. Besides the renormalizations and the form factors, the pion cloud has induced two new interactions. The first, with coefficient A, we might call "weak magnetism," since it bears the same relation to the vector coupling that an anomalous Pauli moment bears to the electric charge. In fact, in the conserved current theory, the value of A can be predicted from the anomalous moments of proton and neutron. It is just this weak magnetism that is tested in the $B^{12}-N^{12}$ experiment. (The conserved current theory, by the way, also permits F_1 and F_3 to be calculated from the electromagnetic form factors of the nucleon.)

The last interaction, with coefficient B, is sometimes called the induced pseudoscalar. It can be shown that in the calculation of B by field theory, one particular type of diagram predominates, in which the nucleon radiates a virtual pion, which decays into electron and neutrino. This contribution can be evaluated exactly,

* The principal uncertainty arises from the mass difference of π^+ and π^0.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

giving a fairly reliable estimate of B, or at least its absolute value.

All these effects are barely detectible in β decay, because of the low energies involved. They may, however, be studied in the absorption of μ^- by nuclei. But how is the basic interaction of nucleons with μ and ν related to that with e and ν? The simplest assumption is that it is absolutely identical. There is very little evidence on this point from μ^- absorption itself. It has not even been proved experimentally that the interaction is V-A or that parity conservation is violated. However, the theory of identical μ and e couplings leads to the famous prediction of the branching ratio for $\pi \rightarrow e+\nu$, which has now been confirmed experimentally with an accuracy that is constantly increasing.

Pending further experimental work, we are certainly justified in supposing that the basic coupling in μ^- absorption is known. The absorption rates and other quantities may then be used to yield information about the pionic corrections of Eq. (6). For this purpose, the ideal nucleus would be the proton, but that poses tremendous experimental problems, and for a while we will have to be content with the current experiments on C^{12} and other light nuclei.

There remains the problem of calculating the absolute rate of the charged pion decay. We have heard from Professor Goldberger an excellent account of a recent attempt to do that. I think we will agree that the remarkable success of the calculation is greater than might have been expected from the approximations involved. But it is very instructive in any case, particularly the result that for large meson coupling constant g^2, the rate of pion decay is inversely proportional to g^2.

All the phenomena we have discussed so far involve the interaction of $e\nu$, $\mu\nu$, and a series of particle pairs beginning with np. The structure of the interaction is rather peculiar; pairs of particles, one neutral and one charged, interacting with one another in identical fashion. It suggests that the coupling Lagrangian is of the form $J_\alpha^+ J_\alpha$, where

$$J_\alpha = 2^{\frac{1}{2}}\sqrt{G}\left\{\bar{e}\gamma_\alpha\frac{1+\gamma_5}{\sqrt{2}}\nu+\bar{\mu}\gamma_\alpha\frac{1+\gamma_5}{\sqrt{2}}\nu+\bar{n}\gamma_\alpha\frac{1+\gamma_5}{\sqrt{2}}p+\cdots\right\}. \quad (7)$$

This idea of a current coupled to itself has certain new consequences, but they are very hard to detect by experiment. One is neutrino-electron scattering with a cross section comparable to that of neutrino absorption by nuclei. (Of course, the absorption has been detected by a coincidence technique, while the scattering gives only electron recoils.) It should be noted that the modern longitudinal or "two-component" neutrino cannot have a magnetic moment, so that if neutrino-electron scattering is ever found with the predicted cross section, it should be attributed to the direct $(e\nu)(e\nu)$ coupling.

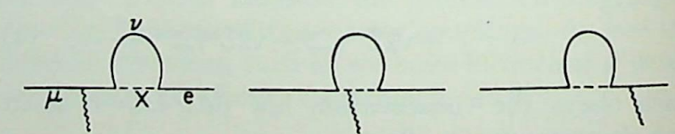
A second consequence, just as difficult to test, is the existence of a parity nonconserving nuclear force arising from the $(np)(np)$ term of the weak coupling. The violation of parity conservation should amount to something like 10^{-7} in amplitude. Present experiments are capable of measuring only one part in 10^3 or 10^4.

If we accept the form $J_\alpha^+ J_\alpha$ for the weak interactions, we are still puzzled by it. True, it is reminiscent of electromagnetism, although weaker, of short range, and not parity conserving. But the electromagnetic current j_α interacts with itself through the photon. Is there a boson to carry the weak interactions?

Let us examine the properties of such a hypothetical boson, a particle that Feynman and I like to call the *uxl* (symbol $X^\pm$). It must be a charged vector meson, say of mass M, with coupling constant (analogous to 1/137) equal to $\sqrt{2}(GM^2/4\pi)$. If M is of the order of the nucleon mass, this comes to around 10^{-6}. Processes involving creation or destruction of the *uxl* have probabilities proportional to this coupling constant, while ordinary weak processes involve the square. Thus a K particle, for example, would much rather decay into $X+\pi$ or even $X+\gamma$ than into its actual disintegration products, provided these channels involving X were open. It follows that M must be $\gtrsim m_K$.

If M is really around the nucleon mass, then the cross section for *uxl* production in, for example, nucleon-nucleon collisions of several Bev, must be around 10^{-6} of geometrical. The time of decay into, say, $e+\nu$, must be something like 10^{-18} sec. Evidently the direct observation of a particle that is rarely produced and decays immediately is a most difficult matter. If M is very much greater than 1 Bev, then the threshold for *uxl* production becomes a problem.

Fortunately, an indirect test of the existence of the *uxl* can be made. If X exists, it induces the decay $\mu \rightarrow e+\gamma$ with a rate that can be estimated. The mechanism is best described by the Feynman diagrams involved:



The rate comes out logarithmically divergent, so that we must introduce a cutoff momentum Λ. The fraction of muon decays into $e+\gamma$ then comes out

$$\Gamma(\mu \rightarrow e+\gamma)/\Gamma(\mu \rightarrow e+\nu+\bar{\nu}) = 3/8\pi\ 1/137\ f(M/\Lambda), \quad (8)$$

where for large cutoffs $\Lambda \gg M$, we have $f \rightarrow (\ln\Lambda^2/M^2)^2$. For reasonable values of the cutoff, we should expect a fraction like 10^{-3} or maybe 10^{-4}. Experimentally the branching ratio is less than 2×10^{-5}. It appears, then, that the *uxl* has flunked the only test of its existence that is available so far. (Of course, if the neutrinos

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

associated with e and μ are not identical, then this was no test at all.)

Formula (8) can also be used to describe what happens when there is no *uxl* but instead a point coupling of $(\mu\nu)$ to $(e\nu)$. Mathematically, that corresponds to the limit of infinite M with the cutoff Λ held fixed. Under these conditions $f(M/\Lambda) \to 0$ and there is no decay $\mu \to e+\gamma$.

We have not succeeded, then, in understanding the proposed form $J_\alpha{}^+ J_\alpha$ of the weak couplings. Nevertheless, I shall assume it in the remaining discussion, which concerns the weak decays of strange particles.

In order to describe decays involving a change of strangeness, we must add new terms to Eq. (7) for the current J_α, which already consists of two parts: the leptonic current $J_\alpha{}^L$ and the current $J_\alpha{}^{(1)}$ comprising $(\bar{n}p)$ and probably other terms like $(\bar{\pi}^0\pi^+)$, $(\bar{\Sigma}^-\Sigma^0)$, etc., all involving baryons or mesons, but with no change of strangeness.

The existence of decays like $K^+ \to \mu^+ + \nu$ requires us to add a current $J_\alpha{}^{(2)}$ consisting of pairs like $(\bar{\Lambda}p)$, $(\bar{\Sigma}^- n)$, etc., in which the partner with higher charge also has strangeness higher by one unit. It is easy to see that the interaction of $J_\alpha{}^{(2)}$ with $J_\alpha{}^{(1)}$ and $J_\alpha{}^L$ is sufficient to account qualitatively for all known weak decays of the strange particles.

The question now arises whether the current $J_\alpha{}^L + J_\alpha{}^{(1)} + J_\alpha{}^{(2)}$ is complete, or whether other terms of still a different character must be included. Such additional terms could be of two kinds: pairs like $(\bar{n}\Sigma^+)$ in which the partner with higher charge has strangeness lower by one unit and pairs like $(\bar{\Xi}^- n)$ in which the partners differ by two units of strangeness. Let us call the corresponding currents $J_\alpha{}^{(3)}$ and $J_\alpha{}^{(4)}$, respectively. There are a number of experimental tests of the existence of $J_\alpha{}^{(3)}$ and $J_\alpha{}^{(4)}$:

(1) The decay $\Sigma^+ \to n + e^+ + \nu$ will have appreciable probability if and only if $J^{(3)}$ is present. (Abbreviated, $\Sigma^+ \to n + e^+ + \nu \sim J^{(3)}$.)

(2) $\Xi^- \to n + e^- + \bar{\nu}$, $\Xi^0 \to p + e^- + \bar{\nu} \sim J^{(4)}$.

(3) $\Xi^- \to n + \pi^-$, $\Xi^0 \to p + \pi^- \sim J^{(3)}$ or $J^{(4)}$.

(4) If $J^{(3)}$ or $J^{(4)}$ exists, so that the weak interactions can induce strangeness changes of two units in the lowest order of G, then the transitions $K^0 \leftrightarrow \bar{K}^0$ occur with an amplitude proportional to G instead of G^2. The mass difference between $K_1{}^0$ and $K_2{}^0$ is then of order G instead of G^2, corresponding to a frequency of, say, 10^{17}/sec instead of, say, 10^{10}/sec. A beam of K^0 particles, then, will be converted immediately (that is, in something like 10^{-17} sec) into a rapidly oscillating half-and-half mixture of K^0 and $\bar{K}^0$. Thus a K^0 produced in a reaction like $\pi^- + p \to \Lambda + K^0$ will be "immediately" capable of behaving like a $\bar{K}^0$ in, for example, the reaction $\bar{K}^0 + p \to \Lambda + \pi^+$.

(5) Only if $J^{(3)}$ exists can the leptonic decay rates of $K_1{}^0$ and $K_2{}^0$ be different. If they are the same, the probability of a neutral K particle decaying into leptons during the lifetime of the $K_1{}^0$ component ($\sim 10^{-10}$ sec) is only around 10^{-3}. (It should be noted, of course, that during the first 10^{-10} sec the amplitudes for leptonic decay of $K_1{}^0$ and $K_2{}^0$ interfere with each other.)

None of these tests has yet given conclusive results. There is some evidence that a beam of K^0 particles does not immediately behave like a 50–50 mixture of K^0 and $\bar{K}^0$. If this is confirmed, we can presumably throw out both $J^{(3)}$ and $J^{(4)}$, but at the moment we cannot be sure. Let us continue, however, on the assumption that $J^{(3)}$ and $J^{(4)}$ are not present.

We must still clear up the forms of $J^{(1)}$ and $J^{(2)}$. The conserved vector current hypothesis, if we take it altogether seriously, together with the assumption that baryons always occur with the factor $1+\gamma_5$ (negative helicity), gives a definite form for $J^{(1)}$, but we are far from being able to test such an assertion today.

However, we can test a much less specific suggestion, in the form of a symmetry rule, that $J^{(1)}$ behaves like an isotopic vector and $J^{(2)}$ like an isotopic spinor. Such a rule is obeyed, for example, by the term $(\bar{n}p)$ in $J^{(1)}$ and the hypothetical term $(\bar{\Lambda}p)$ in $J^{(2)}$. If this rule is right, then apart from electromagnetic corrections, we have $|\Delta \mathbf{I}| = \frac{1}{2}$ or $\frac{3}{2}$ in nonleptonic decays and $|\Delta \mathbf{I}| = \frac{1}{2}$ in leptonic decays (with the leptons defined to carry no isotopic spin). Some experimental consequences are the following.

(1) The fraction of $K^+ \to 3\pi$ decays that yield $\pi^+ + 2\pi^0$ is $\frac{1}{5}$, assuming a totally symmetric spatial wave function.

(2) The fraction of $K_2{}^0 \to 3\pi$ decays that yield $3\pi^0$ is $\frac{3}{5}$, assuming a totally symmetric spatial wave function.

(3) The fraction of $K_1{}^0 \to 2\pi$ decays that yield $2\pi^0$ is between 0.28 and 0.38. (We make use here of the experimental rates of $K_1{}^0 \to 2\pi$ and $K^+ \to 2\pi$.)

(4) The rate of leptonic decay of $K_2{}^0$ (or of $K_1{}^0$, if we forget interference) is twice that of K^+ and the spectra, relative proportions of e and μ, etc., are all the same for $K_2{}^0$ and K^+.

All these statements seem to be roughly true except perhaps the third one, but more experiments are necessary.

We come now to some mysterious features of strange particle decay, which, if we could understand them, would probably help us to pin down the interactions further. The most striking is the fact that $K_1{}^0$ decays into 2π at a rate about 500 times faster than that of $K^+ \to 2\pi$. An explanation has been suggested in the form of an approximate rule (supposedly good to 5% or so in amplitude) that $|\Delta \mathbf{I}| = \frac{1}{2}$ in nonleptonic decays. However, it is not known how to derive any such rule in a convincing way from an interaction of the form $J_\alpha{}^+ J_\alpha$. Several ideas have been discussed, e.g., (a) to divide the strong interactions into classes, of which one is assumed to be less strong and approximately negligible. The stronger one may have a higher symmetry than charge independence, and this symmetry, together with a hypothetical symmetry of the weak

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

currents $J_\alpha^{(1)}$ and $J_\alpha^{(2)}$ may lead to something like the $|\Delta \mathbf{I}| = \frac{1}{2}$ rule. (b) to add to the interaction $J_\alpha^+ J_\alpha$ a term $K_\alpha K_\alpha$ in which the particle pairs have the same charge. The "neutral" current K_α must not contain leptons, however, since emission of pairs like $\bar{\nu}\nu$ and $\bar{\mu}e$ has never been observed. An interaction $J_\alpha^+ J_\alpha + K_\alpha K_\alpha$ can be made to yield the $|\Delta \mathbf{I}| = \frac{1}{2}$ rule.

The first suggestion seems much more attractive than the second. Actually, neither has so far resulted in a convincing theory. For a third suggestion, see below.

In any case, it is worthwhile to see whether the approximate $|\Delta \mathbf{I}| = \frac{1}{2}$ rule works experimentally. Besides the $K \to 2\pi$ situation, it explains the fact that $\Lambda \to n + \pi^0$ occurs at about half the rate of $\Lambda \to p + \pi^-$ and certain relations among the nonleptonic decays of $\Sigma^\pm$. It may be further tested by other predictions, including the following:

(1) The asymmetry of $\Lambda \to n + \pi^0$ for polarized Λ must be the same as that of $\Lambda \to p + \pi^-$.

(2) The rate of $K_2^0 \to 3\pi$ must be twice that of $K^+ \to 3\pi$. At the moment, there seems to be some difficulty with the second prediction, but again more experiments are needed.

Another mystery involves the rate of leptonic decays of hyperons. The decay $\Lambda \to p + e^- + \bar{\nu}$ has been observed, but it is reported to be very rare, occurring in much less than 1% of all Λ disintegrations. The decay $\Sigma^- \to n + e^- + \bar{\nu}$ seems also to be very rare, and has never been detected for certain. Now if the current J_2 contains terms $(\bar{\Lambda} p)$ or $(\bar{\Sigma}^- n)$, if the coefficient of each of these terms is unity, and if renormalization effects are not large (and they seem to be small in the β decay of nucleons), then the fractions of β disintegrations of Λ and Σ^- should be 1.6 and 5.6%, respectively.

While awaiting further experimental results, let us assume the discrepancy is real. If it is really large, it is unlikely to be a renormalization effect but rather an indication that the strangeness-changing weak couplings are even weaker (by a factor f, perhaps $\sim 1/20$) than those that conserve strangeness. Such a situation would permit another explanation of the approximate $|\Delta I| = \frac{1}{2}$ rule, namely that it characterizes a special set of diagrams, occurring only in nonleptonic decays, which are so much larger than other diagrams that they make up for the small factor f and give a "normal" rate for such a process as $\Lambda \to N + \pi$.

It is clear, in any case, that we have an enormous body of information about the weak decays of strange particles but that we need still more information if we are to understand them.

Errata

Errata: Comparative Study of Potential Energy Functions for Diatomic Molecules

[Revs. Modern Phys. 29, 664 (1957)]

YATENDRA PAL VARSHNI
Department of Physics, Allahabad University, Allahabad, India

ON page 670, Eq. (40) should read

$$\alpha_e = 0.$$

In line 4, read "0" in place of "2."

On page 671, Linnett function, Eq. (55) should read

$$\alpha_e = \left[\frac{(m+1)(m-1)-l^2+3l}{3(m+1-l)}\right]\frac{6B_e^2}{\omega_e}.$$

Consequently, F values in Table II are changed as follows:

l	F
0	0.666
1	1.111
1.5	1.366
2	1.666
2.25	1.845
2.5	2.055
2.6	2.152
2.7	2.258
2.75	2.316
2.8	2.37
3.0	2.66

On page 672, Lippincott function, Eq. (61) should read

$$\alpha_e = 0.$$

In line 24, delete "As (61) shows this appears to be in error."

On page 677, Table IX, correct F values are

Linnett $(8+3l-l^2)/3(4-l)$
Lippincott 0.

On page 679, Linnett function, change the discussion for α_e as follows:

"Too high at low Δ. Suitable for CO, N_2, NO, O_2."

Errata: Experimental Results on Charge-Changing Collisions of Hydrogen and Helium Atoms and Ions at Kinetic Energies above 0.2 kev

[Revs. Modern Phys. 30, 1137 (1958)]

SAMUEL K. ALLISON
Enrico Fermi Institute for Nuclear Studies, University of Chicago, Chicago, Illinois

1138 In text, above Eq. (II-1), for "$d\sigma_{if}/d\theta$ would be a function of angle" read "$d\sigma_{if}/d\Omega$ would be a function of angle."

1139 In text, above Eq. (II-5) for "and exists into high vacuum" read "and exits into high vacuum."

1140 Equation (II-12) should read

$$F_i = F_{i\infty} + [P(z,i)\exp(\pi q) + N(z,i)\exp(-\pi q)] \times \exp(-\tfrac{1}{2}\pi \textstyle\sum \sigma_{if}).$$

1141 Equation (II-28) should read

$$P(1,\bar{1}) = \frac{s+q}{2qb}[F_{0\infty}(s-q) - bF_{\bar{1}\infty}].$$

Equation (II-29) should read

$$N(1,\bar{1}) = \frac{s-q}{2qb}[F_{0\infty}(s+q) - bF_{\bar{1}\infty}].$$

Equation (II-31) should read: $dF_0/d_\pi = -(dF_1/d_\pi) = -F_{0\sigma 01} + F_{1\sigma 10}$.

1150 for "antilog 4.030–5" read "antilog (4.030–5)."

1155 Bottom line, left. Actually, Table V-6 shows that the largest observed $F_{\bar{1}\infty}$ for hydrogen is at 4 kev in argon gas.

1162 Table VI-6; for "σ_{11}" read "$\sigma_{1\bar{1}}$."

1164 Center, right, for "from Eqs. (V-1) and (V-2)" read "from equations in Sec. VA-3, page 1156."

Errata: Spin Waves

[Revs. Modern Phys. 30, 1 (1958)]

J. VAN KRANENDONK AND J. H. VAN VLECK
Harvard University, Cambridge, Massachusetts

IN Eq. (28), 0.1187 should be replaced by $\frac{1}{2}(0.1173)$.

In the third member of Eq. (32), 15/8 should be replaced by 15/32.

On the top of page 8, 0.96 $Nk/2S$ should be replaced by 0.96 $(2NkS)$.

In Eq. (97), a term $-NzJS$ should be added to the right-hand side.

In Eq. (120), 0.1187 should be replaced by $0.1173/(S_1-S_2)$ and $2JS_1S_2$ should be replaced by $4JS_1S_2$.

Below Eq. (121), $S_1S_2/S(S_1-S_2)$ should appear as twice this quantity, and $(g_1S_1-g_2S_2)\beta$ should appear multiplied by a factor $(\frac{1}{2})$.

Erratum: Dynamics of a Lattice Universe by the Schwarzschild-Cell Method

[Revs. Modern Phys. 29, 432 (1957)]

RICHARD W. LINDQUIST AND JOHN A. WHEELER
Palmer Physical Laboratory, Princeton, New Jersey

WE are indebted to Professor G. C. McVittie for pointing out to us that the printed version of Eq. (3) omits a factor.[1] It should read

$$ds^2 = [a(T)/a_0]^2\left[\frac{dr^2}{1-r^2/a_0^2} + r^2(d\theta^2+\sin^2\theta d\varphi^2)\right] - dT^2 \quad (3a)$$

$$= a^2(T)[du_1^2+du_2^2+du_3^2+du_4^2] - dT^2, \quad (3b)$$

with

$$u_1 = \sin\chi \sin\theta \sin\varphi,$$
$$u_2 = \sin\chi \sin\theta \cos\varphi,$$
$$u_3 = \sin\chi \cos\theta,$$
$$u_4 = \cos\chi,$$

and

$$r = a_0 \sin\chi. \quad (6)$$

The subsequent calculations and the conclusions drawn from them about the dynamics of a lattice universe remain unchanged.

Errata: Theoretical Results on Orbital Capture

[Revs. Modern Phys. 30, 1169 (1958)]

H. Brysk and M. E. Rose
Oak Ridge National Laboratory, Oak Ridge, Tennessee

In the last of Eq. (4) the first minus sign to the right of the arrow should be deleted.

In the paragraph following Eq. (4) the sentence beginning in the seventh line should read:

"The argument is weakened by the fact that the numerical value of N_0 (which appears in the cross-terms between relativistic and nonrelativistic matrix elements) has the opposite sign for capture as against positron decay; however, this appears unlikely to upset the qualitative features."

Errata: Pair Production and Bremsstrahlung in the Field of Free and Bound Electrons

[Revs. Modern Phys. 30, 354 (1958)]

J. Joseph and F. Rohrlich
Department of Physics, State University of Iowa, Iowa City, Iowa

In Eq. (2) a factor $\frac{1}{2}$ should be added to the constant factor on the right-hand side. The ratio of Eqs. (2) and (1) then becomes 2/9 as stated in the text.

In Eq. (48) $\psi_0(q)$ should be replaced by $\rho_0(q)$, the Fourier transform of $\rho_0(\mathbf{r})=\psi_0^*(\mathbf{r})\psi_0(\mathbf{r})$.

1. INTRODUCTION

THE study of hindered internal rotation in molecules has been a subject of interest for nearly thirty years and numerous methods have been devised for investigating this phenomenon. We discuss one of these—the method of microwave spectroscopy—which has, within the last ten years, been rather extensively employed. Internal rotation interacts with the over-all rotation of a molecule and produces certain effects in its rotational spectrum which can be observed in the microwave region under high resolution. Each rotational transition exhibits a fine structure, the complexity of which depends on the height of the potential barrier hindering the internal rotation. An analysis of this fine structure leads to an accurate evaluation of the potential barrier. Considerable work has been devoted to the studies of the microwave spectra of molecules in which one group may rotate internally with respect to another. This review gives an account of the past work in this field, including certain details of the methods employed.

Potential barriers are presumably caused by the interactions of two groups of electrons and nuclei. In principle, it should be possible to determine the barrier heights from straightforward quantum-mechanical calculations. The mathematical complexity of such a treatment, however, is so great that a rigorous computation seems highly impractical at present. An alternative approach, which is perhaps somewhat empirical, is to try to describe the origin of the barriers in terms of the forces which appear in the study of intermolecular interactions, such as Van der Waals forces and resonance forces. Although many such analyses have been published, none of these results is completely satisfying. With the new data on the barrier heights in various molecules, it may be possible ultimately to formulate a simple theory of the origin of barriers which not only accounts for all the known results but also may serve to make reliable predictions, at least in a semiquantitative way. In view of the presumed similarity in nature between the origin of the potential barriers and the general problem of intermolecular forces, a satisfactory working theory of the former may throw some light on the study of the latter. The bibliography lists a number of papers which consider the origin of potential barriers and various empirical correlations of the barrier heights with the molecular structures. A review of these papers is not covered here. A brief survey of this subject is given in two recent articles by Wilson.[017,018]‡

In addition to the method of microwave spectroscopy, various other procedures have been utilized in order to evaluate potential barriers. Such thermodynamic properties as entropy and vapor heat capacity are probably the most commonly used to calculate barrier heights. Generally, these thermodynamic methods complement the microwave methods and are applicable for molecules with high barriers, greater than say 3 kcal/mole (1000 cm^{-1}). Although the thermodynamic procedure does not usually give quite as accurate barrier heights as the best results from microwave work, the former is applicable to a much larger class of molecules since the latter is limited to molecules with a dipole moment. We do not, however, review the thermodynamic results or methods here. The readers are directed to the reviews by Wilson[119] and by Pitzer.[83]

Infrared and Raman spectra[29] have been used to determine the frequencies of the internal torsional oscillations. In principle, this would be the direct method for determining the torsional frequencies and

‡ References will be found in the Bibliography at the end of the paper.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

the potential barriers. Unfortunately, these torsional oscillations are usually inactive and lie in the very far infrared region so that their detection and assignment are usually difficult, if at all possible. Nuclear magnetic resonance[1,17,85,96] also has been used recently to give a measure of the magnitude of barriers in liquids. Barrier heights in the range of 5 to 20 kcal/mole may be determined by measuring the widths of the resonance lines as functions of temperature. The time scale of nuclear magnetic resonance is such that if the barrier height is less than about 5 kcal/mole, the internal rotation appears to be free.

The phenomenon of internal rotation is similar to the inversion in ammonia,[108] a pyramidal molecule in which the nitrogen atom may be situated at either side of the plane of the hydrogen atoms. Although a small potential barrier restricts the back-and-forth motion and causes the pyramidal structure, the nitrogen atom may move from one side of the plane to the other through the quantum-mechanical tunneling effect, which splits the doubly degenerate vibrational energy levels below the barrier into pairs of levels (one symmetric and one antisymmetric state). Transitions between these states are observed in the microwave region, and the separation is very sensitive to the height of the potential barrier.

For the case of internal rotation of molecules such as ethane, CH_3-CH_3, the situation is similar. In ammonia the nitrogen atom can move back and forth between the two equivalent positions, while in CH_3-CH_3 one methyl group can rotate into one of the three positions which are equivalent with respect to the other methyl group. If each of these configurations were considered to be independent, the torsional energy levels would all be triply degenerate. However, the tunneling effect, analogous to the case of ammonia, splits each torsional level into nondegenerate (A species of the C_3 group) and degenerate (E species) sublevels. This is shown in Fig. 1 for an assumed cosine potential function. On the left are the torsional state quantum numbers. The torsional sublevel spacing increases as the torsional energy increases.

Associated with each of the torsional sublevels, one has a set of energy levels arising from the over-all rotation of the entire molecule (referred to as over-all rotational levels). Because of the interaction between the over-all and internal rotation, the spacings of the over-all rotational levels are different in the different torsional states. A given rotational transition then appears as a number of spectral lines corresponding to the transitions in different torsional states. The separations between these lines are utilized to determine the potential barrier height.

In this review we first formulate the Hamiltonians for various molecular models. The calculations of the eigenvalues and eigenfunctions based on various approximations are given and discussed. The practical aspects of the analysis of microwave spectra are presented in Sec. 5. This section is intended for those interested in evaluating potential barriers from microwave spectra. Finally, the application of group theory, vibration-torsion-rotation interaction, and experimental results are discussed in that order. The casual reader may find it convenient to omit some of the more mathematical sections in this paper. It is recommended that he first read the sections on "Symmetric Molecules" in Secs. 2 and 3 and also Sec. 4 and Sec. 8. The notation has been standardized. A glossary is given in Appendix 4 and a comparison of the notation used by other authors is given in Appendix 5.

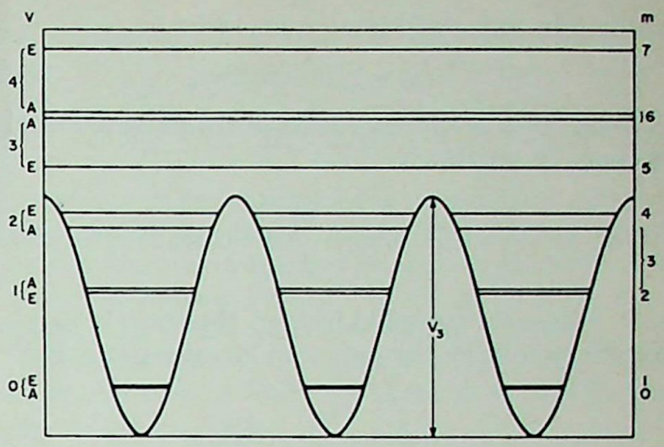

FIG. 1. Hindered rotational energy levels. A cosine potential barrier V_3 and its associated internal rotational energy levels. The torsional quantum numbers v are shown on the left ordinate. The sublevels are denoted by their symmetry under the C_3 group. The free rotational quantum numbers m are shown on the right ordinate.

2. HAMILTONIAN

In order to understand the problem of internal rotation and study its effects, the approximate Hamiltonian of the system must be known. The potential energy hindering a symmetric internal rotor is discussed first. Then the kinetic energy is written for rigid symmetric molecules and for rigid asymmetric molecules with an attached symmetric rotor. Methods of calculation of approximate eigenvalues and eigenfunctions are covered in succeeding sections.

I. Potential Energy

Since the origin of the potential barrier is not clearly understood, the only requirement that can be imposed on the potential function is that it be periodic in the relative angle α between the two parts of the molecule. Within the interval of $\alpha=0$ and $\alpha=2\pi$, the potential function must repeat itself N times, where N is the number of equivalent configurations in one complete internal revolution. For example, N is equal to three for acetaldehyde (CH_3CHO) and six for nitromethane (CH_3NO_2). In most cases the symmetry of the molecule is such that the potential function can be expressed as an even function of the angle α. The potential energy

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

can then be expanded in a cosine series as

$$V(\alpha)=\sum_k a_k \cos kN\alpha. \quad (2\text{-}1a)$$

By a shift in the reference level of the potential energy, this may be written as

$$V(\alpha)=\frac{V_3}{2}(1-\cos 3\alpha)+\frac{V_6}{2}(1-\cos 6\alpha)+\cdots \quad (2\text{-}1b)$$

for the case of a threefold barrier. However, it has been customary to take the potential function as simply[83]

$$V(\alpha)=\frac{V_3}{2}(1-\cos 3\alpha) \quad (2\text{-}2)\S$$

without rigorous justification (Fig. 1).

Serious effort has been made recently[38,39,25b] to examine the effects and magnitude of the V_6 term, and the experimental data strongly suggests that the sixfold term is indeed much smaller than the V_3 term, the ratio being the order of one-hundredth or less. If this is the case, a good approximation can then be obtained by considering only the threefold terms in the Fourier expansion of the potential energy, i.e., Eq. (2-2). The use of this simple potential function leads to solutions for the torsional wave equation in terms of Mathieu functions. In case greater accuracy is desired, the higher terms can be included and the corrections on the energy levels calculated by perturbation methods.

II. Kinetic Energy and Hamiltonian

In order to derive the kinetic energy, a model is used which consists of two rigid groups connected by a bond. *At least one of these groups is a symmetric top.* For convenience *the symmetric group is regarded as rotating internally about the bond with respect to the other group which is taken as the framework.* The entire molecule is also rotating in space. Thus there are four degrees of freedom: the three Eulerian angles θ, Φ, χ of the framework and the relative angle between the two groups, α. The method of solution is dictated by the functional form of the Hamiltonian which depends on the coordinate axes used. In the literature two methods of solution have appeared corresponding to two different frames of reference.

In that originated by Wilson[119] and Crawford[11a] *et al.*, the set of principal axes of the whole molecule is used as the coordinate system (hereafter referred to as the principal axes method or PAM). Since the rotating top possesses an axis of symmetry, the principal axes of the molecule are not altered by a change of the relative orientation of the top and the frame, and the coordinate system may be regarded as rigidly attached to the frame. The Hamiltonian function consists of three groups. The first is recognized as the energy of the rigid rotating system whose moments of inertia are *different* from those of the molecule. The second corresponds to the Hamiltonian of a simple hindered rotor with one degree of freedom. The third appears as the product of the angular momentum of the over-all rotation and the angular momentum associated with the internal motion of the top. This third group represents the interaction of the two kinds of rotation. In the solution the first two groups are taken as the unperturbed system and the cross terms, i.e., the third group, are treated as a perturbation.

In an alternative method originated by Nielsen[76] and Dennison *et al.*,[48,8] the axis about which the top executes internal rotation is chosen as one of the coordinate axes (hereafter referred to as the internal axis method or IAM). The other two axes are fixed with respect to the framework and their orientation is, in principle, arbitrary, but the choice is usually determined to some extent by the symmetry of the molecule. In this coordinate system the terms which describe the interaction between the over-all and internal rotation are considerably smaller than those from PAM. Thus the interaction terms in IAM lend themselves more readily to simple perturbation treatment. The chief disadvantage of this procedure is that, since the coordinate axes are, in general, not principal axes, the Hamiltonian is complicated by the presence of the terms containing the products of inertia.

A. Internal Axis Method

In the derivation of the Hamiltonian by the internal axis method (IAM), the case of a symmetric top (e.g., CH_3SiH_3) is treated first. An asymmetric molecule with a plane of symmetry is then discussed. Methyl alcohol (CH_3OH) and acetaldehyde (CH_3CHO) are examples of this class of molecules.

1. Symmetric molecules.[76,48]—A set of coordinate axes (a,b,c) is chosen with the c axis along the symmetry axis of the molecule through the center of mass. One of the two symmetric groups is designated the frame (a convention set up for comparison with the asymmetric case) and the other symmetric group is designated the internal rotor or top. The a and b axes can be fixed arbitrarily with respect to the frame because of the symmetric nature of this end. The kinetic energy T can then be expressed in tensor notation as (see Appendix 1)

$$T=\tfrac{1}{2}\boldsymbol{\omega}^{+}\cdot\mathbf{I}\cdot\boldsymbol{\omega}+\tfrac{1}{2}(\partial\boldsymbol{\alpha}/\partial t)^{+}\cdot\mathbf{I}_{\alpha}\cdot(\partial\boldsymbol{\alpha}/\partial t)+\tfrac{1}{2}[\boldsymbol{\omega}^{+}\cdot\mathbf{I}_{\alpha}\cdot(\partial\boldsymbol{\alpha}/\partial t)+(\partial\boldsymbol{\alpha}/\partial t)^{+}\cdot\mathbf{I}_{\alpha}\cdot\boldsymbol{\omega}], \quad (2\text{-}3)$$

or in terms of the components along the axes as

$$T=\tfrac{1}{2}I_a\omega_a^2+\tfrac{1}{2}I_b\omega_b^2+\tfrac{1}{2}I_c\omega_c^2+\tfrac{1}{2}I_\alpha\dot{\alpha}^2+I_\alpha\omega_c\dot{\alpha} \quad (2\text{-}4)$$
$$=\tfrac{1}{2}I_a\omega_a^2+\tfrac{1}{2}I_b\omega_b^2+\tfrac{1}{2}(I_c-I_\alpha)\omega_c^2+\tfrac{1}{2}I_\alpha(\omega_c+\dot{\alpha})^2,$$

where $\mathbf{I}$ is the inertial tensor and I_a, I_b, $(I_a=I_b)$, and I_c are the three moments of inertia of the whole molecule about the three coordinate axes; I_α is the moment

§ Some authors have used the form $1+\cos 3\alpha'$ which merely means a shift in α, i.e., $\alpha'=\pi-\alpha$.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

of inertia of the top about its symmetry axis, i.e., the c axis; ω_a, ω_b, and ω_c are the three components of angular velocity ω about the a, b, and c axes; and $\dot{\alpha}$ is the angular velocity of the top relative to the frame. Introduction of the momenta.

$$\begin{aligned} P_a &= \partial T/\partial\omega_a = I_a\omega_a, \\ P_b &= \partial T/\partial\omega_b = I_b\omega_b, \\ P_c &= \partial T/\partial\omega_c = I_c\omega_c + I_\alpha\dot{\alpha}, \end{aligned} \tag{2-5}$$

and

$$p = \partial T/\partial\dot{\alpha} = I_\alpha(\omega_c+\dot{\alpha}),$$

results in the classical Hamiltonian

$$H = \frac{P_a^2}{2I_a}+\frac{P_b^2}{2I_b}+\frac{P_c^2}{2(I_c-I_\alpha)} - \frac{pP_c}{(I_c-I_\alpha)}+\frac{I_c p^2}{2I_\alpha(I_c-I_\alpha)}+V(\alpha). \tag{2-6}$$

The physical meaning of P_a, P_b, and P_c is not immediately obvious. The results of Appendix 1 show that P_a, P_b, and P_c are the components of the total angular momentum (including the internal rotation) about the a, b, and c axes. Therefore they satisfy the usual commutation relations. The quantum-mechanical operators for P_a, P_b, and P_c in the coordinate representation depend only on the Eulerian angles θ, Φ, χ of the framework of the molecule but not on α (see Sec. IIC2). In this case p is the total angular momentum of the top including both the external and internal rotation. As a quantum-mechanical differential operator, p may be expressed as

$$p \rightarrow (\hbar/i)(\partial/\partial\alpha)_{\theta,\Phi,\chi}. \tag{2-7}$$

and therefore p commutes with P_a, P_b, and P_c.

At the limit of a very high potential barrier, Eq. (2-6) does not reduce readily to the case of a rigid rotor plus a simple restricted internal rotor. The reason is that the operator p defined in Eq. (2-5) contains not only the angular momentum of the internal motion of the top but also the contribution from the over-all rotation. When the internal torsion is completely frozen, the classical angular velocity $\dot{\alpha}$ becomes zero and thus p becomes $I_\alpha\omega_c = (I_\alpha/I_c)P_c$. When this expression for p is substituted into Eq. (2-6), the usual energy equation for a rigid symmetric top is recovered.

The connection between Eq. (2-6) and the Hamiltonian for the limiting case of a rigid rotor can be brought out more explicitly through the Nielsen transformation,[76]

$$\begin{aligned} p' &= p-[(I_\alpha/I_c)P_c] = [1-(I_\alpha/I_c)]I_\alpha\dot{\alpha} = rI_\alpha\dot{\alpha}, \\ P_c' &= P_c, \end{aligned} \tag{2-8}$$

which eliminates the cross product pP_c and gives

$$H = \frac{P_a^2}{2I_a}+\frac{P_b^2}{2I_b}+\frac{P_c'^2}{2I_c}+\frac{I_c p'^2}{2I_\alpha(I_c-I_\alpha)}+V(\alpha). \tag{2-9}$$

The quantity p' depends solely on $\dot{\alpha}$, so that it vanishes at the classical high barrier limit when α is a constant. Here p' is not to be taken as the angular momentum of the internal motion (which is $I_\alpha\dot{\alpha}$) but rather $rI_\alpha\dot{\alpha}$. Unlike Eq. (2-6), the coefficients of the P's in Eq. (2-9) are the actual rotational constants of the entire molecule. Furthermore p' does not commute with P_a and P_b since from Eq. (2-8),

$$p'P_a - P_a p' = i\hbar(I_\alpha/I_c)P_b. \tag{2-10}$$

On the other hand, p' does commute with $P_a^2+P_b^2$ and hence the Hamiltonian in Eq. (2-9) is separable into two parts corresponding to the over-all rotation and the internal rotation.

Equation (2-9) may also be derived through a transformation of the angular velocities. In terms of ω_c' and $\dot{\alpha}'$ defined as

$$\begin{aligned} \omega_c' &= \omega_c + (I_\alpha/I_c)\dot{\alpha}, \\ \dot{\alpha}' &= \dot{\alpha}, \end{aligned} \tag{2-11}$$

Eq. (2-4) has the form

$$T = \tfrac{1}{2}I_a(\omega_a^2+\omega_b^2)+\tfrac{1}{2}I_c\omega_c'^2+\tfrac{1}{2}rI_\alpha\dot{\alpha}'^2. \tag{2-12}$$

With the new variable ω_c' it is natural to define

$$\begin{aligned} P_c' &= (\partial T/\partial\omega_c')_{\omega_a,\omega_b,\dot{\alpha}'} = I_c\omega_c' = I_c\omega_c + I_\alpha\dot{\alpha}, \\ p' &= (\partial T/\partial\dot{\alpha}')_{\omega_a,\omega_b,\omega_c'} = [1-(I_\alpha/I_c)]I_\alpha\dot{\alpha} = rI_\alpha\dot{\alpha}. \end{aligned} \tag{2-13}$$

In addition, P_a and P_b are unchanged, i.e.,

$$\begin{aligned} P_a &= (\partial T/\partial\omega_a)_{\omega_b,\omega_c'\dot{\alpha}'} = (\partial T/\partial\omega_a)_{\omega_b,\omega_c,\dot{\alpha}}, \\ P_b &= (\partial T/\partial\omega_b)_{\omega_a,\omega_c',\dot{\alpha}'} = (\partial T/\partial\omega_b)_{\omega_a,\omega_c,\dot{\alpha}}. \end{aligned} \tag{2-14}$$

Now the momenta P_c' and p' defined in Eq. (2-13) are identical to the momenta introduced in Eq. (2-8). Substitution of Eqs. (2-13) and (2-14) into Eq. (2-12) gives Eq. (2-9).

The coordinate transformation corresponding to Eq. (2-11) and also Eq. (2-8) is simply

$$\begin{aligned} \chi' &= \chi + [(I_\alpha/I_c)\alpha] \\ &= (1/I_c)[I_\alpha\chi_2 + (I_c-I_\alpha)\chi_1], \\ \alpha' &= \alpha. \end{aligned} \tag{2-15}$$

Note that χ and α are related to the Eulerian angles of the two groups of the molecule χ_1 and χ_2 as $\chi=\chi_1$, $\alpha=\chi_2-\chi_1$. One may regard θ, Φ, χ' as the Eulerian angles for a new set of axes. This coordinate system is rotating with respect to the one attached to the framework with an angular velocity of $(I_\alpha/I_c)\dot{\alpha}$ about the axis of symmetry of the molecule. These new coordinate

‖ Here, r, the reducing factor, is an important quantity used in both the IAM and the PAM.

¶ χ is the same as Φ used in references 8 and 48.

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

axes are hereafter referred to as "internal rotation axes" (called the "molecule-fixed" system by Hecht and Dennison[20]). It should be remembered that to an observer located in this frame of reference, both the framework and the top appear to be moving. The angular momentum (z component) arising from the internal motion is

$$I_\alpha(\dot{\chi}_2-\dot{\chi}')+(I_c-I_\alpha)(\dot{\chi}_1-\dot{\chi}')=0. \qquad (2\text{-}16)$$

In treating the problem of vibration-rotation interaction the moving axes are usually chosen so that the angular momentum due to the internal motion vanishes to the first approximation.[120] For the present problem it would seem proper to use the internal rotation axes as the frame of reference. By letting the three components of the total angular momentum in this coordinate system be P_a', P_b', and P_c', it follows that

$$\begin{aligned} P_a' &= (\cos\rho\alpha)P_a+(\sin\rho\alpha)P_b, \\ P_b' &= (-\sin\rho\alpha)P_a+(\cos\rho\alpha)P_b, \\ P_c' &= P_c, \end{aligned} \qquad (2\text{-}17)$$

where

$$\rho=I_\alpha/I_c. \qquad (2\text{-}18)$$

For asymmetric molecules,[20] the quantity ρ is a more complicated function of the moments of inertia:

$$\rho=\frac{(I_{bb}^2+I_{bc}^2)^{\frac{1}{2}}I_\alpha}{I_{bb}I_{cc}-I_{bc}^2}, \qquad (2\text{-}19)^{31,**}$$

where I_{bb} and I_{cc} are the moments of inertia about the b and c axis, respectively, and I_{bc} is the product of inertia [see Eq. (2-23)]. For symmetric molecules one has $I_{bc}=0$, so Eq. (2-19) reduces to Eq. (2-18).

Insertion of Eq. (2-17) into Eq. (2-9) gives

$$H=\frac{P_a'^2}{2I_a}+\frac{P_b'^2}{2I_b}+\frac{P_c'^2}{2I_c}+\frac{I_c p'^2}{2I_\alpha(I_c-I_\alpha)}+V(\alpha). \qquad (2\text{-}20)$$

Equations (2-20) and (2-9) have an identical form. This situation occurs because the two principal moments of inertia I_a and I_b of the molecule are equal. One may question the basic differences between Eqs. (2-20) and (2-9) or between P_a', P_b' and P_a, P_b. The answer is that P_a and P_b, as pointed out previously, do not commute with p' while both P_a' and P_b' do. Therefore the matrix elements (diagonal and nondiagonal) of P_a' and P_b' do not involve the quantum number associated with the operator

$$[I_c/2I_\alpha(I_c-I_\alpha)]p'^2+V(\alpha). \qquad (2\text{-}21)$$

The matrices of P_a and P_b, on the other hand, are characterized by the quantum number of the torsional operator in Eq. (2-21) as well as by the over-all rotational quantum numbers. Consequently the Heisenberg matrix elements of P_a and P_b contain both the over-all and internal rotational frequencies. The same results can be anticipated from a classical consideration. When hindered rotation is present[67] the set of the internal rotation axes of the molecule rotate in the same way as the principal axes of a rigid symmetric top, while the two groups execute rapid torsion with respect to each other. As P_a and P_b represent the components of the angular momentum along the axes fixed in one of the groups, the values of these components vary at the rate of the torsional frequency.

The cross term pP_c in Eq. (2-6) implies a coupling between the internal and over-all rotation, while according to Eq. (2-20) the internal and external motion are separable. The discrepancy arises from the different choice of the coordinate systems. When the internal rotation axes are used as the frame of reference as in Eq. (2-20), the internal torsion and over-all rotation are independent of each other and hence the Hamiltonian is separable. When the framework of the molecule is taken as the moving frame, the motion of this set of coordinate axes consists of both rotation and the rapid torsional motion. Mathematically, this is reflected by the cross term in Eq. (2-6). Because of the difference in the frames of reference in Eqs. (2-6) and (2-20), the meaning of the term "over-all rotation" is different in these two cases.

2. Asymmetric molecules with a plane of symmetry.[8,20,31,32,84]—For an asymmetric molecule with a plane of symmetry, a set of coordinate axes is chosen similar to the symmetric top case with the c axis through the center of mass of the whole molecule and parallel to the top (symmetric internal rotor) axis, and the b axis through the center of mass and lying in the plane of symmetry. The inertial tensor assumes the form

$$\begin{bmatrix} I_{aa} & 0 & 0 \\ 0 & I_{bb} & -I_{bc} \\ 0 & -I_{bc} & I_{cc} \end{bmatrix}, \qquad (2\text{-}22)$$

where I_{aa}, I_{bb}, and I_{cc} are the moments of inertia and I_{bc} is the product of inertia. The kinetic energy, according to Eq. (2-3), can then be expressed as

$$T=\tfrac{1}{2}I_{aa}\omega_a^2+\tfrac{1}{2}I_{bb}\omega_b^2+\tfrac{1}{2}I_{cc}\omega_c^2 -I_{bc}\omega_b\omega_c+\tfrac{1}{2}I_\alpha\dot{\alpha}^2+I_\alpha\omega_c\alpha. \qquad (2\text{-}23)$$

Similarly, the momenta are defined as

$$\begin{aligned} P_a &= \partial T/\partial\omega_a = I_{aa}\omega_a, \\ P_b &= \partial T/\partial\omega_b = I_{bb}\omega_b-I_{bc}\omega_c, \\ P_c &= \partial T/\partial\omega_c = I_{cc}\omega_c-I_{bc}\omega_b+I_\alpha\dot{\alpha}, \\ p &= \partial T/\partial\alpha = I_\alpha(\dot{\alpha}+\omega_c). \end{aligned} \qquad (2\text{-}24)$$

As with symmetric molecules, P_a, P_b, and P_c are again the three components of the total angular momentum.

With the substitution of Eq. (2-24) into Eq. (2-23)

** The quantity ρ is the same as Itoh's[31] λ and can be defined somewhat more simply in the principal axes coordinate system [see Eq. (2-30)].

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

the following quantum-mechanical Hamiltonian is obtained:

$$H=A_aP_a^2+B_bP_b^2+C_cP_c^2+D_{bc}(P_bP_c+P_cP_b)-2D_{bc}P_bp-2C_cP_cp+Fp^2+V(\alpha), \quad (2\text{-}25)$$

where

$$A_a=\frac{h^2}{2I_{aa}},$$

$$B_b=\frac{h^2(I_{cc}-I_\alpha)}{2(I_{bb}I_{cc}-I_\alpha I_{bb}-I_{bc}^2)}=\frac{(I_{cc}-I_\alpha)h^2}{2r(I_{bb}I_{cc}-I_{bc}^2)}=\frac{(I_{cc}-I_\alpha)h^2}{2d},$$

$$C_c=\frac{h^2I_{bb}}{2(I_{bb}I_{cc}-I_\alpha I_{bb}-I_{bc}^2)}=\frac{h^2I_{bb}}{2r(I_{bb}I_{cc}-I_{bc}^2)}=\frac{I_{bb}h^2}{2d},$$

$$D_{bc}=\frac{h^2I_{bc}}{2(I_{bb}I_{cc}-I_\alpha I_{bb}-I_{bc}^2)}=\frac{h^2I_{bc}}{2r(I_{bb}I_{cc}-I_{bc}^2)}=\frac{I_{bc}h^2}{2d},$$

$$F=\frac{h^2(I_{bb}I_{cc}-I_{bc}^2)}{2I_\alpha(I_{bb}I_{cc}-I_\alpha I_{bb}-I_{bc}^2)}=\frac{h^2}{2rI_\alpha},$$

$$r=\frac{I_{bb}I_{cc}-I_{bb}I_\alpha-I_{bc}^2}{I_{bb}I_{cc}-I_{bc}^2}=1-\frac{\lambda_y^2I_\alpha}{I_y}-\frac{\lambda_z^2I_\alpha}{I_z}, \quad \text{and}$$

$$d=I_{bb}I_{cc}-I_{bb}I_\alpha-I_{bc}^2=r(I_{bb}I_{cc}-I_{bc}^2)=rI_yI_z.$$

Here I_x, I_y, and I_z are the principal moments of inertia of the whole molecule, and λ_x, λ_y, and λ_z are the direction cosines of the internal axis with respect to the principal axes.

By following the method used for the symmetric case, we can apply the transformation in Eq. (2-8) to eliminate the coupling between over-all rotation and internal rotation. Unfortunately, this transformation does not completely remove the coupling for asymmetric molecules. The results of the transformation on H are given in Eq. (2-26),

$$H=A_aP_a^2+B_bP_b^2+C_c'P_c'^2+\frac{I_{cc}-I_\alpha}{I_{cc}}D_{bc}(P_bP_c'+P_c'P_b)-D_{bc}(P_bp'+p'P_b)-2\frac{I_{bc}}{I_{cc}}D_{bc}P_c'p'+F'p'^2+V(\alpha), \quad (2\text{-}26)$$

where

$$C_c'=\frac{\hbar^2}{2I_{cc}}\left[1+\frac{2I_{bc}^2B_b}{\hbar^2I_{cc}}\right],$$

$$F'=\frac{\hbar^2I_{cc}}{2I_\alpha(I_{cc}-I_\alpha)}+\frac{I_{bc}D_{bc}\hbar^2}{I_{cc}-I_\alpha}.$$

Equation (2-26) is essentially the same Hamiltonian employed by Burkhard and Dennison[8] to obtain the Schroedinger equation. The equivalence between Eq. (2-26) and Burkhard and Dennison's wave equation is discussed later in this section. Again p' in Eq. (2-26) does not commute with P_a and P_b.

Although the coupling between p and P_c can be eliminated for the symmetric case by the transformation (2-8), it is not removed completely for the asymmetric case but is reduced by the factor $I_{bc}^2/I_{bb}I_{cc}$. In order to minimize the coupling term the internal angular momentum must be made to vanish. This is brought about by a slightly different transformation given by Hecht and Dennison[20] or by a modification in the formulation given by Itoh.[31]

Hecht and Dennison apply three transformations to the Hamiltonian given in Eq. (2-25). First, a rotation is performed in order to eliminate the P_bp coupling. Secondly, a modified Nielsen transformation is applied to remove the P_cp coupling. These two transformations are given in Eqs. (2-27) and (2-28),

$$\begin{aligned}P_a''&=P_a,\\ P_b''&=(I_{bb}P_b-I_{bc}P_c)(I_{bb}^2+I_{bc}^2)^{-\frac{1}{2}},\\ P_c''&=(I_{bc}P_b+I_{bb}P_c)(I_{bb}^2+I_{bc}^2)^{-\frac{1}{2}},\end{aligned} \quad (2\text{-}27)$$

and

$$p'=p-\rho P_c''=p-I_\alpha(I_{bb}^2+I_{bc}^2)^{\frac{1}{2}}P_c''(I_{bb}I_{cc}-I_{bc}^2)^{-1}. \quad (2\text{-}28)$$

The transformed Hamiltonian which results from these two operations is

$$H''=A_aP_a''^2+B_b''P_b''^2+C_c''P_c''^2+D_{bc}''(P_b''P_c''+P_c''P_b'')+Fp'^2+V(\alpha), \quad (2\text{-}29)$$

where

$$B_b''=\frac{h^2}{2}I_{bb}(I_{bb}^2+I_{bc}^2)^{-1}=rI_\alpha h^2(1-r)/2\rho^2d,$$

$$C_c''=\frac{h^2}{2}\left[\frac{I_{bb}+I_{cc}}{I_{bb}I_{cc}-I_{bc}^2}-\frac{I_{bb}}{I_{bb}^2+I_{bc}^2}\right]=\frac{h^2}{2}\left(\frac{1}{I_y}+\frac{1}{I_z}\right)-B_b'',$$

$$D_{bc}''=\frac{h^2}{2}I_{bc}(I_{bb}^2+I_{bc}^2)^{-1}=(rI_\alpha)^2D_{bc}/\rho^2d=\frac{h^2}{2}\frac{\rho_y\rho_z}{\rho}\left(\frac{1}{I_y}-\frac{1}{I_z}\right),$$

$$\rho=\frac{(I_{bb}^2+I_{bc}^2)^{\frac{1}{2}}I_\alpha}{(I_{bb}I_{cc}-I_{bc}^2)}=\left[\Sigma_g\left(\frac{\lambda_gI_\alpha}{I_g}\right)^2\right]^{\frac{1}{2}}, \quad (g=x,y,z),$$

$$\rho_g=\lambda_gI_\alpha/I_g. \quad (2\text{-}30)$$

Finally, the transformation described in Eq. (2-17), with ρ given by the more complicated expression Eq. (2-30), is applied to Eq. (2-29). This transformation defines the "internal rotational axes system." Referred to these axes the internal angular momentum vanishes. The resulting Hamiltonian[20] is

$$\begin{aligned}H'=&\tfrac{1}{2}(A_a+B_b'')(P_a'^2+P_b'^2)+C_c''P_c'^2+Fp'^2+V(\alpha)\\&+\tfrac{1}{2}(A_a-B_b'')[(P_a'^2-P_b'^2)\cos2\rho\alpha\\&-(P_a'P_b'+P_b'P_a')\sin2\rho\alpha]\\&+D_{bc}''[(P_b'P_c'+P_c'P_b')\cos\rho\alpha\\&+(P_a'P_c'+P_c'P_a')\sin\rho\alpha].\end{aligned} \quad (2\text{-}31)$$

It can be easily shown that P_a', P_b', and P_c' satisfy

CC-0. Gurukul Kangri University Haridwar Collection. Digitized by S3 Foundation USA

the usual commutation rules and they all commute with p'.

Itoh[31] has derived the Hamiltonian (2-29) in an interesting and useful way. He also expressed the Hamiltonian in a form convenient for comparison with the PAM formulation. The over-all angular velocity is divided into two parts ω_1 and ω_2, such that the angular momentum of the whole molecule associated with ω_1 balances the internal angular momentum. This is equivalent to choosing a set of axes in which the internal angular momentum vanishes. Thus one has

$$\mathbf{I}\cdot\omega_1+I_\alpha(\partial\alpha/\partial t)=0, \tag{2-32a}$$

or

$$\omega_1=-\mathbf{I}^{-1}\cdot\hat{k}(I_\alpha\dot{\alpha})=-\varrho\dot{\alpha}, \tag{2-32b}$$

where

$$\varrho=I_\alpha(\mathbf{I}^{-1}\cdot\hat{k}). \tag{2-32c}$$

Here $\mathbf{I}$ is the inertia tensor and $\hat{k}$ is a unit vector in the direction of $(\partial\alpha/\partial t)$. The components of the vector ϱ can be found from Eqs. (2-22) and (2-32c). Referred to the a, b, and c axes, one obtains

$$\rho_a=0,\quad \rho_b=I_\alpha I_{bc}(I_{bb}I_{cc}-I_{bc}^2)^{-1},$$

and

$$\rho_c=I_\alpha I_{bb}(I_{bb}I_{cc}-I_{bc}^2)^{-1}. \tag{2-33}$$
